Preface

With individual chapters authored by distinguished leaders and experienced professionals in their respective topics, this handbook provides engineers, technicians, designers, researchers, educators, and students with a convenient, thorough, up-to-date, and authoritative reference source on techniques, tools, and data for modeling, analysis, design, monitoring, instrumentation, modification, and control of vibration, shock, noise, and acoustics. The handbook consists of 45 chapters, grouped into nine sections. In these sections, the following are considered: fundamentals and analytical techniques; computer techniques, tools, and signal analysis including finite element methods and wavelet analysis and the use of MATLAB[®] toolboxes; shock and vibration methodologies, particularly for civil and mechanical engineering systems; instrumentation and testing methods, including sensors, exciters, signal acquisition, conditioning, and recording, and LabVIEW[®] tools for virtual instrumentation; vibration suppression, damping, and control; monitoring and diagnosis; design for and control of seismic vibration, and related regulatory issues; system design, application, and control implementation; and acoustics and noise suppression. Important information and results are summarized as windows, tables, graphs, and lists throughout the chapters for easy reference and information tracking. References are given at the end of each chapter for further information and study. An extensive glossary, which defines useful technical terms in the fields of vibration, shock, and acoustics, is provided at the end of the handbook. Cross-referencing is used throughout to indicate other places in the handbook where further information on a particular topic is provided.

In the handbook, equal emphasis is given to theory and practical application. The chapters are grouped into fundamentals, basic theory, advanced theory, analytical techniques, numerical techniques, experimental techniques, design methodology, practical problems and solutions, applications, regulatory considerations, and useful data. Analytical formulations, numerical methods, design approaches, control techniques, and commercial software tools are presented and illustrated. Commercial equipment, computer hardware, and instrumentation are described, analyzed, and demonstrated for field application, practical implementation, and experimentation. Examples and case studies are given throughout the handbook to illustrate the use and application of the included information. The material is presented in a format that is convenient for easy reference and recollection.

Mechanical vibration is a manifestation of oscillatory behavior in mechanical systems, as a result of either the repetitive interchange of kinetic and potential energies among components in the system, or a forcing excitation that is oscillatory. Such oscillatory responses are not limited to purely mechanical systems, and are found in electrical and fluid systems as well. In purely thermal systems, however, free natural oscillations are not possible, and an oscillatory excitation is needed to obtain an oscillatory response. Shock is vibration caused by brief, abrupt, and typically high-intensity excitations. Sound, noise, and acoustics are manifestations of pressure waves, sources of which are often vibratory dynamic systems.

Low levels of vibration mean reduced noise and an improved work environment. Vibration modification and control can be crucial in maintaining high performance and production efficiency, and

prolonging the useful life in industrial machinery. Consequently, a considerable effort is devoted today to studying and controlling the vibration and shock generated by machinery components, machine tools, transit vehicles, impact processes, civil engineering structures, fluid flow systems, and aircraft. Noise and acoustic problems can originate from undesirable vibrations and fluid–structure interactions, as found, for example, in automobile engines. Engine noise, environmental noise, and noise from high-speed and high-temperature exhaust gases in a vehicle will not only cause passenger discomfort and public annoyance, they will also result in damaging effects to the vehicle itself. Noise-suppression methods and devices, and sound-absorption material and structures are crucial in such situations. Before designing or controlling a system for good vibratory or acoustic performance, it is important to understand, analyze, and represent the dynamic characteristics of the system. This may be accomplished through purely analytical means, computer analysis of analytical models, testing and analysis of test data, or by a combination of these approaches. It follows that modeling, analysis, testing, and design are all important aspects of study in vibration, shock, and acoustics.

In recent years, educators, researchers, and practitioners have devoted considerable effort toward studying and controlling vibration, shock, and noise in a range of applications in various branches of engineering, particularly in civil, mechanical, aeronautical and aerospace, and production and manufacturing engineering. Specific applications are found in machine tools, transit vehicles, impact processes, civil engineering structures, construction machinery, industrial processes, product qualification and quality control, fluid flow systems, ships, and aircraft. This handbook is a contribution toward these efforts. In view of the analytical methods, practical considerations, design issues, and experimental techniques that are presented throughout the handbook, and in view of the simplified and snap-shot style presentation of formulas, data, and advanced theory, the handbook serves as a useful reference tool and an extensive information source for engineers and technicians in industry and laboratories, researchers, instructors, and students in the areas of vibration, shock, noise, and acoustics.

Clarence W. de Silva

Editor-in-Chief
Vancouver

Acknowledgments

I wish to express my gratitude to the authors of the chapters for their valuable and highly professional contributions. The assistance of my research engineer, Jian Zhang, in some graphics and formatting of the handbook was quite valuable. I am very grateful to Cindy Renee Carelli, Acquisitions Editor-Engineering, CRC Press, for her enthusiasm, characteristic vigor, and support throughout the project. The editorial and production staff at CRC Press and its affiliates, particularly Jessica Vakili, and Carol Cooper have done an excellent job in getting this handbook in print. Finally, I wish to lovingly acknowledge the patience and understanding of my family.

Editor-in-Chief

Clarence W. de Silva, P. Eng., Fellow ASME and Fellow IEEE, is Professor of Mechanical Engineering at the University of British Columbia, Vancouver, Canada, and has occupied the NSERC Research Chair in Industrial Automation since 1988. He has earned Ph.D. degrees from Massachusetts Institute of Technology (1978) and Cambridge University, England (1998). De Silva has also occupied the Mobil Endowed Chair Professorship in the Department of Electrical and Computer Engineering at the National University of Singapore. He has served as a consultant to several companies, including IBM and Westinghouse in the U.S., and has led the development of six industrial machines. He is recipient of the Killam Research Prize, Outstanding Engineering Educator Award of the Institute of Electrical and Electronics Engineers (IEEE) Canada, Education Award of the Dynamic Systems and Control Division of the American Society of Mechanical Engineers (ASME), Lifetime Achievement Award of the World Automation Congress, IEEE Third Millennium Medal, Meritorious Achievement Award of the Association of Professional Engineers of BC, and the Outstanding Contribution Award of the Systems, Man, and Cybernetics Society of the IEEE. As well as editing or coediting 12 volumes, he has authored or coauthored 16 technical books, over 150 journal papers, and about 200 conference papers and book chapters. He has served on the editorial boards of 12 international journals, in particular as the Editor-in-Chief of the *International Journal of Control and Intelligent Systems*, Editor-in-Chief of the *International Journal of Knowledge-Based Intelligent Engineering Systems*, Senior Technical Editor of *Measurements and Control*, and Regional Editor, North America, of *Engineering Applications of Artificial Intelligence — the International Journal of Intelligent Real-Time Automation*. He is a Lilly Fellow, Senior Fulbright Fellow to Cambridge University, Fellow of the Advanced Systems Institute of British Columbia, and a Killam Fellow.

Summary

This chapter concerns the modeling and analysis of mechanical vibrating systems in the time domain. Useful procedures of time-domain analysis are developed. Techniques of analyzing both free response and forced response are given. Examples of the application of Newton's force-motion approach, energy conservation approach, and Lagrange's energy approach are given. Particular emphasis is placed on the analysis of an undamped oscillator and a damped oscillator. Associated terminology, which is useful in vibration analysis, is defined.

1.1 Introduction

Vibrations can be analyzed both in the time domain and in the frequency domain. Free vibrations and forced vibrations may have to be analyzed. This chapter provides the basics of the time-domain representation and analysis of mechanical vibrations.

Free and natural vibrations occur in systems because of the presence of two modes of energy storage. When the stored energy is repeatedly interchanged between these two forms, the resulting time response of the system is oscillatory. In a mechanical system, natural vibrations can occur because *kinetic energy* (which is manifested as velocities of mass [inertia] elements) may be converted into *potential energy* (which has two basic types: *elastic potential energy* due to the deformation in spring-like elements, and *gravitation potential energy* due to the elevation of mass elements under the Earth's gravitational pull) and back to kinetic energy, repetitively, during motion. An oscillatory excitation (forcing function) is able to make a dynamic system respond with an oscillatory motion (at the same frequency as the forcing excitation) even in the absence of two forms of energy storage. Such motions are forced responses rather than natural or free responses.

An analytical model of a mechanical system is a set of equations. These may be developed either by the Newtonian approach, where Newton's Second Law is explicitly applied to each inertia element, or by the Lagrangian or Hamiltonian approach which is based on the concepts of energy (kinetic and potential energies). A time-domain analytical model is a set of differential equations with respect to the independent variable time (t). A frequency-domain model is a set of input–output transfer functions with respect to the independent variable frequency (ω). The time response will describe how the system moves (responds) as a function of time. The frequency response will describe the way the system moves when excited by a harmonic (sinusoidal) forcing input, and is a function of the frequency of excitation.

1.2 Undamped Oscillator

Consider the mechanical system that is schematically shown in Figure 1.1. The inputs (or excitation) applied to the system are represented by the force $f(t)$. The outputs (or response) of the system are represented by the displacement y . The system boundary (real or imaginary) demarcates the region of interest in the analysis. What is outside the system boundary is the environment in which the system operates. An analytical model of the system may be given by one or more equations relating the outputs to the inputs. If the rates of changes of the response (outputs) are not negligible, the system is a *dynamic* system. In this case the analytical model, in the time domain, becomes one or more differential equations rather than algebraic equations. System parameters (e.g., mass, stiffness, damping constant) are represented in the model, and their values should be known in order to determine the response of the system to a particular excitation. State variables are a minimum set of variables, which completely represent the dynamic state of a system at any given time t . These variables are not unique (more than one choice of a valid set of state variables is possible). For a simple oscillator (a single-degree-of-freedom (DoF) mass–spring–damper system) an appropriate set of state variables would be the displacement y and the velocity \dot{y} . An alternative set would be \dot{y} and the spring force.

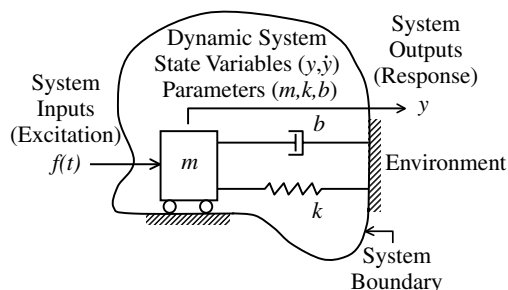

FIGURE 1.1 A mechanical dynamic system.

In the present section, we will first show that many types of oscillatory systems can be represented by the equation of an *undamped simple oscillator*. In particular, mechanical, electrical, and fluid systems will be considered. The *conservation of energy* is a straightforward approach for deriving the equations of motion for undamped oscillatory systems (which fall into the class of conservative systems). The equations of motion for mechanical systems may be derived using the *free-body diagram* approach, with the direct application of *Newton's Second Law*. An alternative and rather convenient approach is the use of *Lagrange's equations*. The natural (free) response of an undamped simple oscillator is a *simple harmonic motion*. This is a periodic, sinusoidal motion.

In the present section, we will first show that many types of oscillatory systems can be represented by the equation of an *undamped simple oscillator*. An alternative and rather convenient approach is the use of *Lagrange's equations*. The natural (free) response of an undamped simple oscillator is a *simple harmonic motion*. This is a periodic, sinusoidal motion.

1.2.1 Energy Storage Elements

Mass (inertia) and spring are the two basic energy storage elements in mechanical systems. The concept of state variables may be introduced as well through these elements.

1.2.1.1 Inertia (m)

Consider an inertia element of lumped mass m , excited by force f , as shown in Figure 1.2.

The resulting velocity is v .

Newton's Second Law gives

$$m \frac{dv}{dt} = f \quad (1.1)$$

Kinetic energy stored in the mass element is equal to the work done by the force f on the mass. Hence,

$$\begin{aligned} \text{Energy } E &= \int f dx = \int f \frac{dx}{dt} dt = \int f v dt = \int \frac{m dv}{dt} v dt \\ &= m \int v dv \end{aligned}$$

or

$$\text{Kinetic energy KE} = \frac{1}{2} m v^2 \quad (1.2)$$

Note: v is an appropriate state variable for a mass element because it can completely represent the energy of the element.

Integrate Equation 1.1:

$$v(t) = v(0^-) + \frac{1}{m} \int_{0^-}^t f dt \quad (1.3)$$

Hence, with $t = 0^+$, we have

$$v(0^+) = v(0^-) + \frac{1}{m} \int_{0^-}^{0^+} f dt \quad (1.4)$$

Since the integral of a finite quantity over an almost zero time interval is zero, these results tell us that a finite force will not cause an instantaneous change in velocity in an inertia element. In particular, for a mass element subjected to finite force, since the integral on the right-hand side of Equation 1.4 is zero, we have

$$v(0^+) = v(0^-) \quad (1.5)$$

1.2.1.2 Spring (k)

Consider a massless spring element of lumped stiffness k , as shown in Figure 1.3. One end of the spring is fixed and the other end is free. A force f is applied at the free end, which results in a displacement (extension) x in the spring.

Hooke's Law gives

$$f = kx \quad \text{or} \quad \frac{df}{dt} = kv \quad (1.6)$$

Elastic potential energy stored in the spring is equal to the work done by the force on the spring. Hence,

$$\text{Energy } E = \int f dx = \int kx dx = \frac{1}{2} kx^2 = \int f \frac{dx}{dt} dt = \int f v dt = \int f \frac{1}{k} \frac{df}{dt} dt = \frac{1}{k} \int f df = \frac{1}{2k} f^2$$

or

$$\text{Elastic potential energy PE} = \frac{1}{2} kx^2 = \frac{1}{2} \frac{f^2}{k} \quad (1.7)$$

Note: f and x are both appropriate state variables for a spring, because both can completely represent the energy in the spring.

FIGURE 1.2 A mass element.

FIGURE 1.3 A spring element.

Integrate Equation 1.6:

$$f(t) = f(0^-) + \frac{1}{k} \int_{0^-}^t v \, dt \quad (1.8)$$

Set $t = 0^+$. We have

$$f(0^+) = f(0^-) + \frac{1}{k} \int_{0^-}^{0^+} v \, dt \quad (1.9)$$

From these results, it follows that at finite velocities there cannot be an instantaneous change in the force of a spring. In particular, from Equation 1.9 we see that when the velocities of a spring are finite:

$$f(0^+) = f(0^-) \quad (1.10)$$

Also, it follows that

$$x(0^+) = x(0^-) \quad (1.11)$$

1.2.1.3 Gravitation Potential Energy

The work done in raising an object against the gravitational pull is stored as gravitational potential energy of the object. Consider a lumped mass m , as shown in Figure 1.4, which is raised to a height y from some reference level.

The work done gives

$$\text{Energy } E = \int f \, dy = \int mg \, dy$$

Hence,

$$\text{Gravitational potential energy PE} = mgy \quad (1.12)$$

FIGURE 1.4 A mass element subjected to gravity.

1.2.2 The Method of Conservation of Energy

There is no energy dissipation in undamped systems which contain energy storage elements only. In other words, energy is conserved in these systems, which are known as *conservative systems*. For mechanical systems, conservation of energy gives

$$\text{KE} + \text{PE} = \text{const.} \quad (1.13)$$

These systems tend to be oscillatory in their natural motion, as noted before. Also, analogies exist with other types of systems (e.g., fluid and electrical systems). Consider the six systems sketched in Figure 1.5.

1.2.2.1 System 1 (Translatory)

Figure 1.5(a) shows a translatory mechanical system (an undamped oscillator) which has just one degree of freedom x . This may represent a simplified model of a rail car that is impacting against a snubber. The conservation of energy (Equation 1.13) gives

$$\frac{1}{2} m \dot{x}^2 + \frac{1}{2} k x^2 = \text{const.} \quad (1.14)$$

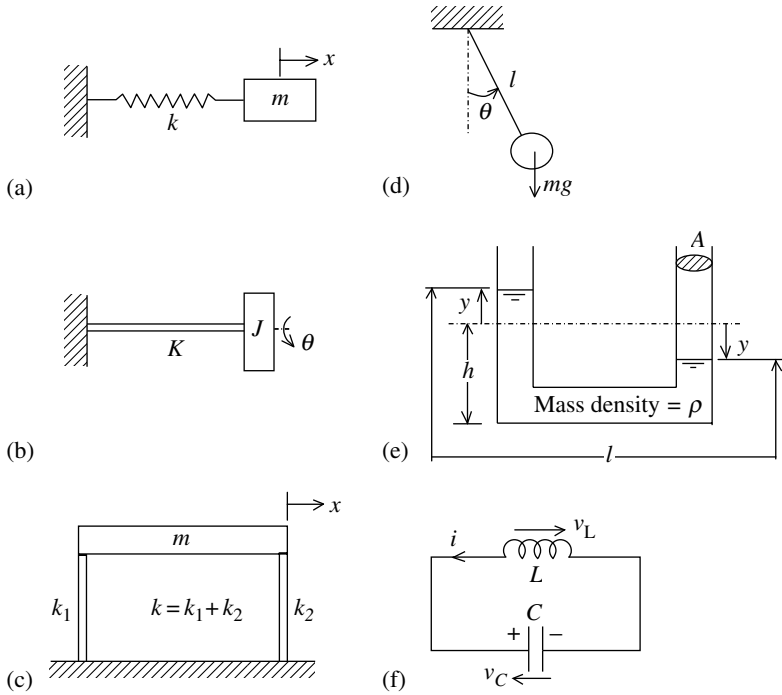

FIGURE 1.5 Six examples of single-degree-of-freedom oscillatory systems: (a) translatory; (b) rotatory; (c) flexural; (d) pendulous; (e) liquid slosh; (f) electrical.

Here, m is the mass and k is the spring stiffness. Differentiate Equation 1.14 with respect to time t . We obtain

$$m\dot{x}\ddot{x} + kx\dot{x} = 0$$

Since generally $\dot{x} \neq 0$ at all t , we can cancel it out. Hence, we obtain the equation of motion:

$$\ddot{x} + \frac{k}{m}x = 0 \quad (1.15)$$

1.2.2.2 System 2 (Rotatory)

Figure 1.5(b) shows a rotational system with the single DoF θ . It may represent a simplified model of a motor drive system. As before, the conservation energy gives

$$\frac{1}{2}J\dot{\theta}^2 + \frac{1}{2}K\theta^2 = \text{const.} \quad (1.16)$$

In this equation, J is the moment of inertia of the rotational element and K is the torsional stiffness of the shaft. Then, by differentiating Equation 1.16 with respect to t and canceling $\dot{\theta}$, we obtain the equation of motion:

$$\ddot{\theta} + \frac{K}{J}\theta = 0 \quad (1.17)$$

1.2.2.3 System 3 (Flexural)

Figure 1.5(c) is a lateral bending (flexural) system, which is a simplified model of a building structure. Again, a single DoF x is assumed. Conservation of energy gives

$$\frac{1}{2}m\dot{x}^2 + \frac{1}{2}kx^2 = \text{const.} \quad (1.18)$$

Here, m is the lumped mass at the free end of the support and k is the lateral bending stiffness of the support structure. Then, as before, the equation of motion becomes

$$\ddot{x} + \frac{k}{m}x = 0 \quad (1.19)$$

1.2.2.4 System 4 (Pendulous)

Figure 1.5(d) shows a simple pendulum. It may represent a swinging-type building demolisher or a ski lift, and has a single-DoF θ . We have

$$\text{KE} = \frac{1}{2}m(l\dot{\theta})^2$$

$$\text{Gravitational PE} = E_{\text{ref}} - mgl \cos \theta$$

Here, m is the pendulum mass, l is the pendulum length, and g is the acceleration due to gravity. Hence, conservation of energy gives

$$\frac{1}{2}ml^2\dot{\theta}^2 - mgl \cos \theta = \text{const.} \quad (1.20)$$

Differentiate with respect to t after canceling the common ml :

$$l\dot{\theta}\ddot{\theta} + g \sin \theta \dot{\theta} = 0$$

Since, $\dot{\theta} \neq 0$ at all t , we have the equation of motion:

$$\ddot{\theta} + \frac{g}{l} \sin \theta = 0 \quad (1.21)$$

This system is nonlinear, in view of the term $\sin \theta$.

For small θ , $\sin \theta$ is approximately equal to θ . Hence, the linearized equation of motion is

$$\ddot{\theta} + \frac{g}{l} \theta = 0 \quad (1.22)$$

1.2.2.5 System 5 (Liquid Slosh)

Consider a liquid column system shown in Figure 1.5(e). It may represent two liquid tanks linked by a pipeline. The system parameters are: area of cross section of each column = A ; mass density of liquid = ρ ; length of liquid mass = l .

We have

$$\text{KE} = \frac{1}{2}(\rho l A)\dot{y}^2$$

$$\text{Gravitational PE} = \rho A(h+y)\frac{g}{2}(h+y) + \rho A(h-y)\frac{g}{2}(h-y)$$

Hence, conservation of energy gives

$$\frac{1}{2}\rho l A\dot{y}^2 + \frac{1}{2}\rho A g(h+y)^2 + \frac{1}{2}\rho A g(h-y)^2 = \text{const.} \quad (1.23)$$

Differentiate:

$$l\dot{y}\ddot{y} + g(h+y)\dot{y} - g(h-y)\dot{y} = 0$$

But, we have

$$\dot{y} \neq 0 \quad \text{for all } t$$

Hence,

$$\ddot{y} + g(h+y) - g(h-y) = 0$$

or

$$\ddot{y} + \frac{2g}{l} y = 0 \quad (1.24)$$

1.2.2.6 System 6 (Electrical)

Figure 1.5(f) shows an electrical circuit with a single capacitor and a single inductor. Again, conservation of energy may be used to derive the equation of motion.

Voltage balance gives

$$v_L + v_C = 0 \quad (1.25)$$

where v_L and v_C are voltages across the inductor and the capacitor, respectively.

Constitutive equation for the inductor is

$$L \frac{di}{dt} = v_L \quad (1.26)$$

Constitutive equation for the capacitor is

$$C \frac{dv_C}{dt} = i \quad (1.27)$$

Hence, by differentiating Equation 1.26, substituting Equation 1.25, and using Equation 1.27, we obtain

$$L \frac{d^2 i}{dt^2} = \frac{dv_L}{dt} = -\frac{dv_C}{dt} = -\frac{i}{C}$$

or

$$LC \frac{d^2 i}{dt^2} + i = 0 \quad (1.28)$$

Now consider the energy conservation approach for this electrical circuit, which will give the same result. Note that power is given by the product vi .

1.2.2.7 Capacitor

$$\text{Electrostatic energy } E = \int vi \, dt = \int vC \frac{dv}{dt} dt = C \int v \, dv = \frac{Cv^2}{2} \quad (1.29)$$

Here, v denotes v_C . Also,

$$v = \frac{1}{C} \int i \, dt \quad (1.30)$$

Since the current i is finite for a practical circuit, we have $\int_0^+ i \, dt = 0$.

Hence, in general, the voltage across a capacitor cannot change instantaneously. In particular,

$$v(0^+) = v(0^-) \quad (1.31)$$

1.2.2.8 Inductor

$$\text{Electromagnetic energy } E = \int vi \, dt = \int L \frac{di}{dt} i \, dt = L \int i \, di = \frac{Li^2}{2}$$

Here, v denotes v_L . Also,

$$i = \frac{1}{L} \int v \, dt \quad (1.32)$$

Since v is finite in a practical circuit, we have $\int_0^+ v \, dt = 0$.

Hence, in general, the current through an inductor cannot change instantaneously. In particular,

$$i(0^+) = i(0^-) \quad (1.33)$$

Since the circuit in [Figure 1.5\(f\)](#) does not have a resistor, there is no energy dissipation. As a result, energy conservation gives

$$\frac{Cv^2}{2} + \frac{Li^2}{2} = \text{const.} \quad (1.34)$$

Differentiate Equation 1.34 with respect to t :

$$Cv \frac{dv}{dt} + Li \frac{di}{dt} = 0$$

Substitute the capacitor constitutive equation 1.27:

$$iv + Li \frac{di}{dt} = 0$$

Since $i \neq 0$ in general, we can cancel it. Now, by differentiating Equation 1.27, we have $di/dt = C(d^2v/dt^2)$. Substituting this in the above equation, we obtain

$$LC \frac{d^2v}{dt^2} + v = 0 \quad (1.35)$$

Similarly, we obtain

$$LC \frac{d^2i}{dt^2} + i = 0 \quad (1.36)$$

1.2.3 Free Response

The equation of free motion (i.e., without an excitation force) of the six linear systems considered above (Figure 1.5) is of the same general form:

$$\ddot{x} + \omega_n^2 x = 0 \quad (1.37)$$

This is the equation of an undamped, simple oscillator. The parameter ω_n is the *undamped natural frequency* of the system. For a mechanical system of mass m and stiffness k , we have

$$\omega_n = \sqrt{\frac{k}{m}} \quad (1.38)$$

To determine the time response x of this system, we use the trial solution:

$$x = A \sin(\omega_n t + \phi) \quad (1.39)$$

in which A and ϕ are unknown constants, to be determined by the initial conditions (for x and \dot{x}); say,

$$x(0) = x_0, \quad \dot{x}(0) = v_0 \quad (1.40)$$

Substitute the trial solution into Equation 1.37. We obtain

$$(-A\omega_n^2 + A\omega_n^2)\sin(\omega_n t + \phi) = 0$$

This equation is identically satisfied for all t . Hence, the general solution of Equation 1.37 is indeed Equation 1.39, which is periodic and sinusoidal.

This response is sketched in Figure 1.6. Note that this sinusoidal oscillatory motion has a *frequency* of oscillation of ω (radians/sec). Hence, a system that provides this type of natural motion is called a *simple oscillator*. In other words, the response exactly repeats itself in time periods of T or a cyclic frequency $f = 1/T$ (Hz). The frequency ω is in fact the *angular frequency* given by $\omega = 2\pi f$. Also, the response has an *amplitude* A , which is the peak value of the sinusoidal response. Now, suppose that we shift this response curve to the right through ϕ/ω . Consider the resulting curve to be the reference signal (with signal value = 0 at $t = 0$, and increasing). It should be clear that the response shown in Figure 1.6 leads the reference signal by a time period of ϕ/ω . This may be verified from the fact that the value of the reference signal at time t is the same as that of the signal in Figure 1.6 at time $t - \phi/\omega$. Hence, ϕ is termed the *phase angle* of the response, and it is a *phase lead*.

The left-hand-side portion of Figure 1.6 is the phasor representation of a sinusoidal response. In this representation, an arm of length A rotates in the counterclockwise direction at angular speed ω . This is the phasor. The arm starts at an angular position ϕ from the horizontal axis, at time $t = 0$. The projection of the arm onto the vertical (x) axis is the time response. In this manner, the phasor representation can conveniently indicate the amplitude, frequency, phase angle, and the actual time response (at any time t) of a sinusoidal motion. A repetitive (periodic) motion of the type 1.39 is called a *simple harmonic motion*, meaning it is a pure sinusoidal oscillation at a single frequency.

Next, we will show that the amplitude A and the phase angle ϕ both depend on the initial conditions. Substitute the initial conditions (Equation 1.40) into Equation 1.39 and its time derivative. We obtain

$$x_0 = A \sin \phi \quad (1.41)$$

$$v_0 = A\omega_n \cos \phi \quad (1.42)$$

Now divide Equation 1.41 by Equation 1.42, and also use the fact that $\sin^2 \phi + \cos^2 \phi = 1$. We obtain

$$\tan \phi = \omega_n \frac{x_0}{v_0}$$

$$\left(\frac{x_0}{A}\right)^2 + \left(\frac{v_0}{A\omega_n}\right)^2 = 1$$

Hence,

$$\text{Amplitude } A = \sqrt{x_0^2 + \frac{v_0^2}{\omega_n^2}} \quad (1.43)$$

$$\text{Phase } \phi = \tan^{-1} \frac{\omega_n x_0}{v_0} \quad (1.44)$$

Example 1.1

A simple model for a tracked gantry conveyor system in a factory is shown in Figure 1.7.

The carriage of mass (m) moves on a frictionless track. The pulley is supported on frictionless bearings, and its axis of rotation is fixed. Its moment of inertia about this axis is J . The motion of the carriage is restrained by a spring of stiffness k_1 , as shown. The belt segment that drives the carriage runs over the

FIGURE 1.6 Free response of an undamped simple oscillator.

Eliminate the common velocity variable \dot{x} (which cannot be zero for all t). We obtain

$$\left(m + \frac{J}{r^2}\right)\ddot{x} + (k_1 + k_2)x = k_2x_{20} - k_1x_{10}$$

which is the same result as before.

Solution Using Lagrange's Equations

$$\text{Lagrangian } L = T - V = \frac{1}{2}m\dot{x}^2 + \frac{1}{2}J\dot{\theta}^2 - \frac{1}{2}k_1(x_{10} + x)^2 - \frac{1}{2}k_2(x_{20} - x)^2$$

Now, substituting for θ in terms of x (Equation v), we obtain

$$L = \frac{1}{2}\left(m + \frac{J}{r^2}\right)\dot{x}^2 - \frac{1}{2}k_1(x_{10} + x)^2 - \frac{1}{2}k_2(x_{20} - x)^2$$

Use Lagrange's equation (see Box 1.1):

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = Q_i \quad \text{for } i = 1, 2, \dots, n$$

where the generalized coordinate $q_i = x$ and the corresponding generalized force $Q_i = 0$ because there are no nonconservative and external forces. We obtain

$$\begin{aligned} \frac{\partial L}{\partial \dot{x}} &= \left(m + \frac{J}{r^2}\right)\dot{x} \\ \frac{\partial L}{\partial x} &= -k_1(x_{10} + x) + k_2(x_{20} - x) \end{aligned}$$

From this, we obtain the equation of motion:

$$\left(m + \frac{J}{r^2}\right)\ddot{x} + (k_1 + k_2)x = k_2x_{20} - k_1x_{10}$$

which is identical to what we obtained before.

Natural Frequency

From the equivalent translational system, the natural frequency (undamped) of the system is obtained as

$$\omega_n = \sqrt{k_{eq}/m_{eq}} = \sqrt{(k_1 + k_2)/\left(m + \frac{J}{r^2}\right)} \quad (\text{vii})$$

Substitute for x and its derivatives into Equation vi using the compatibility condition (Equation v). We obtain the equivalent rotational system:

$$(r^2m + J)\ddot{\theta} + r^2(k_1 + k_2)\theta = rk_2x_{20} - rk_1x_{10}$$

The equivalent moment of inertia:

$$J_{eq} = r^2m + J$$

The equivalent torsional stiffness:

$$K_{eq} = r^2(k_1 + k_2)$$

Therefore, the corresponding natural frequency is

$$\omega_n = \sqrt{r^2(k_1 + k_2)/(r^2m + J)} = \sqrt{(k_1 + k_2)/\left(m + \frac{J}{r^2}\right)} \quad (\text{viii})$$

This result is identical to the previous result (vii). This is to be expected, as the system has not changed (only the response variable was changed).

Common methods of developing equations of motion for mechanical systems are summarized in Box 1.1.

Box 1.1

APPROACHES FOR DEVELOPING EQUATIONS OF MOTION

1. Conservative Systems (No Nonconservative Forces/No Energy Dissipation):

Kinetic energy = T

Potential energy = V

Conservation of energy: $T + V = \text{const.}$

Differentiate with respect to time t

2. Lagrange's Equations:

Lagrangian $L = T - V$

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = Q_i \quad \text{for } i = 1, 2, \dots, n$$

n = number of DoFs

Q_i = generalized force corresponding to generalized coordinate q_i .

Find Q_i using:

$$\delta W = \sum Q_i \delta q_i$$

where δW = work done by nonconservative forces in a general incremental motion ($\delta q_1, \delta q_2, \dots, \delta q_n$).

3. Newtonian Approach:

$$\sum \text{Forces} = \frac{d}{dt} \sum \text{Linear Momentum}$$

$$\sum \text{Torques} = \frac{d}{dt} \sum \text{Angular Momentum}$$

(About centroid or a fixed point)

1.3 Heavy Springs

A heavy spring has its mass and flexibility properties continuously distributed throughout its body. In that sense it has an infinite number of DoF(s), and a single coordinate cannot represent its motion. However, for many practical purposes, a lumped-parameter approximation with just one lumped mass to represent the inertial characteristics of the spring may be sufficient. Such an approximation may be obtained by using the energy approach. Here, we represent the spring by a lumped-parameter "model" such that the original spring and the model have the same net kinetic energy and potential energy. This *energy equivalence* is used in deriving a lumped mass parameter for the model. Even though damping (energy dissipation) is neglected in the present analysis, it is not difficult to incorporate that as well in the model.

1.3.1 Kinetic Energy Equivalence

Consider the uniform, heavy spring shown in Figure 1.9, with one end fixed and the other end moving at velocity v .

Note that:

k = stiffness of spring

m_s = mass of spring

l = length of spring

FIGURE 1.9 A uniform heavy spring.

Local speed of element δx of the spring is given by $(x/l)v$. Element mass = $(m_s/l)\delta x$. Hence,

$$\text{Element KE} = \frac{1}{2} \frac{m_s}{l} \delta x \left(\frac{x}{l} v \right)^2$$

In the limit, we have $\delta x \rightarrow dx$. Then,

$$\text{Total KE} = \int_0^l \frac{1}{2} \frac{m_s}{l} dx \left(\frac{x}{l} v \right)^2 = \frac{1}{2} \frac{m_s v^2}{l^3} \int_0^l x^2 dx = \frac{1}{2} \frac{m_s v^2}{3} \quad (1.45)$$

Hence, the equivalent lumped mass concentrated at the free end = $(1/3) \times$ spring mass.

Note: This derivation assumes that one end of the spring is fixed. Furthermore, the conditions are assumed to be *uniform* along the spring.

An example of utilizing this result is shown in Figure 1.10. Here, a system with a heavy spring and a lumped mass is approximated by a light spring (having the same stiffness) and a lumped mass.

Another example is shown in Figure 1.11. In this case, it is not immediately clear which of the approximations shown on the right-hand side is most appropriate.

Example 1.2

A uniform heavy spring of mass m_s and stiffness k is attached at one end to a mass m that is free to roll on a frictionless horizontal plane. The other end is anchored to a vertical post. A schematic diagram of this arrangement is shown in Figure 1.12.

FIGURE 1.10 Lumped-parameter approximation for an oscillator with heavy spring.

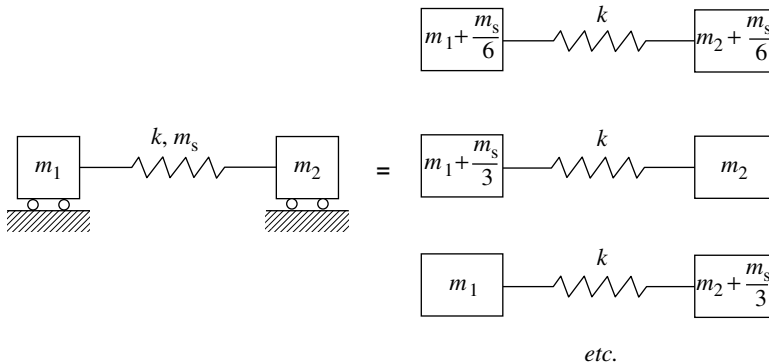

FIGURE 1.11 An example where lumped-parameter approximation for spring is ambiguous.

The unstretched length of the spring is l . Assume that, when the velocity of the connected mass is v , the velocity distribution along the spring is given by

$$v_s(x) = v \sin \frac{\pi x}{2l}$$

where x is the distance of a point along the spring, as measured from the fixed end. We will determine an equivalent lumped mass located at the moving end of the spring (i.e., at the moving mass m) to represent the inertia effects of the spring.

Consider an element of length δx at location x of the spring. Since the spring is uniform, we have element mass $= (m_s/l)\delta x$. Also, according to the given assumption, element velocity $= v \sin(\pi x/2l)$. Hence, kinetic energy of the spring is

$$\begin{aligned} \int_0^l \frac{1}{2} \left(v \sin \frac{\pi x}{2l} \right)^2 \frac{m_s}{l} dx &= \frac{1}{2} \frac{m_s}{l} v^2 \int_0^l \sin^2 \frac{\pi x}{2l} dx = \frac{1}{4} \frac{m_s}{l} v^2 \int_0^l \left[1 - \cos \frac{\pi x}{l} \right] dx \\ &= \frac{1}{4} \frac{m_s}{l} v^2 \left[x - \frac{l}{\pi} \sin \frac{\pi x}{l} \right]_0^l = \frac{1}{4} \frac{m_s}{l} v^2 l = \frac{1}{2} \frac{m_s}{2} v^2 \end{aligned}$$

It follows that the equivalent lumped mass to be located at the moving end of the spring is $m_s/2$. This result is valid only for the assumed velocity distribution, and corresponds to the first mode of motion only. In fact, a linear velocity distribution would be more realistic in this low frequency (quasi-static motion) region, which will give an equivalent lumped mass of $(1/3)m_s$, as we have seen before. Such approximations will not be valid for high frequencies (say, higher than $\sqrt{k/m_s}$).

FIGURE 1.12 A heavy spring connected to a rolling stock.

1.4 Oscillations in Fluid Systems

Fluid systems can undergo oscillations (vibrations) quite analogous to mechanical and electrical systems. Again, the reason for their natural oscillation is the ability to store and repeatedly interchange two types of energy — kinetic energy and potential energy. The kinetic energy comes from the velocity of fluid particles during motion. The potential energy arises primarily from the following three main sources:

1. Gravitational potential energy
2. Compressibility of the fluid volume
3. Flexibility of the fluid container

A detailed analysis of these three effects is not undertaken here. However, we have seen from the example in Figure 1.5(e) how a liquid column can oscillate due to repeated interchange between kinetic energy and gravitational potential energy. Now, let us consider another example.

Example 1.3

Consider a cylindrical wooden peg of uniform cross section and height h , floating in a tank of water, as in Figure 1.13(a). It is pushed by hand until completely immersed in water, in an upright orientation. When released, the object will oscillate up and down while floating in the tank. Let ρ_b and ρ_l be the mass

FIGURE 1.13 (a) A buoyancy experiment; (b) upright oscillations of the body; (c) restoring buoyancy couple due to a stable metacenter.

densities of the body (peg) and the liquid (water), respectively. The natural oscillations and the stability of this system may be studied as below.

Suppose that, under equilibrium in the upright position of the body, the submersed length is l . The mass of the body is

$$m = Ah\rho_b \quad (\text{i})$$

where A is the area of cross section (uniform).

By the Archimedes principle, the buoyancy force R is equal to the weight of the liquid displaced by the body. Hence,

$$R = Al\rho_1 g \quad (\text{ii})$$

For equilibrium, we have

$$R = mg \quad (\text{iii})$$

or

$$Al\rho_1 g = Ah\rho_b g$$

Hence,

$$l = \frac{\rho_b}{\rho_1} h \quad \text{for } \rho_b < \rho_1 \quad (\text{iv})$$

For a vertical displacement y from the equilibrium position, the equation of motion is (Figure 1.13(b))

$$m\ddot{y} = mg - A(l + y)\rho_1 g$$

Substitute Equation ii and Equation iii. We obtain

$$m\ddot{y} = -A\rho_1 g y$$

Substitute Equation i:

$$Ah\rho_b \ddot{y} + A\rho_1 g y = 0$$

or

$$\ddot{y} + \frac{\rho_l g}{\rho_b h} y = 0$$

The natural frequency of oscillations is

$$\omega_n = \sqrt{\frac{\rho_l g}{\rho_b h}}$$

Note that this result is independent of the area of the cross section of the body.

Assumptions made:

1. The tank is very large compared to the body. The change in liquid level is negligible as the body is depressed into the water.
2. Fluid resistance (viscous effects, drag, etc.) is negligible.
3. Dynamics of the liquid itself is negligible. Hence, “added inertia” due to liquid motion is neglected.

To study stability of the system, note that the buoyancy for R acts through the centroid of the volume of displaced water (Figure 1.13(c)). Its line of action passes through the central axis of the body at point M . The point is known as the *metacenter*. Let C be the centroid of the body.

If M is above C , then, when tilted, there will be a restoring couple that will tend to restore the body to its upright position. Otherwise the body will be in an unstable situation, and the buoyancy couple will tend to tilt it further towards a horizontal configuration.

1.5 Damped Simple Oscillator

Now we will consider free (natural) response of a simple oscillator in the presence of energy dissipation (damping).

Assume viscous damping, and consider the oscillator shown in Figure 1.14. The free-body diagram of the mass is shown separately.

We use the following notation:

- ω_n = undamped natural frequency
- ω_d = damped natural frequency
- ω_r = resonant frequency
- ω = frequency of excitation

The concept of resonant frequency will be addressed in Chapter 2.

Usually, the viscous damping constant of a single DoF is denoted by b (but, sometimes c is used instead of b , particularly for multi-DoF systems).

Apply Newton's Second Law. From the free-body diagram in Figure 1.14, we have the equation of motion $m\ddot{x} = -kx - b\dot{x}$

or

$$m\ddot{x} + b\dot{x} + kx = 0 \quad (1.46)$$

or

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2 x = 0 \quad (1.47)$$

FIGURE 1.14 A damped simple oscillator and its free-body diagram.

This is a free (or unforced, or *homogeneous*) equation of motion. Its solution is the free (natural) response of the system and is also known as the *homogeneous solution*. Note that $\omega_n = \sqrt{k/m}$, which is the natural frequency when there is no damping, and

$$2\zeta\omega_n = \frac{b}{m} \quad (1.48)$$

Hence,

$$\zeta = \frac{1}{2} \sqrt{\frac{m}{k}} \frac{b}{m}$$

or

$$\zeta = \frac{1}{2} \frac{b}{\sqrt{km}} \quad (1.49)$$

Note that ζ is called the *damping ratio*. The formal definition of, and the rationale for, this terminology will be discussed later.

Assume an exponential solution:

$$x = C e^{\lambda t} \quad (1.50)$$

This is justified by the fact that linear systems have exponential or oscillatory (i.e., complex exponential) free responses. A more detailed justification will be provided later.

Substitute Equation 1.50 into Equation 1.47 to obtain

$$[\lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2]C e^{\lambda t} = 0$$

Note that $C e^{\lambda t}$ is not zero in general. It follows that, when λ satisfies the equation

$$\lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 = 0 \quad (1.51)$$

then Equation 1.50 will represent a solution of Equation 1.47.

Equation 1.51 is called the *characteristic equation* of the system. This equation depends on the natural dynamics of the system, not on forcing excitation or initial conditions.

The solution of Equation 1.51 gives the two roots:

$$\lambda = -\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n = \lambda_1 \text{ and } \lambda_2 \quad (1.52)$$

These are called *eigenvalues* or *poles* of the system.

When $\lambda_1 \neq \lambda_2$, the general solution is

$$x = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t} \quad (1.53)$$

The two unknown constants C_1 and C_2 are related to the integration constants and can be determined by two initial conditions which should be known.

If $\lambda_1 = \lambda_2 = \lambda$, we have the case of repeated roots. In this case, the general solution (Equation 1.53) does not hold because C_1 and C_2 would no longer be independent constants to be determined by two initial conditions. The repetition of the roots suggests that one term of the homogenous solution should have the multiplier t (a result of the double integration of zero). Then the general solution is

$$x = C_1 e^{\lambda t} + C_2 t e^{\lambda t} \quad (1.54)$$

We can identify three categories of damping level, as discussed below, and the nature of the response will depend on the particular category of damping.

1.5.1 Case 1: Underdamped Motion ($\zeta < 1$)

In this case it follows from Equation 1.52 that the roots of the characteristic equation are

$$\lambda = -\zeta\omega_n \pm j\sqrt{1 - \zeta^2}\omega_n = -\zeta\omega_n \pm j\omega_d = \lambda_1 \quad \text{and} \quad \lambda_2 \quad (1.55)$$

where the damped natural frequency is given by

$$\omega_d = \sqrt{1 - \zeta^2}\omega_n \quad (1.56)$$

Note that λ_1 and λ_2 are complex conjugates. The response (Equation 1.53) in this case may be expressed as

$$x = e^{-\zeta\omega_n t} [C_1 e^{j\omega_d t} + C_2 e^{-j\omega_d t}] \quad (1.57)$$

The term within the square brackets of Equation 1.57 has to be real, because it represents the time response of a real physical system. It follows that C_1 and C_2 have to be complex conjugates.

Note:

$$e^{j\omega_d t} = \cos \omega_d t + j \sin \omega_d t$$

$$e^{-j\omega_d t} = \cos \omega_d t - j \sin \omega_d t$$

So, an alternative form of the general solution would be

$$x = e^{-\zeta\omega_n t} [A_1 \cos \omega_d t + A_2 \sin \omega_d t] \quad (1.58)$$

Here, A_1 and A_2 are the two unknown constants. By equating the coefficients it can be shown that

$$A_1 = C_1 + C_2 \quad \text{and} \quad A_2 = j(C_1 - C_2) \quad (1.59)$$

Hence,

$$C_1 = \frac{1}{2}(A_1 - jA_2) \quad \text{and} \quad C_2 = \frac{1}{2}(A_1 + jA_2) \quad (1.60)$$

1.5.1.1 Initial Conditions

Let $x(0) = x_0$, $\dot{x}(0) = v_0$ as before. Then,

$$x_0 = A_1 \quad \text{and} \quad v_0 = -\zeta\omega_n A_1 + \omega_d A_2 \quad (1.61)$$

or

$$A_2 = \frac{v_0}{\omega_d} + \frac{\zeta\omega_n x_0}{\omega_d} \quad (1.62)$$

Yet, another form of the solution would be

$$x = A e^{-\zeta\omega_n t} \sin(\omega_d t + \phi) \quad (1.63)$$

Here, A and ϕ are the unknown constants with

$$A = \sqrt{A_1^2 + A_2^2} \quad \text{and} \quad \sin \phi = \frac{A_2}{\sqrt{A_1^2 + A_2^2}} \quad (1.64)$$

Also,

$$\cos \phi = \frac{A_1}{\sqrt{A_1^2 + A_2^2}} \quad \text{and} \quad \tan \phi = \frac{A_2}{A_1} \quad (1.65)$$

Note that the response $x \rightarrow 0$ as $t \rightarrow \infty$. This means the system is *asymptotically stable*.

1.5.2 Logarithmic Decrement Method

The damping ratio ζ may be experimentally determined from the free response by the logarithmic decrement method. To illustrate this approach, note from Equation 1.63 that the period of damped oscillations is

$$T = \frac{2\pi}{\omega_d} \quad (1.66)$$

Also, from Equation 1.63, we have

$$\frac{x(t)}{x(t+nT)} = \frac{A e^{-\zeta\omega_n t} \sin(\omega_d t + \phi)}{A e^{-\zeta\omega_n(t+nT)} \sin[\omega_d(t+nT) + \phi]}$$

But, $\sin[\omega_d(t+nT) + \phi] = \sin(\omega_d t + \phi + 2n\pi) = \sin(\omega_d t + \phi)$.

Hence,

$$\frac{x(t)}{x(t+nT)} = \frac{e^{-\zeta\omega_n t}}{e^{-\zeta\omega_n(t+nT)}} = e^{\zeta\omega_n nT} \quad (1.67)$$

Take the natural logarithm of Equation 1.67, the logarithmic decrement,

$$\zeta\omega_n nT = \ln \left[\frac{x(t)}{x(t+nT)} \right]$$

However,

$$\omega_n T = \omega_n \frac{2\pi}{\omega_d} = \frac{\omega_n 2\pi}{\sqrt{1-\zeta^2}\omega_n} = \frac{2\pi}{\sqrt{1-\zeta^2}}$$

Hence, with $x(t)/x(t+nT) = r$ we have the logarithmic decrement.

$$\frac{2\pi n\zeta}{\sqrt{1-\zeta^2}} = \ln r$$

Note that $(1/n)\ln r$ is the “per-cycle” logarithmic decrement and $(1/2\pi n)\ln r$ is the “per-radian” logarithmic decrement. The latter is

$$\frac{\zeta}{\sqrt{1-\zeta^2}} = \frac{1}{2\pi n} \ln r = \alpha \quad (1.68)$$

Then, we have

$$\zeta = \sqrt{\frac{\alpha^2}{1+\alpha^2}} \quad (1.69)$$

This is the basis of the logarithmic decrement method of measuring damping. Start by measuring a point $x(t)$ and another point $x(t+nT)$ at n cycles later. For high accuracy, pick the peak points of the response curve for the measurement of $x(t)$ and $x(t+nT)$. From Equation 1.68 it is clear that, for small damping, $\zeta = \alpha$ = per-radian logarithmic decrement.

1.5.3 Case 2: Overdamped Motion ($\zeta > 1$)

In this case, roots λ_1 and λ_2 of the characteristic equation (Equation 1.51) are real. Specifically, we have

$$\lambda_1 = -\zeta\omega_n + \sqrt{\zeta^2 - 1}\omega_n < 0 \quad (1.70)$$

$$\lambda_2 = -\zeta\omega_n - \sqrt{\zeta^2 - 1}\omega_n < 0 \quad (1.71)$$

and the response equation (Equation 1.53) is nonoscillatory. Also, it should be clear from Equation 1.70 and Equation 1.71 that both λ_1 and λ_2 are negative. Hence, $x \rightarrow 0$ as $t \rightarrow \infty$. This means the system is asymptotically stable.

From the initial conditions

$$x(0) = x_0, \quad \dot{x}(0) = v_0$$

we obtain

$$x_0 = C_1 + C_2 \quad (i)$$

and

$$v_0 = \lambda_1 C_1 + \lambda_2 C_2 \quad (ii)$$

Multiply the first initial condition (Equation i) by λ_1 :

$$\lambda_1 x_0 = \lambda_1 C_1 + \lambda_1 C_2 \quad (iii)$$

Subtract Equation iii from Equation ii:

$$v_0 - \lambda_1 x_0 = C_2(\lambda_2 - \lambda_1)$$

We obtain

$$C_2 = \frac{v_0 - \lambda_1 x_0}{\lambda_2 - \lambda_1} \quad (1.72)$$

Similarly, multiply the first initial condition (Equation i) by λ_2 and subtract from Equation ii. We obtain

$$v_0 - \lambda_2 x_0 = C_1(\lambda_1 - \lambda_2)$$

Hence,

$$C_1 = \frac{v_0 - \lambda_2 x_0}{\lambda_1 - \lambda_2} \quad (1.73)$$

1.5.4 Case 3: Critically Damped Motion ($\zeta = 1$)

Here, we have repeated roots, given by

$$\lambda_1 = \lambda_2 = -\omega_n \quad (1.74)$$

The response for this case is given by (see Equation 1.54)

$$x = C_1 e^{-\omega_n t} + C_2 t e^{-\omega_n t} \quad (1.75)$$

Since the term $e^{-\omega_n t}$ goes to zero faster than t goes to infinity, we have $t e^{-\omega_n t} \rightarrow 0$ as $t \rightarrow \infty$. Hence, the system is asymptotically stable.

Now use the initial conditions $x(0) = x_0$, $\dot{x}(0) = v_0$. We obtain

$$x_0 = C_1$$

$$v_0 = -\omega_n C_1 + C_2$$

Hence,

$$C_1 = x_0 \quad (1.76)$$

$$C_2 = v_0 + \omega_n x_0 \quad (1.77)$$

Note: When $\zeta = 1$ we have the critically damped response because below this value the response is oscillatory (underdamped) and above this value, the response is nonoscillatory (overdamped). It follows

that we may define the damping ratio as

$$\zeta = \text{damping ratio} = \frac{\text{damping constant}}{\text{damping constant for critically damped conditions}} \quad (1.78)$$

1.5.5 Justification for the Trial Solution

In the present analysis, the trial solution (Equation 1.50) has been used for the response of a linear system having constant parameter values. A justification for this is provided now.

1.5.5.1 First-Order System

Consider a first-order (homogeneous, no forcing input) linear system given by

$$\left(\frac{d}{dt} - \lambda \right) x = \dot{x} - \lambda x = 0 \quad (1.79)$$

This equation can be written as

$$\frac{dx}{x} = \lambda dt$$

Integrate:

$$\ln x = \lambda t + \ln C$$

Here, $\ln C$ is the constant of integration. Hence,

$$x = C e^{\lambda t} \quad (1.80)$$

This is then the general form of the free response of a first-order system. It incorporates one constant of integration, and hence will need one initial condition.

1.5.5.2 Second-Order System

We can write the equation of a general second-order (homogeneous, unforced) system in the operational form:

$$\left(\frac{d}{dt} - \lambda_1 \right) \left(\frac{d}{dt} - \lambda_2 \right) x = 0 \quad (1.81)$$

By reasoning as before, the general solution would be of the form $x = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t}$. Here, C_1 and C_2 are the constants of integration, which are determined using two initial conditions.

1.5.5.3 Repeated Roots

The case of repeated roots deserves a separate treatment. First, consider

$$\frac{d^2 x}{dt^2} = 0 \quad (1.82)$$

Integrate twice:

$$\frac{dx}{dt} = C; \quad x = Ct + D \quad (1.83)$$

Note the term with t in this case. Hence, a suitable trial solution for the system

$$\left(\frac{d}{dt} - \lambda \right) \left(\frac{d}{dt} - \lambda \right) x = 0 \quad (1.84)$$

would be $x = C_1 e^{\lambda t} + C_2 t e^{\lambda t}$.

The main results for the free (natural) response of a damped oscillator are given in Box 1.2.

Box 1.2

FREE (NATURAL) RESPONSE OF A DAMPED SINGLE OSCILLATOR

System Equation: $m\ddot{x} + b\dot{x} + kx = 0$ or $\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = 0$

Undamped natural frequency $\omega_n = \sqrt{k/m}$

Damping ratio $\zeta = b/2\sqrt{km}$

Characteristic Equation: $\lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 = 0$

Roots (Eigenvalues or Poles): λ_1 and $\lambda_2 = -\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n$

Response:

$$x = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t} \text{ for unequal roots } (\lambda_1 \neq \lambda_2)$$

$$x = (C_1 + C_2 t)e^{\lambda t} \text{ for equal roots } (\lambda_1 = \lambda_2 = \lambda)$$

Initial Conditions: $x(0) = x_0$ and $\dot{x}(0) = v_0$

Case 1: Underdamped ($\zeta < 1$)

Poles are complex conjugates: $-\zeta\omega_n \pm j\omega_d$

Damped natural frequency $\omega_d = \sqrt{1 - \zeta^2}\omega_n$

$$x = e^{-\zeta\omega_n t} [C_1 e^{j\omega_d t} + C_2 e^{-j\omega_d t}] = e^{-\zeta\omega_n t} [A_1 \cos \omega_d t + A_2 \sin \omega_d t] = A e^{-\zeta\omega_n t} \sin(\omega_d t + \phi)$$

$$A_1 = C_1 + C_2 \quad \text{and} \quad A_2 = j(C_1 - C_2)$$

$$C_1 = \frac{1}{2}(A_1 - jA_2) \quad \text{and} \quad C_2 = \frac{1}{2}(A_1 + jA_2)$$

$$A = \sqrt{A_1^2 + A_2^2} \quad \text{and} \quad \tan \phi = \frac{A_2}{A_1}$$

Initial conditions give:

$$A_1 = x_0 \quad \text{and} \quad A_2 = \frac{v_0 + \zeta\omega_n x_0}{\omega_d}$$

Logarithmic Decrement per Radian:

$$\alpha = \frac{1}{2\pi n} \ln r = \frac{\zeta}{\sqrt{1 - \zeta^2}}$$

where $r = x(t)/[x(t + nT)]$ = decay ratio over n complete cycles.

For small ζ : $\zeta \cong \alpha$

Case 2: Overdamped ($\zeta > 1$)

Poles are real and negative: $\lambda_1, \lambda_2 = -\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n$

$$x = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t}$$

$$C_1 = \frac{v_0 - \lambda_2 x_0}{\lambda_1 - \lambda_2} \quad \text{and} \quad C_2 = \frac{v_0 - \lambda_1 x_0}{\lambda_2 - \lambda_1}$$

Case 3: Critically Damped ($\zeta = 1$)

Two identical poles: $\lambda_1 = \lambda_2 = \lambda = -\omega_n$

$$x = (C_1 + C_2 t)e^{-\omega_n t} \quad \text{with} \quad C_1 = x_0 \quad \text{and} \quad C_2 = v_0 + \omega_n x_0$$

1.5.6 Stability and Speed of Response

The free response of a dynamic system, particularly a vibrating system, can provide valuable information concerning the natural characteristics of the system. The free (unforced) excitation may be obtained, for example, by giving an initial-condition excitation to the system and then allowing it to respond freely. Two important characteristics which can be determined in this manner are:

1. Stability
2. Speed of response

The stability of a system implies that the response will not grow without bounds when the excitation force itself is finite. This is known as bounded-input bounded-output (BIBO) stability. In particular, if the free response eventually decays to zero, in the absence of a forcing input, the system is said to be *asymptotically stable*. We have seen that a damped simple oscillator is asymptotically stable, but an undamped oscillator, while being stable in a general (BIBO) sense, is not asymptotically stable.

The speed of response of a system indicates how fast the system responds to an excitation force. It is also a measure of how fast the free response (1) rises or falls if the system is oscillatory; or (2) decays, if the system is nonoscillatory. Hence, the two characteristics, stability and speed of response, are not completely independent. In particular, for nonoscillatory (overdamped) systems these two properties are very closely related. It is clear then that stability and speed of response are important considerations in the analysis, design, and control of vibrating systems.

The level of stability of a linear dynamic system depends on the real parts of the eigenvalues (or poles), which are the roots of the characteristic equation. Specifically, if all the roots have real parts that are negative, then the system is stable. Also, the more negative the real part of a pole, the faster the decay of the free response component corresponding to that pole. The inverse of the negative real part is the time constant. The smaller the time constant, the faster the decay of the corresponding free response, and hence, the higher the level of stability associated with that pole. We can summarize these observations as follows:

Level of stability. Depends on decay rate of free response (and hence on time constants or real parts of poles)

Speed of response. Depends on natural frequency and damping for oscillatory systems and decay rate for nonoscillatory systems

Time constant. Determines stability and decay rate of free response (and speed of response in nonoscillatory systems)

Now let us consider the specific case of a damped simple oscillator given by Equation 1.47.

Case 1 ($\zeta < 1$)

The free response is given by $x = A e^{-\zeta\omega_n t} \sin(\omega_d t + \phi)$

$$\text{Time constant } \tau = \frac{1}{\zeta\omega_n} \quad (1.85)$$

The system is asymptotically stable. The larger $\zeta\omega_n$, the more stable the system. Also, the speed of response increases with both ω_d and $\zeta\omega_n$.

Case 2 ($\zeta > 1$)

The response is nonoscillatory, and is given by

$$x = A_1 e^{\lambda_1 t} \text{ (decays slower)} + A_2 e^{\lambda_2 t} \text{ (decays faster)}$$

where $\lambda_1 = -\zeta\omega_n + \sqrt{\zeta^2 - 1}\omega_n$ and $\lambda_2 = -\zeta\omega_n - \sqrt{\zeta^2 - 1}\omega_n$.

This system has two time constants:

$$\tau_1 = \frac{1}{|\lambda_1|} \quad \text{and} \quad \tau_2 = \frac{1}{|\lambda_2|} \quad (1.86)$$

Note that τ_1 is the dominant (slower) time constant. The system is also asymptotically stable. The larger the $|\lambda_1|$ the faster and more stable the system.

Consider an underdamped system and an overdamped system with damping ratios ζ_u and ζ_o , respectively. We can show that the underdamped system is more stable than the overdamped system if and only if

$$\zeta_o - \sqrt{\zeta_o^2 - 1} < \zeta_u \quad (1.87a)$$

or equivalently,

$$\zeta_o > \frac{\zeta_u^2 + 1}{2\zeta_u} \quad (1.87b)$$

where $\zeta_o > 1 > \zeta_u > 0$ by definition.

Proof

To be more stable, we should have the underdamped pole located farther away than the dominant overdamped pole from the imaginary axis of the pole plane; thus

$$\zeta_u \omega_n > \zeta_o \omega_n - \sqrt{\zeta_o^2 - 1} \omega_n$$

Hence,

$$\zeta_u > \zeta_o - \sqrt{\zeta_o^2 - 1}$$

Now, bring the square-root term to the left-hand side and square it:

$$\zeta_o^2 - 1 > (\zeta_o - \zeta_u)^2 = \zeta_o^2 - 2\zeta_o\zeta_u + \zeta_u^2$$

Hence,

$$2\zeta_o\zeta_u > \zeta_u^2 + 1$$

or

$$\zeta_o > \frac{\zeta_u^2 + 1}{2\zeta_u}$$

This completes the proof. \square

To explain this result further, consider an undamped ($\zeta = 0$) simple oscillator of natural frequency ω_n . Its poles are at $\pm j\omega_n$ (on the imaginary axis of the pole plane). Now let us add damping and increase ζ from 0 to 1. Then the complex conjugates poles $-\zeta\omega_n \pm j\omega_d$ will move away from the imaginary axis as ζ increases (because $\zeta\omega_n$ increases) and hence the level of stability will increase. When ζ reaches the value 1 (critical damping) we obtain two identical and real poles at $-\omega_n$. When ζ is increased beyond 1, the poles will be real and unequal, with one pole having a magnitude smaller than ω_n and the other having a magnitude larger than ω_n . The former (closer to the “origin” of zero) is the dominant pole, and will determine both stability and the speed of response of the overdamped system. It follows that, as ζ increases beyond 1, the two poles will branch out from the location $-\omega_n$, one moving towards the origin (becoming less stable) and the other moving away from the origin. It is now clear that as ζ is increased beyond the point of critical damping, the system becomes less stable. Specifically, for a given value of $\zeta_u < 1$, there is a value of $\zeta_o > 1$, governed by Equation 1.87, above which the overdamped system is less stable and slower than the underdamped system.

Example 1.4

Consider the simple oscillator shown in Figure 1.14, with parameters $m = 4$ kg, $k = 1.6 \times 10^3$ N/m, and the two cases of damping:

1. $b = 80$ N/m/sec
2. $b = 320$ N/m/sec

We will study the nature of the free response in each case.

The undamped natural frequency of the system is

$$\omega_n = \sqrt{\frac{k}{m}} = \sqrt{\frac{1.6 \times 10^3}{4}} \text{ rad/sec} = 20.0 \text{ rad/sec}$$

Case 1

$$2\zeta\omega_n = \frac{b}{m} \quad \text{or} \quad 2\zeta \times 20 = \frac{80}{4}$$

Then,

$$\zeta_u = 0.5$$

The system is underdamped in this case.

Case 2

$$2\zeta \times 20 = \frac{320}{4}$$

Then,

$$\zeta_o = 2.0$$

The system is overdamped in this case.

Case 3

The characteristic equation is

$$\lambda^2 + 2 \times 0.5 \times 20\lambda + 20^2 = 0$$

or

$$\lambda^2 + 20\lambda + 20^2 = 0$$

The roots (eigenvalues or poles) are

$$\lambda = -10 \pm j\sqrt{20^2 - 10^2} = -10 \pm j10\sqrt{3}$$

The free (no force) response is given by

$$x = A e^{-10t} \sin(10\sqrt{3}t + \phi)$$

The amplitude A and the phase angle ϕ can be determined using initial conditions.

$$\text{Time constant } \tau = \frac{1}{10} = 0.1 \text{ sec}$$

Case 4

The characteristic equation is

$$\lambda^2 + 2 \times 2 \times 20\lambda + 20^2 = 0$$

or

$$\lambda^2 + 80\lambda + 20^2 = 0$$

The roots are

$$\begin{aligned}\lambda &= -40 \pm \sqrt{40^2 - 20^2} = -40 \pm 20\sqrt{3} \\ &= -5.36, -74.64\end{aligned}$$

The free response is given by

$$x = C_1 e^{-5.36t} + C_2 e^{-74.64t}$$

The constants C_1 and C_2 can be determined using initial conditions. The second term on the right-hand side goes to zero much faster than the first term, as shown in Figure 1.15. Hence, the first term will dominate and will determine the dominant time constant, level of stability, and speed of response. Specifically, the response may be approximated as

$$x \cong C_1 e^{-5.36t}$$

Hence,

$$\text{Time constant } \tau = \frac{1}{5.36} = 0.19 \text{ sec}$$

This value is double that of Case 1. Consequently, it is clear that the underdamped system (Case 1) decays faster than the overdamped system (Case 2). In fact, according to Equation 1.87b, with $\zeta_u = 0.5$ we have

$$\zeta_u > \frac{0.5^2 + 1}{2 \times 0.5} = 1.25$$

Hence, an overdamped system of damping ratio greater than 1.25 will be less stable than the underdamped system of damping ratio 0.5.

Table 1.1 summarizes some natural characteristics of a damped simple oscillator under three different levels of damping. The nature of the natural response for these three cases is sketched in Figure 1.16. In general, the natural response of a system is governed by its eigenvalues (or poles), which are the roots of the characteristic equation. The poles may be marked on a complex plane (s-plane), with the horizontal axis representing the real part and the vertical axis representing the imaginary part. The nature of the free response depending on the pole location of the system is shown in Figure 1.17.

FIGURE 1.15 The free (homogeneous) response components of an overdamped system.

TABLE 1.1 Natural Characteristics of a Damped Oscillator

	Damping Ratio		
	$\zeta < 1$	$\zeta > 1$	$\zeta = 1$
Level of damping	Underdamped	Overdamped	Critically damped
Oscillatory response	Yes	No	No
Stability	Asymptotically stable (less stable than $\zeta = 1$ case but not necessarily less stable than the overdamped case)	Asymptotically stable (less stable than the critically damped case)	Asymptotically stable (most stable)
Speed of response	Better than overdamped	Lower than critical	Good
Time constant	$1/(\zeta\omega_n)$	$1/(\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n)$	$1/\omega_n$

FIGURE 1.16 Free response of a damped oscillator: (a) underdamped; (b) critically damped; (c) overdamped.

1.6 Forced Response

The *free response* of a vibratory system is the response to some initial excitation and in the absence of any subsequent forcing input. This corresponds to the “natural” response of the system. Mathematically, it is the homogeneous solution, because it is obtained by solving the homogeneous equation of the system (i.e., without the input terms). The natural response, the free response, and the homogeneous solution are synonymous, in the absence of a forcing input to the system.

The *forced response* of a dynamic (vibratory) system is the response of the system to a forcing input. When there is a forcing excitation (i.e., an input) on a system, the equation of motion will be nonhomogeneous (i.e., the right-hand side will not be zero). Then, the total solution (total response T) will be given by the sum of the homogeneous solution (H) and the particular integral (P), subject to the system initial conditions. This may be determined by the mathematical solution of the equation of motion. The total response can be separated into the terms that depend on the initial conditions (X) and the terms that depend on the forcing excitation (F). This is in fact the physical interpretation of the total solution. Note that X is called the “free response,” “initial-condition response,” or the “zero-input

FIGURE 1.17 Dependence of free response (or stability) on the pole location. (A and B are stable; C is marginally stable; D and E are unstable.)

response.” The term F is called the “forced response” or the “zero-initial-condition response” or the “zero-state response.” In general H is not identical to X and P is not identical to F . But, when there is no forcing excitation (no input), by definition H and X will be identical. Furthermore, under steady-state conditions the homogeneous part or initial-condition response will die down (assuming that there is some damping, and the system is stable). Then, F will become equal to P . Note that, even when the initial conditions are zero, F and P may not be identical because F may contain a natural response component that is excited by the forcing input. This component will die out with time, however.

The total response will depend on the natural characteristics of the system (as for the free response) and also on the nature of the forcing excitation. Mathematically, then, the total response will be determined by both the homogeneous solution and the particular solution. The complete solution will require a knowledge of the input (forcing excitation) and the initial conditions.

The behavior of a dynamic system when subjected to a certain forcing excitation may be studied by analyzing a model of the system. This is commonly known as system-response analysis. System response may be studied either in the *time domain*, where the independent variable of the system response is time, or in the *frequency domain*, where the independent variable of the system response is frequency. Time-domain analysis and frequency-domain analysis are equivalent. Variables in the two domains are connected through the Fourier (integral) transform. The preference of one domain over the other depends on such factors as the nature of the excitation input, the type of the available analytical model, the time duration of interest, and the quantities that need to be determined. The frequency-domain analysis will be addressed in [Chapter 2](#).

1.6.1 Impulse-Response Function

Principle of superposition. Consider a linear dynamic (vibratory) system. The principle of superposition holds for a linear system. More specifically, if y_1 is the system response to excitation $u_1(t)$ and y_2 is the response to excitation $u_2(t)$, then $\alpha y_1 + \beta y_2$ is the system response to input $\alpha u_1(t) + \beta u_2(t)$ for any

FIGURE 1.18 Illustrations of (a) unit pulse and (b) unit impulse.

constants α and β and any excitation functions $u_1(t)$ and $u_2(t)$. This is true for both time-variant-parameter linear systems and constant-parameter linear systems.

Unit impulse. A *unit pulse* of width $\Delta\tau$ starting at time $t = \tau$ is shown in Figure 1.18(a). Its area is unity. A *unit impulse* is the limiting case of a unit pulse when $\Delta\tau \rightarrow 0$. Unit impulse acting at time $t = \tau$ is denoted by $\delta(t - \tau)$ and is graphically represented as in Figure 1.18(b). In mathematical analysis, this is known as the *Dirac delta function*. It is mathematically defined by the two conditions:

$$\delta(t - \tau) = \begin{cases} 0 & \text{for } t \neq \tau \\ \infty & \text{for } t = \tau \end{cases} \quad (1.88)$$

and

$$\int_{-\infty}^{\infty} \delta(t - \tau) dt = 1 \quad (1.89)$$

The Dirac delta function has the following well-known and useful properties:

$$\int_{-\infty}^{\infty} f(t) \delta(t - \tau) dt = f(\tau) \quad (1.90)$$

and

$$\int_{-\infty}^{\infty} \frac{d^n f(t)}{dt^n} \delta(t - \tau) dt = \left. \frac{d^n f(t)}{dt^n} \right|_{t=\tau} \quad (1.91)$$

for any well-behaved time function $f(t)$.

Impulse-response function. The system response (output) to a unit-impulse excitation (input) acted at time $t = 0$ is known as the *impulse-response function* and is denoted by $h(t)$.

1.6.2 Forced Response

The system output to an arbitrary input may be expressed in terms of its impulse-response function. This is the essence of the impulse-response approach to determining the forced response of a dynamic system.

Without loss of generality, assume that the system input $u(t)$ starts at $t = 0$; that is,

$$u(t) = 0 \quad \text{for } t < 0 \quad (1.92)$$

For a *physically realizable system*, the response does not depend on the future values of the input. Consequently,

$$y(t) = 0 \quad \text{for } t < 0 \quad (1.93)$$

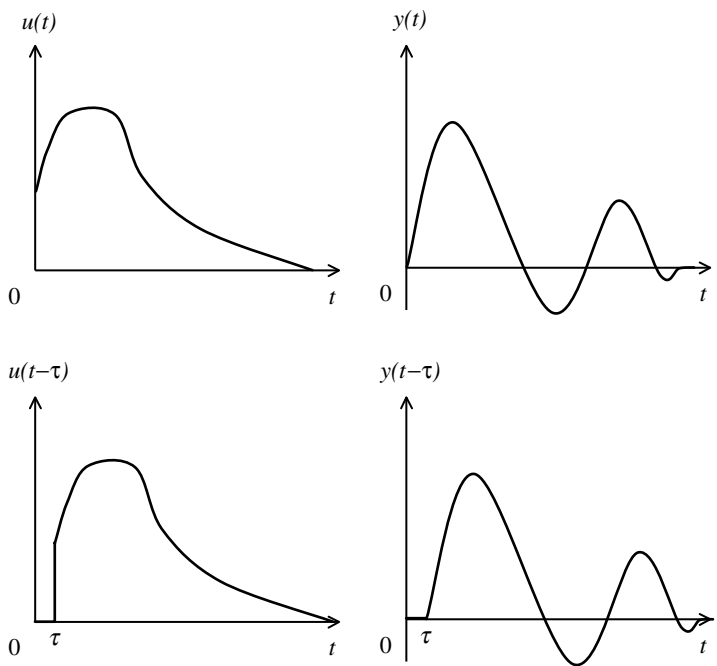

FIGURE 1.19 Response to a delayed input.

and

$$h(t) = 0 \quad \text{for } t < 0 \tag{1.94}$$

where $y(t)$ is the response of the system to any general excitation $u(t)$.

Furthermore, if the system is a *constant-parameter system*, then the response does not depend on the time origin used for the input. Mathematically, this is stated as follows: if the response to input $u(t)$ satisfying Equation 1.92 is $y(t)$, which satisfies Equation 1.93, then the response to input $u(t - \tau)$, which satisfies,

$$u(t - \tau) = 0 \quad \text{for } t < \tau \tag{1.95}$$

is $y(t - \tau)$, and it satisfies

$$y(t - \tau) = 0 \quad \text{for } t < \tau \tag{1.96}$$

This situation is illustrated in Figure 1.19. It follows that the delayed-impulse input $\delta(t - \tau)$, having time delay τ , produces the delayed response $h(t - \tau)$.

Convolution integral. A given input $u(t)$ can be divided approximately into a series of pulses of width $\Delta\tau$ and magnitude $u(\tau) \Delta\tau$. In Figure 1.20, as $\Delta\tau \rightarrow 0$, the pulse shown by the shaded area becomes an impulse acting at $t = \tau$, having the magnitude $u\tau d\tau$. The value of this impulse is given by $\delta(t - \tau)u(\tau)d\tau$. In a linear, constant-parameter system, it produces the response $h(t - \tau)u(\tau)d\tau$. By integrating over the entire time duration of the input $u(t)$, the overall response $y(t)$ is obtained as

$$y(t) = \int_0^\infty h(t - \tau)u(\tau)d\tau \tag{1.97}$$

FIGURE 1.20 A general input treated as a continuous series of impulses.

Equation 1.97 is known as the *convolution integral*. This is in fact the forced response, under zero initial conditions.

In view of Equation 1.94, it follows that $h(t - \tau) = 0$ for $\tau > t$. Consequently, the upper limit of integration in Equation 1.97 could be made equal to t without affecting the result. Similarly, in view of Equation 1.92, the lower limit of integration in Equation 1.97 could be made $-\infty$. Furthermore, by introducing the change of variable $\tau \rightarrow t - \tau$, an alternative version of the convolution integral is obtained. Several valid versions of the convolution integral (or response equation) for a linear, constant-parameter system are given below:

$$y(t) = \int_0^{\infty} h(\tau)u(t - \tau)d\tau \quad (1.97a)$$

$$y(t) = \int_{-\infty}^{\infty} h(t - \tau)u(\tau)d\tau \quad (1.97b)$$

$$y(t) = \int_{-\infty}^{\infty} h(\tau)u(t - \tau)d\tau \quad (1.97c)$$

$$y(t) = \int_{-\infty}^t h(t - \tau)u(\tau)d\tau \quad (1.97d)$$

$$y(t) = \int_{-\infty}^t h(\tau)u(t - \tau)d\tau \quad (1.97e)$$

$$y(t) = \int_0^t h(t - \tau)u(\tau)d\tau \quad (1.97f)$$

$$y(t) = \int_0^t h(\tau)u(t - \tau)d\tau \quad (1.97g)$$

In fact, the lower limit of integration in the convolution integral could be any value satisfying $\tau \leq 0$, and the upper limit could be any value satisfying $\tau \geq t$. The use of a particular pair of integration limits depends on whether the functions $h(t)$ and $u(t)$ implicitly satisfy the conditions given by Equation 1.93 and Equation 1.94, or whether these conditions have to be imposed on them by means of the proper integration limits. It should be noted that the two versions given by Equation 1.97f and Equation 1.97g take these conditions into account explicitly and therefore are valid for all inputs and impulse-response functions.

It should be emphasized that the response given by the convolution integral assumes a zero initial state, and is known as the *zero-state response*, because the impulse response itself assumes a zero initial state. As we have stated, this is not necessarily equal to the “particular solution” in mathematical analysis. Also, as t increases ($t \rightarrow \infty$), this solution approaches the *steady-state response* denoted by y_{ss} , which is typically the particular solution. The impulse response of a system is the inverse Laplace transform of the transfer function. Hence, it can be determined using Laplace transform techniques. This aspect will be addressed in [Chapter 3](#). Some useful concepts of forced response are summarized in Box 1.3.

1.6.3 Response to a Support Motion

An important consideration in vibration analysis and in the testing of machinery and equipment is the response to a support motion. To illustrate the method of analysis, consider the linear, single-DoF system consisting of mass m , spring constant k , and damping constant b , subjected to support motion (displacement) $u(t)$. Vertical and horizontal configurations of this system are shown in [Figure 1.21](#).

Both configurations possess the same equation of motion, provided the support motion $u(t)$ and the mass response (displacement) y are measured from the fixed points that correspond to the initial, static-equilibrium position of the system. In the vertical configuration, the compressive force in the spring exactly balances the weight of the mass when it is in static equilibrium. In the horizontal configuration, the spring is unstretched when in static equilibrium. It may be easily verified that the equation of motion

Box 1.3

CONCEPTS OF FORCED RESPONSE

Total Response (T) = Homogeneous Solution (H) + Particular Integral (P)

= Free Response (X) + Forced Response (F)

= Initial-Condition Response (X) + Zero-Initial-Condition Response (F)

= Zero-Input Response (X) + Zero-State Response (F)

Note: In general, $H \neq X$ and $P \neq F$

With no input (no forcing excitation), by definition, $H \equiv X$

At steady state, F becomes equal to P .

Convolution Integral: Response $y = \int_0^t h(t - \tau)u(\tau)d\tau = \int_0^t h(\tau)u(t - \tau)d\tau$, where u = excitation (input) and h = impulse-response function (response to a unit-impulse input).

Damped Simple Oscillator: $\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2y = \omega_n^2u(t)$

$$\text{Poles (eigenvalues)} \lambda_1, \lambda_2 = \begin{cases} -\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n & \text{for } \zeta \geq 1 \\ -\zeta\omega_n \pm j\omega_d & \text{for } \zeta < 1 \end{cases}$$

ω_n = undamped natural frequency, ω_d = damped natural frequency, ζ = damping ratio.

Note: $\omega_d = \sqrt{1 - \zeta^2}\omega_n$.

Impulse-Response Function (Zero Initial Conditions):

$$h(t) = \begin{cases} \frac{\omega_n}{\sqrt{1 - \zeta^2}} \exp(-\zeta\omega_n t) \sin \omega_d t & \text{for } \zeta < 1 \\ \frac{\omega_n}{2\sqrt{\zeta^2 - 1}} [\exp \lambda_1 t - \exp \lambda_2 t] & \text{for } \zeta > 1 \\ \omega_n^2 t \exp(-\omega_n t) & \text{for } \zeta = 1 \end{cases}$$

Unit Step Response (Zero Initial Conditions):

$$y_{\text{step}}(t) = \begin{cases} 1 - \frac{1}{\sqrt{1 - \zeta^2}} \exp(-\zeta\omega_n t) \sin(\omega_d t + \phi) & \text{for } \zeta < 1 \\ 1 - \frac{1}{2\sqrt{\zeta^2 - 1}\omega_n} [\lambda_1 \exp \lambda_2 t - \lambda_2 \exp \lambda_1 t] & \text{for } \zeta > 1 \\ 1 - (\omega_n t + 1) \exp(-\omega_n t) & \text{for } \zeta = 1 \end{cases}$$

with

$$\cos \phi = \zeta$$

Note:

$$\text{Impulse Response} = \frac{d}{dt} (\text{Step Response})$$

FIGURE 1.21 A system subjected to support motion: (a) vertical configuration; (b) horizontal configuration.

is given by

$$m\ddot{y} + b\dot{y} + ky = ku(t) + bu(t) \quad (1.98)$$

in which $(\dot{}) = d/dt$ and $(\ddot{}) = d^2/dt^2$. The two parameters ω_n and ζ are undamped natural frequency and damping ratio, respectively, given by $\omega_n = \sqrt{k/m}$ and $2\zeta\omega_n = b/m$, as usual. This results in the equivalent equation of motion:

$$\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2y = \omega_n^2u(t) + 2\zeta\omega_n\dot{u}(t) \quad (1.99)$$

There are several ways to determine the response y from Equation 1.99 once the excitation function $u(t)$ is specified. The procedure used below is to first solve the modified equation:

$$\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2y = \omega_n^2u(t) \quad (1.100)$$

This can be identified as the equation of motion of the single-DoF system shown in Figure 1.15. Once this response is known, the response of the system (Equation 1.99) is obtained by applying the principle of superposition.

1.6.3.1 Impulse Response

Many important characteristics of a system can be studied by analyzing the system response to an impulse or a step-input excitation. Such characteristics include system stability, speed of response, time constants, damping properties, and natural frequencies. In this way, a knowledge of the system response to an arbitrary excitation is gained. A unit impulse or a unit step are baseline inputs or test inputs. Responses to such inputs can also serve as the basis for system comparison. In particular, it is usually possible to determine the degree of nonlinearity in a system by exciting it at two input intensity levels, separately, and checking whether proportionality is retained at the output; or by applying a harmonic excitation and checking whether limit cycles are encountered by the response.

The response of the system (Equation 1.100) to a unit impulse $u(t) = \delta(t)$ may be conveniently determined by the Laplace transform approach. Here, we will use a time-domain approach, instead. First, integrate Equation 1.100 over the almost zero time interval from $t = 0^-$ to $t = 0^+$. We obtain

$$\dot{y}(0^+) = \dot{y}(0^-) - 2\zeta\omega_n[y(0^+) - y(0^-)] - \omega_n^2 \int_{0^-}^{0^+} y \, dt + \omega_n^2 \int_{0^-}^{0^+} u(t) \, dt \quad (1.101)$$

Suppose that the system starts from rest. Hence, $y(0^-) = 0$ and $\dot{y}(0^-) = 0$. Also, when an impulse is applied over an infinitesimal time period $[0^-, 0^+]$ the system will not be able to move through a finite distance during that period. Hence, $y(0^+) = 0$ as well, and furthermore, the integral of y on the right-hand side of Equation 1.101 will also be zero. Now, by the definition of a unit impulse, the integral of u

on the right-hand side of Equation 1.101 will be unity. Hence, we have $y(0^+) = \omega_n^2$. It follows that as soon as a unit impulse is applied to the system (Equation 1.100) the initial conditions will become

$$y(0^+) = 0 \quad \text{and} \quad \dot{y}(0^+) = \omega_n^2 \quad (1.102)$$

Also, beyond $t = 0^+$ the excitation $u(t) = 0$, according to the definition of an impulse. Then, the impulse response of the system (Equation 1.100) is obtained by its homogeneous solution (as carried out before, under free response), but with the initial conditions given in Equation 1.102. The three cases of damping ratio ($\zeta < 1$, $\zeta > 1$, and $\zeta = 1$) should be considered separately. We obtain the following results:

$$y_{\text{impulse}}(t) = h(t) = \frac{\omega_n}{\sqrt{1 - \zeta^2}} \exp(-\zeta \omega_n t) \sin \omega_d t \quad \text{for } \zeta < 1 \quad (1.103a)$$

$$y_{\text{impulse}}(t) = h(t) = \frac{\omega_n}{2\sqrt{\zeta^2 - 1}} [\exp \lambda_1 t - \exp \lambda_2 t] \quad \text{for } \zeta > 1 \quad (1.103b)$$

$$y_{\text{impulse}}(t) = h(t) = \omega_n^2 t \exp(-\omega_n t) \quad \text{for } \zeta = 1 \quad (1.103c)$$

An explanation concerning the dimensions of $h(t)$ is appropriate here. Note that $y(t)$ has the same dimensions as $u(t)$. Since $h(t)$ is the response to a unit impulse, $\delta(t)$, it follows that they have the same dimensions. The magnitude of $\delta(t)$ is represented by a unit area in the $u(t)$ versus t plane. Consequently, $\delta(t)$ has the dimensions of (1/time) or (frequency). Clearly then, $h(t)$ also has the dimensions of (1/time) or (frequency).

1.6.3.2 The Riddle of Zero Initial Conditions

For a second-order system, zero initial conditions correspond to $y(0) = 0$ and $\dot{y}(0) = 0$. It is clear from Equations 1.103 that $h(0) = 0$, but $\dot{h}(0) \neq 0$, which appears to violate the zero-initial-conditions assumption. This situation is characteristic in a system response to an impulse and its derivatives. This may be explained as follows. When an impulse is applied to a system at rest (zero initial state), the highest derivative of the system differential equation momentarily becomes infinity.

FIGURE 1.22 Impulse-response functions of a damped oscillator.

As a result, the next lower derivative becomes finite (nonzero) at $t = 0^+$. The remaining lower derivatives maintain their zero values at that instant. When an impulse is applied to the system given by Equation 1.100, for example, the acceleration $\ddot{y}(t)$ becomes infinity, and the velocity $\dot{y}(t)$ takes a nonzero (finite) value shortly after its application ($t = 0^+$). The displacement $y(t)$, however, would not have sufficient time to change at $t = 0^+$. The impulse input is therefore equivalent to a velocity initial condition, in this case. This initial condition is determined by using the integrated version (Equation 1.101) of the system (Equation 1.100), as has been done.

The impulse-response functions given by Equations 1.103 are plotted in Figure 1.22 for some representative values of the damping ratio. It should be noted that for $0 < \zeta < 1$ the angular frequency of damped vibrations is ω_d , the *damped natural frequency*, which is smaller than the *undamped natural frequency* ω_n .

1.6.3.3 Step Response

A unit-step excitation is defined by

$$u(t) = \begin{cases} 1 & \text{for } t > 0 \\ 0 & \text{for } t \leq 0 \end{cases} \quad (1.104)$$

Unit-impulse excitation $\delta(t)$ may be interpreted as the time derivative of $u(t)$,

$$\delta(t) = \frac{du(t)}{dt} \quad (1.105)$$

Note that Equation 1.105 re-establishes the fact that for a nondimensional $u(t)$, the dimension of $\delta(t)$ is $(\text{time})^{-1}$. Then, since a unit step is the integral of a unit impulse, the step response can be obtained directly as the integral of the impulse response; thus,

$$y_{\text{step}}(t) = \int_0^t h(\tau) d\tau \quad (1.106)$$

This result also follows from the convolution integral (Equation 1.97g) because, for a delayed unit step, we have

$$u(t - \tau) = \begin{cases} 1 & \text{for } \tau < t \\ 0 & \text{for } \tau \geq t \end{cases} \quad (1.107)$$

Thus, by integrating Equations 1.103 with zero initial conditions, the following results are obtained for step response:

$$y_{\text{step}}(t) = 1 - \frac{1}{\sqrt{1 - \zeta^2}} \exp(-\zeta \omega_n t) \sin(\omega_d t + \phi) \quad \text{for } \zeta < 1 \quad (1.108a)$$

$$y_{\text{step}} = 1 - \frac{1}{2\sqrt{1 - \zeta^2} \omega_n} [\lambda_1 \exp \lambda_2 t - \lambda_2 \exp \lambda_1 t] \quad \text{for } \zeta > 1 \quad (1.108b)$$

$$y_{\text{step}} = 1 - (\omega_n t + 1) \exp(-\omega_n t) \quad \text{for } \zeta = 1 \quad (1.108c)$$

with

$$\cos \phi = \zeta \quad (1.109)$$

The step responses given by Equations 1.108 are plotted in Figure 1.23 for several values of damping ratio.

Note that, since a step input does not cause the highest derivative of the system equation to approach infinity at $t = 0^+$, the initial conditions that are required to solve the system equation remain unchanged at $t = 0^+$, provided that there are no derivative terms on the input side of the system equation. If there are derivative terms in the input, then, for example, a step can become an impulse and the situation changes.

Now, the response of the system in Figure 1.21, when subjected to a unit step of support excitation (see Equation 1.99), is obtained by using the principle of superposition, as the sum of the unit-step

FIGURE 1.23 Unit-step response of a damped simple oscillator.

response and $(2\zeta/\omega_n)$ times the unit-impulse response of Equation 1.100. Thus, from Equation 1.103 and Equation 1.108, we obtain the step response of the system in Figure 1.21 as

$$y(t) = 1 - \frac{\exp(-\zeta\omega_n t)}{\sqrt{1-\zeta^2}} [\sin(\omega_d t + \phi) - 2\zeta \sin \omega_d t] \quad \text{for } \zeta < 1 \quad (1.110a)$$

$$y(t) = 1 + \frac{1}{2\sqrt{1-\zeta^2}\omega_n} [\lambda_2 \exp \lambda_2 t - \lambda_1 \exp \lambda_1 t] \quad \text{for } \zeta > 1 \quad (1.110b)$$

$$y(t) = 1 + (\omega_n t - 1)\exp(-\omega_n t) \quad \text{for } \zeta = 1 \quad (1.110c)$$

1.6.3.4 Liebnitz's Rule

The time derivative of an integral whose limits of integration are also functions of time may be obtained using Liebnitz's rule. It is expressed as

$$\frac{d}{dt} \int_{a(t)}^{b(t)} f(\tau, t) d\tau = f[b(t), t] \frac{db(t)}{dt} - f[a(t), t] \frac{da(t)}{dt} + \int_{a(t)}^{b(t)} \frac{\partial f}{\partial t}(\tau, t) d\tau \quad (1.111)$$

By repeated application of Liebnitz's rule to Equation 1.97g, we can determine the i th derivative of the response variable; thus,

$$\begin{aligned} \frac{d^i y(t)}{dt^i} = & \left[h(t) + \frac{dh(t)}{dt} + \cdots + \frac{d^{i-1}h(t)}{dt^{i-1}} \right] u(0) + \left[h(t) + \frac{dh(t)}{dt} + \cdots + \frac{d^{i-2}h(t)}{dt^{i-2}} \right] \frac{du(0)}{dt} \\ & + \cdots + h(t) \frac{d^{i-1}u(0)}{dt^{i-1}} + \int_0^t h(\tau) \frac{d^i u(t-\tau)}{dt^i} d\tau \end{aligned} \quad (1.112)$$

From this result, it follows that the zero-state response to input $[d^i u(t)]/dt^i$ is $[d^i y(t)]/dt^i$, provided that all lower-order derivatives of $u(t)$ vanish at $t = 0$. This result verifies the fact that, for instance, the first derivative of the unit-step response gives the impulse-response function.

It should be emphasized that the convolution integral (Equation 1.97) gives the forced response of a system, assuming that the initial conditions are zero. For nonzero initial conditions, the homogeneous

solution (e.g., Equation 1.54 or Equation 1.58) should be added to this zero-initial-condition response and then the unknown constants should be evaluated by using the initial conditions. Care should be exercised in the situation in which there is an initial velocity in the system and to this an impulsive excitation is applied. In this case, one approach would be to first determine the velocity at $t = 0^+$ by adding to the initial velocity at $t = 0^-$, the velocity change in the system due to the impulse. The initial displacement will not change, however, due to the impulse. Once the initial conditions at $t = 0^+$ are determined in this manner, the complete solution can be obtained as usual.

Summary

This chapter presents the frequency-domain analysis of mechanical vibrating systems. In the frequency domain, the independent variable is frequency. The response of a vibrating system to harmonic excitations under various levels of damping (overdamped, underdamped, and critically damped) is analyzed. Frequency transfer function techniques including impedance, mobility, force transmissibility, motion transmissibility, and receptance are studied. Transform techniques (Fourier and Laplace) are applicable in the frequency-domain analysis. The Q-factor method of measuring damping is derived. Component interconnection laws are established for frequency-domain analysis. The emphasis is on single-degree-of-freedom (single-DoF) systems.

2.1 Introduction

In many vibration problems, the primary excitation force typically has a repetitive periodic nature, and in some cases this periodic forcing function may be even purely sinusoidal. Examples are excitations due to mass eccentricity and misalignments in rotational components, tooth meshing in gears, and electromagnetic devices excited by AC or periodic electrical signals. In basic terms, the frequency-response of a dynamic system is the response to a pure sinusoidal excitation. As the amplitude and the frequency of the excitation are changed, the response also changes. In this manner, the response of the system over a range of excitation frequencies can be determined. This represents the frequency response. In this case, frequency (ω) is the independent variable and hence we are dealing with the *frequency domain*.

Frequency-domain considerations are applicable even when the signals are not periodic. In fact, a time signal can be transformed into its frequency spectrum through the Fourier transform. For a given time signal, an equivalent Fourier spectrum, which contains all the frequency (sinusoidal) components of the signal, can be determined either analytically or computationally. Hence, a time-domain representation and analysis has an equivalent frequency-domain representation and analysis, at least for linear dynamic systems. For this reason, and also because of the periodic nature of typical vibration signals, frequency-response analysis is extremely useful in the subject of mechanical vibrations. The response to a particular form of “excitation” is what is considered in the frequency-domain analysis. Hence, we are specifically dealing with the subject of “forced response” analysis, albeit in the frequency domain.

2.2 Response to Harmonic Excitations

Consider a simple oscillator with an excitation force $f(t)$, as shown in Figure 2.1.

The equation of motion is given by

$$m\ddot{x} + b\dot{x} + kx = f(t) \quad (2.1)$$

Suppose that $f(t)$ is sinusoidal (i.e., harmonic). Pick the time reference such that

$$f(t) = f_0 \cos \omega t \quad (2.2)$$

where

ω = excitation frequency

f_0 = forcing excitation amplitude

FIGURE 2.1 A forced simple oscillator.

For a system subjected to a forcing excitation, we have

$$\begin{aligned} \text{Total Response} &= \text{Homogeneous Response } x_h + \text{Particular Response } x_p \\ &\quad \begin{matrix} T \\ \text{(Natural Response)} \end{matrix} \quad \begin{matrix} H \\ \text{(Enforced Response)} \end{matrix} \\ &= \text{Free Response} \quad + \quad \text{Forced Response} \\ &\quad \begin{matrix} X \\ \text{(Depends only on initial conditions)} \\ \text{does not contain enforced response} \\ \text{and depends entirely on the} \\ \text{natural/homogeneous response} \end{matrix} \quad \begin{matrix} F \\ \text{(Depends only on } f_0) \\ \text{but contains a natural/homogeneous component} \end{matrix} \end{aligned}$$

Using these concepts, we analyze the forced problem, which may be written as

$$\ddot{x} + \frac{b}{m}\dot{x} + \frac{k}{m}x = \frac{f_0}{m} \cos \omega t = u(t) \quad (2.3)$$

or

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = a \cos \omega t = u(t) \quad (2.4)$$

where $u(t)$ is the modified excitation. Also,

ω_n = undamped natural frequency

ζ = damping ratio

The total response is given by

$$x = x_h + x_p \quad (2.5)$$

with

$$x_h = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t} \quad (2.6)$$

The particular solution x_p , by definition, is one solution that satisfies Equation 2.4. It should be intuitively clear that this will be of the form

$$x_p = a_1 \cos \omega t + a_2 \sin \omega t \text{ \{except for the case: } \zeta = 0 \text{ and } \omega = \omega_n \text{\}} \quad (2.7)$$

where the constants a_1 and a_2 are determined by substituting Equation 2.7 into the system Equation 2.4 and equating the like coefficient. This is known as the method of undetermined coefficients.

We will consider several important cases.

2.2.1 Response Characteristics

Case 1: Undamped oscillator with excitation frequency \neq natural frequency

We have

$$\ddot{x} + \omega_n^2 x = a \cos \omega t \quad \text{with } \omega \neq \omega_n \quad (2.8)$$

Homogeneous solution:

$$x_h = A_1 \cos \omega_n t + A_2 \sin \omega_n t \quad (2.9)$$

Particular solution:

$$x_p = \frac{a}{(\omega_n^2 - \omega^2)} \cos \omega t \quad (2.10)$$

It can be easily verified that x_p given by Equation 2.10 satisfies the forced system Equation 2.4, with $\zeta = 0$. Hence, it is a particular solution.

Complete solution:

$$x = \underbrace{A_1 \cos \omega_n t + A_2 \sin \omega_n t}_H + \underbrace{\frac{a}{(\omega_n^2 - \omega^2)} \cos \omega t}_P \quad (2.11)$$

Satisfies the homogeneous equation Satisfies the equation with input

Now A_1 and A_2 are determined using the initial conditions:

$$x(0) = x_0 \text{ and } \dot{x}(0) = v_0 \quad (2.12)$$

Specifically, we obtain

$$x_0 = A_1 + \frac{a}{\omega_n^2 - \omega^2} \quad (2.13a)$$

$$v_0 = A_2 \omega_n \quad (2.13b)$$

Hence, the complete response is

$$x = \underbrace{\left[x_0 - \frac{a}{(\omega_n^2 - \omega^2)} \right] \cos \omega_n t + \frac{v_0}{\omega_n} \sin \omega_n t}_{\substack{H \\ \text{Homogeneous solution}}} + \underbrace{\frac{a}{\omega_n^2 - \omega^2} \cos \omega t}_{\substack{P \\ \text{Particular solution}}} \quad (2.14a)$$

$$= \underbrace{x_0 \cos \omega_n t + \frac{v_0}{\omega_n} \sin \omega_n t}_{\substack{X \\ \text{Free response} \\ \text{(depends only on initial conditions)} \\ \text{comes from } x_h \\ \text{*Sinusoidal at } \omega_n}} + \underbrace{\frac{a}{(\omega_n^2 - \omega^2)} \frac{[\cos \omega t - \cos \omega_n t]}{2 \sin \frac{(\omega_n + \omega)}{2} t \sin \frac{(\omega_n - \omega)}{2} t}}_{\substack{F \\ \text{Forced response (depends on input)} \\ \text{comes from both } x_h \text{ and } x_p \\ \text{*Will exhibit a beat phenomenon for } \omega_n - \omega; \text{ i.e.,} \\ \text{ } (\omega_n + \omega)/2 \text{ wave modulated by } (\omega_n - \omega)/2 \text{ wave}}} \quad (2.14b)$$

This is a stable response in the sense of bounded-input bounded-output (BIBO) stability, as it is bounded and does not increase steadily.

Note: If there is no forcing excitation, the homogeneous solution H and the free response X will be identical. With a forcing input, the natural response (the homogeneous solution) will be influenced by it in general, as is clear from Equation 2.14b.

Case 2: Undamped oscillator with $\omega = \omega_n$ (resonant condition)

In this case, the x_p that was used before is no longer valid. This is the degenerate case, because otherwise the particular solution cannot be distinguished from the homogeneous solution and the former will be completely absorbed into the latter. Instead, in view of the “double-integration” nature of the forced system equation when $\omega = \omega_n$, we use the particular solution (P):

$$x_p = \frac{at}{2\omega} \sin \omega t \quad (2.15)$$

This choice of particular solution is strictly justified by the fact that it satisfies the forced system equation.

Complete solution:

$$x = A_1 \cos \omega t + A_2 \sin \omega t + \frac{at}{2\omega} \sin \omega t \quad (2.16)$$

Initial conditions:

$$x(0) = x_0 \text{ and } \dot{x}(0) = v_0.$$

We obtain

$$x_0 = A_1 \quad (2.17a)$$

$$v_0 = \omega A_2 \quad (2.17b)$$

The total response is

$$x = \underbrace{x_0 \cos \omega t + \frac{v_0}{\omega} \sin \omega t}_{\substack{X \\ \text{Free response (depends on initial conditions)} \\ \text{*Sinusoidal at } \omega}} + \underbrace{\frac{at}{2\omega} \sin \omega t}_{\substack{F \\ \text{Forced response (depends on input)} \\ \text{*Amplitude increases linearly}}} \quad (2.18)$$

Since the forced response increases steadily, this is an *unstable* response in the BIBO sense. Furthermore, the homogeneous solution H and the free response X are identical, and the particular solution P is identical to the forced response F in this case.

FIGURE 2.2 Forced response of a harmonically excited undamped simple oscillator: (a) for a large frequency difference; (b) for a small frequency difference (beat phenomenon); (c) response at resonance.

Note that the same system (undamped oscillator) gives a bounded response for some excitations, while producing an unstable (steady linear increase) response when the excitation frequency is equal to its natural frequency. Hence, the system is not quite unstable, but is not quite stable either. In fact, the undamped oscillator is said to be marginally stable. When the excitation frequency is equal to the natural frequency it is reasonable for the system to respond in a complementary and steadily increasing manner because this corresponds to the most “receptive” excitation. Specifically, in this case, the excitation complements the natural response of the system. In other words, the system is “in resonance” with the excitation, and the condition is called a resonance. We will address this aspect for the more general case of a damped oscillator, in the sequel.

Figure 2.2 shows typical forced responses of an undamped oscillator when there is a large difference between the excitation and the natural frequencies (Case 1); a small difference between the excitation and the natural frequencies when a beat phenomenon is clearly manifested (also Case 1); and for the resonant case (Case 2).

Case 3: Damped oscillator

The equation of forced motion is

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = a \cos \omega t \quad (2.19)$$

Particular Solution (Method 1):

Since derivatives of both odd order and even order are present in this equation, the particular solution should have terms corresponding to odd and even derivatives of the

forcing function (i.e., $\sin \omega t$ and $\cos \omega t$). Hence, the appropriate particular solution will be of the form:

$$x_p = a_1 \cos \omega t + a_2 \sin \omega t \quad (2.20)$$

Substitute Equation 2.20 into Equation 2.19. We obtain

$$-\omega^2 a_1 \cos \omega t - \omega^2 a_2 \sin \omega t + 2\zeta\omega_n[-\omega a_1 \sin \omega t + \omega a_2 \cos \omega t] + \omega_n^2[a_1 \cos \omega t + a_2 \sin \omega t] = a \cos \omega t$$

Equate like coefficients:

$$-\omega^2 a_1 + 2\zeta\omega_n \omega a_2 + \omega_n^2 a_1 = a$$

$$-\omega^2 a_2 - 2\zeta\omega_n \omega a_1 + \omega_n^2 a_2 = 0$$

Hence, we have

$$(\omega_n^2 - \omega^2)a_1 + 2\zeta\omega_n \omega a_2 = a \quad (2.21a)$$

$$-2\zeta\omega_n \omega a_1 + (\omega_n^2 - \omega^2)a_2 = 0 \quad (2.21b)$$

This can be written in the matrix–vector form:

$$\begin{bmatrix} (\omega_n^2 - \omega^2) & 2\zeta\omega_n \omega \\ -2\zeta\omega_n \omega & (\omega_n^2 - \omega^2) \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = \begin{bmatrix} a \\ 0 \end{bmatrix} \quad (2.21c)$$

The solution is

$$\begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = \frac{1}{D} \begin{bmatrix} (\omega_n^2 - \omega^2) & -2\zeta\omega_n \omega \\ 2\zeta\omega_n \omega & (\omega_n^2 - \omega^2) \end{bmatrix} \begin{bmatrix} a \\ 0 \end{bmatrix} \quad (2.22)$$

with the determinant

$$D = (\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n \omega)^2 \quad (2.23)$$

On simplification, we obtain

$$a_1 = \frac{(\omega_n^2 - \omega^2)}{D} a \quad (2.24a)$$

$$a_2 = \frac{2\zeta\omega_n \omega}{D} a \quad (2.24b)$$

This is the method of undetermined coefficients.

Particular Solution (Method 2): Complex Function Method

Consider

$$\ddot{x} + 2\zeta\omega_n \dot{x} + \omega_n^2 x = a e^{j\omega t} \quad (2.25)$$

where the excitation is complex. (Note: $e^{j\omega t} = \cos \omega t + j \sin \omega t$.)

The resulting complex particular solution is

$$x_p = X(j\omega) e^{j\omega t} \quad (2.26)$$

Note that we should take the real part of this solution as the true particular solution.

First substitute Equation 2.26 into Equation 2.25:

$$X[-\omega^2 + 2\zeta\omega_n j\omega + \omega_n^2] e^{j\omega t} = a e^{j\omega t}$$

Hence, since $e^{j\omega t} \neq 0$ in general,

$$X = \frac{a}{[-\omega^2 + 2\zeta\omega_n j\omega + \omega_n^2]} \quad (2.27)$$

The characteristic polynomial of the system is

$$\Delta(\lambda) = \lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 \quad (2.28a)$$

or, with the Laplace variable s ,

$$\Delta(s) = s^2 + 2\zeta\omega_n s + \omega_n^2 \quad (2.28b)$$

If we set $s = j\omega$, we have

$$\Delta(j\omega) = -\omega^2 + 2\zeta\omega_n j\omega + \omega_n^2 \quad (2.28c)$$

Note that Equation 2.28c is the denominator of Equation 2.27. Hence, Equation 2.27 can be written as

$$X = \frac{a}{\Delta(j\omega)} \quad (2.29)$$

It follows from Equation 2.26 that the complex particular solution is

$$x_p = \frac{a}{\Delta(j\omega)} e^{j\omega t} \quad (2.30)$$

Next let

$$\Delta(j\omega) = |\Delta| e^{j\phi} \quad (2.31)$$

Then, by substituting Equation 2.31 in Equation 2.30, we obtain

$$x_p = \frac{a}{|\Delta|} e^{j(\omega t - \phi)} \quad (2.32)$$

where it is clear from Equation 2.31 that

$$|\Delta| = \text{magnitude of } \Delta(j\omega)$$

$$\phi = \text{phase angle of } \Delta(j\omega)$$

The actual real particular solution is the real part of Equation 2.32 and is given by

$$x_p = \frac{a}{|\Delta|} \cos(\omega t - \phi) \quad (2.33)$$

It can easily be verified that this result is identical to what was obtained previously by Method 1, as given by Equation 2.20 together with Equations 2.23 and 2.24.

In passing, we will note here that the frequency-domain transfer function (i.e., response and excitation in the frequency domain) of the system Equation 2.19 is:

$$G(j\omega) = \frac{1}{\Delta} = \left[\frac{1}{s^2 + 2\zeta\omega_n s + \omega_n^2} \right]_{s=j\omega} \quad (2.34)$$

This frequency transfer function (also known as the frequency-response function) is obtained from the Laplace transfer function $G(s)$ by setting $s = j\omega$. We will discuss this aspect in more detail later.

The particular section (P) is equal to the steady-state solution, because the homogeneous solution dies out due to damping.

The particular solution (Equation 2.33) has the following characteristics:

1. The frequency is the same as the excitation frequency ω .
2. The amplitude is amplified by the magnitude $1/|\Delta| = |G(j\omega)|$.

3. The response is “lagged” by the phase angle ϕ of Δ (or “led” by the phase angle of $G(j\omega)$, denoted by $\angle G(j\omega)$).
4. Since the homogeneous solution of a stable system decays to zero, the particular solution is also the *steady-state* solution.

Resonance

The amplification ($|G(j\omega)| = 1/|\Delta|$) is maximum (i.e., resonance) when $|\Delta|$ is a minimum or $|\Delta|^2$ is a minimum. As noted earlier, this condition of peak amplification of a system when excited by a sinusoidal input is called resonance and the associated frequency of excitation is called resonant frequency. We can determine the resonance of the system (Equation 2.19) as follows:

Equation 2.28c is $\Delta = \omega_n^2 - \omega^2 + 2\zeta\omega_n\omega j$

Hence,

$$|\Delta|^2 = (\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2 = D \quad (2.35)$$

The resonance corresponds to a minimum value of D , or

$$\frac{dD}{d\omega} = 2(\omega_n^2 - \omega^2)(-2\omega) + 2(2\zeta\omega_n)^2\omega = 0 \quad \text{For a minimum.} \quad (2.36)$$

Hence, with straightforward algebra, the required condition for resonance is

$$-\omega_n^2 + \omega^2 + 2\zeta^2\omega_n^2 = 0$$

or

$$\omega^2 = (1 - 2\zeta^2)\omega_n^2$$

or

$$\omega = \sqrt{1 - 2\zeta^2}\omega_n$$

This is the resonant frequency, and is denoted as

$$\omega_r = \sqrt{1 - 2\zeta^2}\omega_n \quad (2.37)$$

Note that $\omega_r \leq \omega_d \leq \omega_n$, where ω_d is the damped natural frequency given by $\omega_d = \sqrt{1 - \zeta^2}\omega_n$. These three frequencies (resonant frequency, damped natural frequency, and undamped natural frequency) are almost equal for small ζ (i.e., for light damping).

The magnitude and the phase angle plots of $G(j\omega)$ are shown in [Figure 2.3](#). These curves correspond to the amplification and the phase change of the particular response (the steady-state response) with respect to the excitation input. This pair, the magnitude and phase angle plots of a transfer function with respect to frequency, is termed a Bode plot. Usually, logarithmic scales are used for both magnitude (e.g., decibels) and frequency (e.g., decades). In summary, the steady-state response of a linear system to a sinusoidal excitation is completely determined by the frequency transfer function of the system. The total response is determined by adding H to P and substituting initial conditions, as usual.

For an undamped oscillator ($\zeta = 0$), we notice from Equation 2.34 that the magnitude of $G(j\omega)$ becomes infinity when the excitation frequency is equal to the natural frequency (ω_n) of the oscillator. This frequency (ω_n) is clearly the resonant frequency (as well as natural frequency) of the oscillator. This fact has been further supported by the nature of the corresponding time response (see Equation 2.18 and [Figure 2.2\(c\)](#)), which grows (linearly) with time.

2.2.2 Measurement of Damping Ratio (Q-Factor Method)

The frequency transfer function of a simple oscillator (Equation 2.19) may be used to determine the damping ratio. This frequency-domain method is also termed the *half-power* point method, for reasons that should become clear from the following development.

FIGURE 2.3 Magnitude and phase angle curves of a simple oscillator (A Bode plot).

First we assume that $\zeta < 1/\sqrt{2}$. Strictly speaking, we should assume that $\zeta < 1/2\sqrt{2}$.

Without loss of generality, consider the normalized (or, non-dimensionalized) transfer function

$$G(j\omega) = \left[\frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \right]_{s=j\omega} = \frac{\omega_n^2}{\omega_n^2 - \omega^2 + 2\zeta\omega_n j\omega} \quad (2.38)$$

As noted before, the transfer function $G(s)$, where s is the Laplace variable, can be converted into the corresponding frequency transfer function simply by setting $s = j\omega$. Its value at the undamped natural frequency is

$$G(j\omega)|_{\omega=\omega_n} = \frac{1}{2\zeta j} \quad (2.39a)$$

Hence, the magnitude of $G(j\omega)$ (amplification) at $\omega = \omega_n$ is

$$|G(j\omega)|_{\omega=\omega_n} = \frac{1}{2\zeta} \quad (2.39b)$$

For small ζ we have $\omega_r \cong \omega_n$. Hence, $1/2\zeta$ is approximately the peak magnitude at resonance (the resonant peak). The actual peak is slightly larger.

It is clear from Equation 2.39a that the phase angle of $G(j\omega)$ at $\omega = \omega_n$ is $-\pi/2$.

When power is half of the peak power value (e.g., because the displacement squared is proportional to potential energy), then the velocity squared is proportional to kinetic energy, and power is the rate of

change of energy. Therefore, when the amplification is $1/\sqrt{2}$ of the peak value we have half-power points, given by:

$$\frac{1}{\sqrt{2}} \frac{1}{2\zeta} = \left| \frac{\omega_n^2}{\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega} \right| = \left| \frac{1}{1 - \left(\frac{\omega}{\omega_n}\right)^2 + 2j\zeta\left(\frac{\omega}{\omega_n}\right)} \right| \quad (2.40)$$

Square Equation 2.40:

$$\frac{1}{2 \times 4\zeta^2} = \frac{1}{\left[1 - \left(\frac{\omega}{\omega_n}\right)^2\right]^2 + 4\zeta^2\left(\frac{\omega}{\omega_n}\right)^2}$$

Hence,

$$\left(\frac{\omega}{\omega_n}\right)^4 - 2\left(\frac{\omega}{\omega_n}\right)^2 + 1 + 4\zeta^2\left(\frac{\omega}{\omega_n}\right)^2 = 8\zeta^2$$

or

$$\left(\frac{\omega}{\omega_n}\right)^4 - 2(1 - 2\zeta^2)\left(\frac{\omega}{\omega_n}\right)^2 + \underbrace{(1 - 8\zeta^2)}_{>0} = 0 \quad (2.41)$$

Now assume that $\zeta^2 < 1/8$ or $\zeta < 1/2\sqrt{2}$. Otherwise, we will not obtain two positive roots for $(\omega/\omega_n)^2$. Solve for $(\omega/\omega_n)^2$, which will give two roots ω_1^2 and ω_2^2 for ω^2 . Next, assume $\omega_2^2 > \omega_1^2$. Compare $(\omega^2 - \omega_1^2)(\omega^2 - \omega_2^2) = 0$ with Equation 2.41.

Sum of roots:

$$\frac{\omega_2^2 + \omega_1^2}{\omega_n^2} = 2(1 - 2\zeta^2) \quad (2.42)$$

Product of roots:

$$\frac{\omega_2^2 \omega_1^2}{\omega_n^4} = (1 - 8\zeta^2) \quad (2.43)$$

Hence,

$$\begin{aligned} \left(\frac{\omega_2 - \omega_1}{\omega_n}\right)^2 &= \left(\frac{\omega_2^2 + \omega_1^2 - 2\omega_2\omega_1}{\omega_n^2}\right) = 2(1 - 2\zeta^2) - 2\sqrt{1 - 8\zeta^2} \\ &= 2 - 4\zeta^2 - 2\left[1 - \frac{1}{2} \times 8\zeta^2 + O(\zeta^4)\right] \\ &\cong 2 - 4\zeta^2 - 2 + 8\zeta^2 \quad \{\text{because } O(\zeta^4) \rightarrow 0 \text{ for small } \zeta\} \\ &\cong 4\zeta^2 \end{aligned}$$

or

$$\frac{\omega_2 - \omega_1}{\omega_n} \cong 2\zeta$$

Hence, the damping ratio

$$\zeta \cong \frac{(\omega_2 - \omega_1)}{2\omega_n} = \frac{\Delta\omega}{2\omega_n} \cong \frac{\omega_2 - \omega_1}{\omega_2 + \omega_1} \quad (2.44)$$

It follows that, once the magnitude of the frequency-response function $G(j\omega)$ is experimentally determined, the damping ratio can be estimated from Equation 2.44, as illustrated in [Figure 2.4](#).

FIGURE 2.4 The Q-factor method of damping measurement.

The Q-factor, which measures the sharpness of resonant peak, is defined by

$$\text{Q-factor} = \frac{\omega_n}{\Delta\omega} = \frac{1}{2\zeta} \quad (2.45)$$

The term originated from the field of electrical tuning circuits where a sharp resonant peak is a desirable thing (*quality factor*). Some useful results on the frequency-response of a simple oscillator are summarized in Box 2.1.

Example 2.1

A dynamic model of a fluid coupling system is shown in Figure 2.5. The fluid coupler is represented by a rotatory viscous damper with damping constant b . It is connected to a rotatory load of moment of inertia J , restrained by a torsional spring of stiffness k , as shown. We now obtain the frequency transfer function of the system that relates the restraining torque τ of the spring to the angular displacement excitation $\alpha(t)$ that is applied at the free end of the fluid coupler. If $\alpha(t) = \alpha_0 \sin \omega t$, what is the magnitude (i.e., amplitude) of τ at steady state?

Solution

Newton's Second Law gives

$$J\ddot{\theta} = b(\dot{\alpha} - \dot{\theta}) - k\theta$$

Hence,

$$J\ddot{\theta} + b\dot{\theta} + k\theta = b\dot{\alpha} \quad (i)$$

Motion transfer function is

$$\frac{\theta}{\alpha} = \frac{bs}{Js^2 + bs + k} \quad (ii)$$

Note that the frequency transfer function is obtained simply by setting $s = j\omega$.

The restraining torque of the spring is $\tau = k\theta$. Hence,

$$\frac{\tau}{\alpha} = \frac{k\theta}{\alpha} = \frac{kbs}{Js^2 + bs + k} = G(s) \quad (iii)$$

Box 2.1

HARMONIC RESPONSE OF A SIMPLE OSCILLATOR

Undamped Oscillator:

$$\ddot{x} + \omega_n^2 x = a \cos \omega t; \quad x(0) = x_0, \quad \dot{x}(0) = v_0$$

$$x = \underbrace{x_0 \cos \omega_n t + \frac{v_0}{\omega_n} \sin \omega_n t}_X + \underbrace{\frac{a}{\omega_n^2 - \omega^2} [\cos \omega t - \cos \omega_n t]}_F \quad \text{for } \omega \neq \omega_n$$

$$x = \text{Same } X + \frac{at}{2\omega} \sin \omega t \quad \text{for } \omega = \omega_n \text{ (resonance)}$$

Damped Oscillator:

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2 x = a \cos \omega t$$

$$x = H + \underbrace{\frac{a}{|\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega|}}_P \cos(\omega t - \phi)$$

where

$$\tan \phi = \frac{2\zeta\omega_n\omega}{\omega_n^2 - \omega^2}; \quad \phi = \text{phase lag.}$$

Particular solution P is also the steady-state response.

Homogeneous solution $H = A_1 e^{\lambda_1 t} + A_2 e^{\lambda_2 t}$
 where λ_1 and λ_2 are roots of $\lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 = 0$
 (characteristic equation)

A_1 and A_2 are determined from initial conditions: $x(0) = x_0, \dot{x}(0) = v_0$

Resonant Frequency: $\omega_r = \sqrt{1 - 2\zeta^2} \omega_n$

The magnitude of P will peak at resonance.

Damping Ratio:

$$\zeta = \frac{\Delta\omega}{2\omega_n} = \frac{\omega_2 - \omega_1}{\omega_2 + \omega_1} \quad \text{for low damping}$$

where, $\Delta\omega = \text{half-power bandwidth} = \omega_2 - \omega_1$

Note: Q-factor = $\frac{\omega_n}{\Delta\omega} = \frac{1}{2\zeta}$ for low damping.

Then, the corresponding frequency-response function (frequency transfer function) is

$$G(j\omega) = \frac{k b j \omega}{(k - J \omega^2) + b j \omega} \quad (\text{iv})$$

For a harmonic excitation of

$$\alpha = \alpha_0 e^{j\omega t} \quad (\text{v})$$

we have

$$\tau = |G(j\omega)|\alpha_0 e^{(j\omega t + \phi)} \quad (\text{vi})$$

at steady state.

Here, the phase lead of τ with respect to α is

$$\begin{aligned} \phi &= \angle G(j\omega) = \angle j\omega - \angle(k - J\omega^2 + bj\omega) \\ &= \frac{\pi}{2} - \tan^{-1} \frac{b\omega}{(k - J\omega^2)} \end{aligned} \quad (\text{vii})$$

The magnitude of the restraining torque, at steady state, is

$$\begin{aligned} \tau_0 &= \alpha_0 |G(j\omega)| = \alpha_0 \frac{kb\omega}{|k - J\omega^2 + bj\omega|} \\ &= \frac{\alpha_0 kb\omega}{\sqrt{(k - J\omega^2)^2 + b^2\omega^2}} \end{aligned}$$

Hence,

$$\tau_0 = \frac{J\alpha_0\omega_n^2\omega \times 2\zeta\omega_n}{\sqrt{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}} \quad (\text{viii})$$

or

$$\tau_0 = \frac{\alpha_0 k 2\zeta\omega_n\omega}{\sqrt{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}} \quad (\text{ix})$$

with $k/J = \omega_n^2$; $b/J = 2\zeta\omega_n$; and ω_n equal to the undamped natural frequency of the load.

Now, define the normalized frequency

$$r = \frac{\omega}{\omega_n} \quad (\text{x})$$

Then, from (ix) we have

$$\tau_0 = \frac{2k\alpha_0\zeta r}{\sqrt{(1 - r^2)^2 + (2\zeta r)^2}} \quad (\text{xi})$$

For $r = 1$:

$$\tau_0 = \frac{2k\alpha_0\zeta}{2\zeta} = k\alpha_0 \quad (\text{xii})$$

This means, at resonance, the applied twist is directly transmitted to the load spring.

For small r :

$$\tau_0 = \frac{2k\alpha_0\zeta r}{1} \quad (\text{xiii})$$

which is small, and becomes zero at $r = 0$. Hence, at low frequencies, the transmitted torque is small.

For larger r :

$$\tau_0 = \frac{2k\alpha_0\zeta r}{r^2} = \frac{2k\alpha_0\zeta}{r} \quad (\text{xiv})$$

which is small and goes to zero. Hence, at high frequencies as well, the transmitted torque is small.

The variation of τ_0 with the frequency ratio r is sketched in [Figure 2.6](#).

FIGURE 2.5 A fluid coupling system.

FIGURE 2.6 Variation of the steady-state transmitted torque with frequency.

2.3 Transform Techniques

Concepts of frequency-response analysis originate from the nature of the response of a dynamic system to a sinusoidal (i.e., harmonic) excitation. These concepts can be generalized because the time-domain analysis, where the independent variable is time (t), and the frequency-domain analysis, where the independent variable is frequency (ω), are linked through the Fourier transformation. Analytically, it is more general and versatile to use the Laplace transformation, where the independent variable is the Laplace variable (s) which is complex (i.e., non-real). This is true because analytical Laplace transforms may exist even for time functions that do not have “analytical” Fourier transforms. But with compatible definitions, the Fourier transform results can be obtained from the Laplace transform results simply by setting $s = j\omega$. In the present section, we will formally introduce the Laplace transformation and the Fourier transformation, and will illustrate how these techniques are useful in the response analysis of vibrating systems. The preference of one domain over another will depend on such factors as the nature of the excitation input, the type of the analytical model available, the time duration of interest, and the quantities that need to be determined.

2.3.1 Transfer Function

The Laplace transform of a piecewise-continuous function $f(t)$ is denoted here by $F(s)$ and is given by the Laplace transformation

$$F(s) = \int_0^{\infty} f(t) \exp(-st) dt \quad (2.46)$$

in which s is a complex independent variable known as the Laplace variable, expressed as

$$s = \sigma + j\omega \quad (2.47)$$

and $j = \sqrt{-1}$. Laplace transform operation is denoted as $\mathcal{L}f(t) = F(s)$. The inverse Laplace transform operation is denoted by $f(t) = \mathcal{L}^{-1}F(s)$ and is given by

$$f(t) = \frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} F(s) \exp(st) ds \quad (2.48)$$

The integration is performed along a vertical line parallel to the imaginary (vertical) axis, located at σ from the origin in the complex Laplace plane (s -plane). For a given piecewise-continuous function

$f(t)$, the Laplace transform exists if the integral in Equation 2.46 converges. A sufficient condition for this is

$$\int_0^{\infty} |f(t)| \exp(-\sigma t) dt < \infty \quad (2.49)$$

Convergence is guaranteed by choosing a sufficiently large and positive σ . This property is an advantage of the Laplace transformation over the Fourier transformation. (For a more complete discussion of the Fourier transformation, see later in this chapter and in [Chapter 4](#).)

By the use of Laplace transformation, the convolution integral equation can be converted into an algebraic relationship. To illustrate this, consider the convolution integral which gives the response $y(t)$ of a dynamic system to an excitation input $u(t)$, with zero initial conditions. By definition (Equation 2.46), its Laplace transform is written as

$$Y(s) = \int_0^{\infty} \int_0^{\infty} h(\tau) u(t - \tau) d\tau \exp(-st) dt \quad (2.50)$$

Note that $h(t)$ is the impulse-response function of the system. Since the integration with respect to t is performed while keeping τ constant, we have $dt = d(t - \tau)$. Consequently,

$$Y(s) = \int_{-\tau}^{\infty} u(t - \tau) \exp[-s(t - \tau)] d(t - \tau) \int_0^{\infty} h(\tau) \exp(-s\tau) d\tau$$

The lower limit of the first integration can be made equal to zero, in view of the fact that $u(t) = 0$ for $t < 0$. Again using the definition of Laplace transformation, the foregoing relation can be expressed as

$$Y(s) = H(s)U(s) \quad (2.51)$$

in which

$$H(s) = \mathcal{L}h(t) = \int_0^{\infty} h(t) \exp(-st) dt \quad (2.52)$$

Note that, by definition, the transfer function of a system, denoted by $H(s)$, is given by Equation 2.51. More specifically, the system transfer function is given by the ratio of the Laplace-transformed output and the Laplace-transformed input, with zero initial conditions. In view of Equation 2.52, it is clear that the system transfer function can be expressed as the Laplace transform of the impulse-response function of the system. The transfer function of a linear and constant-parameter system is a unique function that completely represents the system. A physically realizable, linear, constant-parameter system possesses a unique transfer function, even if the Laplace transforms of a particular input and the corresponding output do not exist. This is clear from the fact that the transfer function is a system model and does not depend on the system input itself.

Note: The transfer function is also commonly denoted by $G(s)$. However, in the present context we use $H(s)$ in view of its relation to $h(t)$. Some useful Laplace transform relations are given in [Table 2.1](#). Also, note that the Fourier transform (set $s = j\omega$) is given by

Forward:

$$F(j\omega) = \int_0^{\infty} f(t) \exp(-j\omega t) dt$$

Inverse:

$$f(t) = \int_{-j\infty}^{j\infty} F(j\omega) \exp(j\omega t) d\omega$$

Consider the n th-order linear, constant-parameter dynamic system given by

$$a_n \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_0 y = b_0 u + b_1 \frac{du(t)}{dt} + \cdots + b_m \frac{d^m u(t)}{dt^m} \quad (2.53)$$

TABLE 2.1 Important Laplace Transform Relations

$\mathcal{L}^{-1}F(s) = f(t)$	Conversion $\mathcal{L}f(t) = F(s)$
$\frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} F(s) \exp(st) ds$	$\int_0^\infty f(t) \exp(-st) dt$
$k_1 f_1(t) + k_2 f_2(t)$	$k_1 F_1(s) + k_2 F_2(s)$
$\exp(-at)f(t)$	$F(s+a)$
$f(t-\tau)$	$\exp(-s\tau)F(s)$
$f^{(n)}(t) = \frac{d^n f(t)}{dt^n}$	$s^n F(s) - s^{n-1}f(0^+) - s^{n-2}f'(0^+) - \dots - f^{(n-1)}(0^+)$
$\int_{-\infty}^t f(t) dt$	$\frac{F(s)}{s} + \frac{\int_{-\infty}^0 f(t) dt}{s}$
Impulse function, $\delta(t)$	1
Step function, $\mathcal{U}(t)$	$\frac{1}{s}$
t^n	$\frac{n!}{s^{n+1}}$
$\exp(-at)$	$\frac{1}{s+a}$
$\sin \omega_n t$	$\frac{\omega_n}{s^2 + \omega_n^2}$
$\cos \omega_n t$	$\frac{s}{s^2 + \omega_n^2}$

for physically realizable systems, $m \leq n$. By applying a Laplace transformation and then integrating by parts, it may be verified that

$$\mathcal{L} \frac{d^k f(t)}{dt^k} = s^k \hat{F}(s) - s^{k-1} f(0) - s^{k-2} \frac{df(0)}{dt} - \dots + \frac{d^{k-1} f(0)}{dt^{k-1}} \tag{2.54}$$

By definition, the initial conditions are set to zero in obtaining the transfer function. This results in

$$H(s) = \frac{b_0 + b_1 s + \dots + b_m s^m}{a_0 + a_1 s + \dots + a_n s^n} \tag{2.55}$$

for $m \leq n$. Note that Equation 2.55 contains all the information that is contained in Equation 2.53. Consequently, the transfer function is an analytical model of a system. The transfer function may be employed to determine the total response of a system for a given input, even though it is defined in terms of the response under zero initial conditions. This is quite logical because the analytical model of a system is independent of the system's initial conditions.

The denominator polynomial of a transfer function is the system's *characteristic polynomial*. Its roots are the poles or the eigenvalues of the system. If all the eigenvalues have negative real parts, the system is stable. The response of a stable system is bounded (that is, remains finite) when the input is bounded (which is the BIBO stability). The zero-input response of an asymptotically stable system approaches zero with time.

2.3.2 Frequency-Response Function (Frequency Transfer Function)

The Fourier integral transform of the impulse-response function is given by

$$H(f) = \int_{-\infty}^\infty h(t) \exp(-j2\pi ft) dt \tag{2.56}$$

where f is the *cyclic frequency* (measured in cps or hertz). This is known as the frequency-response function (or frequency transfer function) of a system. The Fourier transform operation is denoted as $\mathcal{F}h(t) = H(f)$.

In view of the fact that $h(t) = 0$ for $t < 0$, the lower limit of integration in Equation 2.56 could be made zero. Then, from Equation 2.52, it is clear that $H(f)$ is obtained simply by setting $s = j2\pi f$ in $H(s)$. Hence, strictly speaking, we should use the notation $H(j2\pi f)$ and not $H(f)$. However, for notational simplicity, we denote $H(j2\pi f)$ by $H(f)$. Furthermore, since the angular frequency $\omega = 2\pi f$, we can express the frequency-response function by $H(j\omega)$, or simply by $H(\omega)$ for notational convenience. It should be noted that the frequency-response function, like the Laplace transfer function, is a complete representation of a linear, constant-parameter system. In view of the fact that both $u(t) = 0$ and $y(t) = 0$ for $t < 0$, we can write the Fourier transforms of the input and the output of a system directly by setting $s = j2\pi f = j\omega$ in the corresponding Laplace transforms. Specifically, we have, according to the notation used here

$$U(f) = U(j2\pi f) = U(j\omega)$$

and

$$Y(f) = Y(j2\pi f) = Y(j\omega).$$

Then, from Equation 2.51, we have

$$Y(f) = H(f)U(f) \quad (2.57)$$

Note: Sometimes, for notational convenience, the same lowercase letters are used to represent the Laplace and Fourier transforms as well as the original time-domain variables.

If the Fourier integral transform of a function exists, then its Laplace transform also exists. The converse is not generally true, however, because of the poor convergence of the Fourier integral in comparison to the Laplace integral. This arises from the fact that the factor $\exp(-\sigma t)$ is not present in the Fourier integral. For a physically realizable, linear, constant-parameter system, $H(f)$ exists even if $U(f)$ and $Y(f)$ do not exist for a particular input. The experimental determination of $H(f)$, however, requires system stability. For the n th-order system given by Equation 2.53, the frequency-response function is determined by setting $s = j2\pi f$ in Equation 2.55 as

$$H(f) = \frac{b_0 + b_1 j2\pi f + \cdots + b_m (j2\pi f)^m}{a_0 + a_1 j2\pi f + \cdots + a_n (j2\pi f)^n} \quad (2.58)$$

This, generally, is a complex function of f that has a magnitude denoted by $|H(f)|$ and a phase angle denoted by $\angle H(f)$.

A further interpretation of the frequency-response function can be given in view of the developments given in Section 2.2. Consider a harmonic input having cyclic frequency f , expressed by

$$u(t) = u_0 \cos 2\pi ft \quad (2.59a)$$

In analysis, it is convenient to use the complex input

$$u(t) = u_0 (\cos 2\pi ft + j \sin 2\pi ft) = u_0 \exp(j2\pi ft) \quad (2.59b)$$

and take only the real part of the final result. Note that Equation 2.59b does not implicitly satisfy the requirement of $u(t) = 0$ for $t < 0$. Therefore, an appropriate version of the convolution integral, where the limits of integration automatically account for this requirement, should be used. For instance, we can write

$$y(t) = \operatorname{Re} \left[\int_{-\infty}^t h(\tau) u_0 \exp[j2\pi f(t - \tau)] d\tau \right] \quad (2.60a)$$

or

$$y(t) = \operatorname{Re} \left[u_0 \exp(j2\pi ft) \int_{-\infty}^t h(\tau) \exp(-j2\pi f\tau) d\tau \right] \quad (2.60b)$$

in which $\operatorname{Re}[\cdot]$ denotes the real part. As $t \rightarrow \infty$, the integral term in Equation 2.60b becomes the frequency-response function $H(f)$, and the response $y(t)$ becomes the steady-state response y_{ss} . Accordingly,

$$y_{ss} = \operatorname{Re}[H(f)u_0 \exp(j2\pi ft)] \quad (2.61a)$$

or

$$y_{ss} = u_0 |H(f)| \cos(2\pi ft + \phi) \quad (2.61b)$$

for a harmonic excitation, in which the phase lead angle $\phi = \angle H(f)$. It follows from Equation 2.61b that, when a harmonic excitation is applied to a stable, linear, constant-parameter dynamic system having frequency-response function $H(f)$, its steady-state response will also be harmonic at the same frequency, but with an amplification factor of $|H(f)|$ in its amplitude and a phase lead of $\angle H(f)$. This result has been established previously, in Section 2.2. Consequently, the frequency-response function of a stable system can be experimentally determined using a sine-sweep test or a sine-dwell test. With these methods, a harmonic excitation is applied as the system input, and the amplification factor and the phase-lead angle in the corresponding response are determined at steady state. The frequency of excitation is varied continuously for a sine sweep and in steps for a sine dwell. The sweep rate should be slow enough, and the dwell times should be long enough, to guarantee steady-state conditions at the output. The pair of plots of $|H(f)|$ and $\angle H(f)$ against f completely represent the complex frequency-response function, and are Bode plots or Bode diagrams, as noted earlier. In Bode plots, logarithmic scales are normally used for both frequency f and magnitude $|H(f)|$.

Impulse Response

The impulse-response function of a system can be obtained by taking the inverse Laplace transform of the system transfer function. For example, consider the damped simple oscillator given by the normalized transfer function:

$$H(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (2.62)$$

The characteristic equation of this system is given by

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = 0 \quad (2.63)$$

The eigenvalues (poles) are given by its roots. Three possible cases exist, as given below.

Case 1: ($\zeta < 1$)

This is the case of complex eigenvalues λ_1 and λ_2 . Since the coefficients of the characteristic equation are real, the complex roots should occur in conjugate pairs. Hence,

$$\lambda_1, \lambda_2 = -\zeta\omega_n \pm j\omega_d \quad (2.64)$$

in which

$$\omega_d = \sqrt{1 - \zeta^2} \omega_n \quad (2.65)$$

is the damped natural frequency.

Case 2: ($\zeta > 1$)

This case corresponds to real and unequal eigenvalues,

$$\lambda_1, \lambda_2 = -\zeta\omega_n \pm \sqrt{\zeta^2 - 1} \omega_n = -a, -b \quad (2.66)$$

with $a \neq b$, in which

$$ab = \omega_n^2 \quad (2.67)$$

and

$$a + b = 2\zeta\omega_n \quad (2.68)$$

Case 3: ($\zeta = 1$)

In this case, the eigenvalues are real and equal:

$$\lambda_1 = \lambda_2 = -\omega_n \quad (2.69)$$

In all three cases, the real parts of the eigenvalues are negative. Consequently, these second-order systems of a damped simple oscillator are always stable.

The impulse-response functions $h(t)$ corresponding to these three cases are determined by taking the inverse Laplace transform (Table 2.1) of Equation 2.62 for $\zeta < 1$, $\zeta > 1$, and $\zeta = 1$, respectively. The following results are obtained:

$$y_{\text{impulse}}(t) = h(t) = \frac{\omega_n}{\sqrt{1 - \zeta^2}} \exp(-\zeta\omega_n t) \sin \omega_d t \quad \text{for } \zeta < 1 \quad (2.70a)$$

$$y_{\text{impulse}}(t) = h(t) = \frac{ab}{(b - a)} [\exp(-at) - \exp(-bt)] \quad \text{for } \zeta > 1 \quad (2.70b)$$

$$y_{\text{impulse}}(t) = h(t) = \omega_n^2 t \exp(-\omega_n t) \quad \text{for } \zeta = 1 \quad (2.70c)$$

Step Response

Unit-step function is defined by

$$\mathcal{U}(t) = \begin{cases} 1 & \text{for } t > 0 \\ 0 & \text{for } t \leq 0 \end{cases} \quad (2.71)$$

Unit-impulse function $\delta(t)$ may be interpreted as the time derivative of $\mathcal{U}(t)$; thus,

$$\delta(t) = \frac{d\mathcal{U}(t)}{dt} \quad (2.72)$$

Note that Equation 2.72 re-establishes the fact that for non-dimensional $\mathcal{U}(t)$, the dimension of $\delta(t)$ is $(\text{time})^{-1}$. Since $\mathcal{L}\mathcal{U}(t) = 1/s$ (see Table 2.1), the unit-step response of the dynamic system (Equation 2.62) can be obtained by taking the inverse Laplace transform of

$$Y_{\text{step}}(s) = \frac{1}{s} \frac{\omega_n^2}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} \quad (2.73)$$

which follows from Equation 2.73.

To facilitate using Table 2.1, partial fractions of Equation 2.73 are determined in the form

$$\frac{a_1}{s} + \frac{a_2 + a_3 s}{(s^2 + 2\zeta\omega_n s + \omega_n^2)}$$

in which the constants a_1 , a_2 , and a_3 are determined by comparing the numerator polynomial; thus,

$$\omega_n^2 = a_1(s^2 + 2\zeta\omega_n s + \omega_n^2) + s(a_2 + a_3 s)$$

Then $a_1 = 1$, $a_2 = -2\zeta\omega_n$, and $a_3 = 1$.

The following results are obtained:

$$y_{\text{step}}(t) = 1 - \frac{1}{\sqrt{1 - \zeta^2}} \exp(-\zeta\omega_n t) \sin(\omega_d t + \phi) \quad \text{for } \zeta < 1 \quad (2.74a)$$

$$y_{\text{step}} = 1 - \frac{1}{(b - a)} [b \exp(-at) - a \exp(-bt)] \quad \text{for } \zeta > 1 \quad (2.74b)$$

$$y_{\text{step}} = 1 - (\omega_n t + 1) \exp(-\omega_n t) \quad \text{for } \zeta = 1 \quad (2.74c)$$

In Equation 2.74c,

$$\cos \phi = \zeta \quad (2.75)$$

Transfer Function Matrix

Consider the state-space model of a linear dynamic system as given by

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (2.76a)$$

$$\mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \quad (2.76b)$$

where, \mathbf{x} = the n th order state vector, \mathbf{u} = the r th order input vector, \mathbf{y} = the m th order output vector, \mathbf{A} = the system matrix, \mathbf{B} = the input gain matrix, \mathbf{C} = the output (measurement) gain matrix, and \mathbf{D} = the feedforward gain matrix. We can express the input–output relation between u and y , in the Laplace domain, by a transfer function matrix of the order $m \times r$.

To obtain this relation, let us Laplace transform the Equations 2.76a and 2.76b and use zero initial conditions for \mathbf{x} ; thus,

$$s\mathbf{X}(s) = \mathbf{A}\mathbf{X}(s) + \mathbf{B}\mathbf{U}(s) \quad (2.77a)$$

$$\mathbf{Y}(s) = \mathbf{C}\mathbf{X}(s) + \mathbf{D}\mathbf{U}(s) \quad (2.77b)$$

From Equation 2.77a it follows that,

$$\mathbf{X}(s) = (s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{U}(s) \quad (2.78)$$

in which \mathbf{I} is the n th order identity matrix. By substituting Equation 2.78 into Equation 2.77b, we obtain the transfer relation

$$\mathbf{Y}(s) = [\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}]\mathbf{U}(s) \quad (2.79a)$$

or

$$\mathbf{Y}(s) = \mathbf{G}(s)\mathbf{U}(s) \quad (2.79b)$$

The transfer-function matrix $\mathbf{G}(s)$ is an $m \times r$ matrix given by

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D} \quad (2.80)$$

In practical systems with dynamic delay, the excitation $u(t)$ is not fed forward into the response y . Consequently, $\mathbf{D} = 0$ for systems that we normally encounter. For such systems

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} \quad (2.81)$$

Several examples are given now to illustrate the approaches of obtaining transfer function models when the time domain differential equation models are given, and to indicate some uses of a transfer function model. Some useful results in the frequency domain are summarized in Box 2.2.

Example 2.2

Consider the simple oscillator equation given by

$$m\ddot{y} + b\dot{y} + ky = ku(t) \quad (i)$$

Note that $u(t)$ can be interpreted as a displacement input (e.g., support motion) or $ku(t)$ can be interpreted as the input force applied to the mass. Take the Laplace transform of the system equation (i) with zero initial conditions; thus,

$$(ms^2 + bs + k)Y(s) = kU(s) \quad (ii)$$

The corresponding transfer function is

$$G(s) = \frac{Y(s)}{U(s)} = \frac{k}{ms^2 + bs + k} \quad (iii)$$

Box 2.2

USEFUL FREQUENCY-DOMAIN RESULTS

Laplace Transform (\mathcal{L}):

$$F(s) = \int_0^{\infty} f(t) \exp(-st) dt$$

Fourier Transform (\mathcal{F}):

$$F(j\omega) = \int_{-\infty}^{\infty} f(t) \exp(-j\omega t) dt$$

Note: May use $F(\omega)$ to denote $F(j\omega)$

Note: Set $s = j\omega = j2\pi f$ to convert Laplace results into Fourier results.

ω = angular frequency (rad/sec)

f = cyclic frequency (cps or Hz)

Transfer function $H(s)$ = output/input in Laplace domain, with zero initial conditions.

Frequency transfer function (or frequency-response function) = $H(j\omega)$

Note: Notation $(G(s))$ is also used to denote a system transfer function

Note:

$$H(s) = \mathcal{L}h(t)$$

$h(t)$ = impulse-response function = response to a unit impulse input.

Frequency response:

$$Y(j\omega) = H(j\omega)U(j\omega)$$

where

$U(j\omega)$ = Fourier spectrum of input $u(t)$

$Y(j\omega)$ = Fourier spectrum of output $y(t)$

Note:

$|H(j\omega)|$ = response amplification for a harmonic excitation of frequency ω

$\angle H(j\omega)$ = response phase “lead” for a harmonic excitation

Multivariable Systems:

State-Space Model:

$$\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu}$$

$$\mathbf{y} = \mathbf{Cx} + \mathbf{Du}$$

Transfer-Matrix Model:

$$\mathbf{Y}(s) = \mathbf{G}(s)\mathbf{U}(s)$$

where

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}$$

or, in terms of the undamped natural frequency ω_n and the damping ratio ζ , where $\omega_n^2 = k/m$ and $2\zeta\omega_n = b/m$, the transfer function is given by

$$G(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (\text{iv})$$

This is the transfer function corresponding to the displacement output. It follows that the output velocity transfer function is

$$\frac{sY(s)}{U(s)} = sG(s) = \frac{s\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (\text{v})$$

and the output acceleration transfer function is

$$\frac{s^2 Y(s)}{U(s)} = s^2 G(s) = \frac{s^2 \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (\text{vi})$$

In the output acceleration transfer function, we have $m = n = 2$. This means that if the acceleration of the mass that is caused by an applied force is measured, the input (applied force) is instantly felt by the acceleration. This corresponds to a feedforward action of the input excitation or a lack of dynamic delay. For example, this is the primary mechanism through which road disturbances are felt inside a vehicle that has very hard suspension.

Example 2.3

Again let us consider the simple oscillator differential equation

$$\ddot{y} + 2\zeta\omega_n \dot{y} + \omega_n^2 y = \omega_n^2 u(t) \quad (\text{i})$$

By defining the state variables as

$$\mathbf{x} = [x_1, x_2]^T = [y, \dot{y}]^T \quad (\text{ii})$$

a state model for this system can be expressed as

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 \\ -\omega_n^2 & -2\zeta\omega_n \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} u(t) \quad (\text{iii})$$

If we consider both displacement and velocity as outputs, we have

$$\mathbf{y} = \mathbf{x} \quad (\text{iv})$$

Note that the output gain matrix \mathbf{C} is the identity matrix in this case. From Equation 2.79b and Equation 2.81 it follows that:

$$\mathbf{Y}(s) = \begin{bmatrix} s & -1 \\ \omega_n^2 & s + 2\zeta\omega_n \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} U(s) \quad (\text{v})$$

$$\mathbf{Y}(s) = \frac{1}{[s^2 + 2\zeta\omega_n s + \omega_n^2]} \begin{bmatrix} s + 2\zeta\omega_n & 1 \\ -\omega_n^2 & s \end{bmatrix} \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} U(s)$$

$$\mathbf{Y}(s) = \frac{1}{[s^2 + 2\zeta\omega_n s + \omega_n^2]} \begin{bmatrix} \omega_n^2 \\ s\omega_n^2 \end{bmatrix} U(s) \quad (\text{vi})$$

The transfer function matrix is

$$\mathbf{G}(s) = \begin{bmatrix} \omega_n^2/\Delta(s) \\ s\omega_n^2/\Delta(s) \end{bmatrix} \quad (\text{vii})$$

in which $\Delta(s) = s^2 + 2\zeta\omega_n s + \omega_n^2$ is the characteristic polynomial of the system. The first element in the only column in $G(s)$ is the displacement-response transfer function and the second element is the velocity-response transfer function. These results agree with the expressions obtained in the previous example.

Now, let us consider the acceleration \ddot{y} as an output and denote it by y_3 . It is clear from the system equation (i) that

$$y_3 = \ddot{y} = -2\zeta\omega_n \dot{y} - \omega_n^2 y + \omega_n^2 u(t) \quad (\text{viii})$$

or, in terms of the state variables,

$$y_3 = -2\zeta\omega_n x_2 - \omega_n^2 x_1 + \omega_n^2 u(t) \quad (\text{ix})$$

Note that this output explicitly contains the input variable. The feedforward situation implies that the matrix \mathbf{D} is non-zero for the output y_3 . Now,

$$Y_3(s) = -2\zeta\omega_n X_2(s) - \omega_n^2 X_1(s) + \omega_n^2 U(s) = -2\zeta\omega_n \frac{s\omega_n^2}{\Delta(s)} U(s) - \omega_n^2 \frac{\omega_n^2}{\Delta(s)} U(s) + \omega_n^2 U(s)$$

which simplifies to

$$Y_3(s) = \frac{s^2 \omega_n^2}{\Delta(s)} U(s) \quad (\text{x})$$

This again confirms the result for the acceleration output transfer function that was obtained in the previous example.

Example 2.4

- Briefly explain an approach that you could use to measure the resonant frequency of a mechanical system. Do you expect this measured frequency to depend on whether displacement, velocity, or acceleration is used as the response variable? Justify your answer.
- A vibration test setup is schematically shown in Figure 2.7.

In this experiment, a mechanical load is excited by a linear motor and its acceleration response is measured by an accelerometer and charge amplifier combination. The force applied to the load by the linear motor is also measured, using a force sensor (strain-gauge type). The frequency-response function acceleration/force is determined from the sensor signals, using a spectrum analyzer.

FIGURE 2.7 Measurement of the acceleration spectrum of a mechanical system.

Suppose that the mechanical load is approximated by a damped oscillator with mass m , stiffness k , and damping constant b , as shown in Figure 2.7. If the force applied to this load is $f(t)$ and the displacement in the same direction is y , show that the equation of motion of the system is given by

$$m\ddot{y} + b\dot{y} + ky = f(t)$$

Obtain an expression for the acceleration frequency-response function $G(j\omega)$ in the frequency domain, with excitation frequency ω as the independent variable. Note that the applied force f is the excitation input and the acceleration a of the mass is the response, in this case.

Express $G(j\omega)$ in terms of (normalized) frequency ratio $r = \omega/\omega_n$, where ω_n is the undamped natural frequency.

Giving all the necessary steps, determine an expression for r at which the acceleration frequency-response function will exhibit a resonant peak. What is the corresponding peak magnitude of $|G|$?

For what range of values of damping ratio ζ would such a resonant peak be possible?

Solution

- (a) For a single DoF system, apply a sinusoidal forcing excitation at the DoF and measure the displacement response at the same location. Vary the excitation frequency ω in small steps, and for each frequency at steady state determine the amplitude ratio of the (displacement response/forcing excitation). The peak amplitude ratio will correspond to the resonance. For a multi-DoF system, several tests may be needed, with excitations applied at different locations of freedom and the response measured at various locations as well (see Chapters 10 and 11). In the frequency domain we have,

$$|\text{Velocity response spectrum}| = \omega x |\text{Displacement response spectrum}|$$

$$|\text{Acceleration response spectrum}| = \omega x |\text{Velocity response spectrum}|$$

It follows that the shape of the frequency-response function will depend on whether the displacement, velocity, or acceleration is used as the response variable. Hence it is likely that the frequency at which the peak amplification occurs (i.e., resonance) will also depend on the type of response variable that is used.

- (b) A free-body diagram of the mass element is shown in Figure 2.8.

Newton's Second Law gives

$$m\ddot{y} = f(t) - b\dot{y} - ky \quad (\text{i})$$

Hence, the equation of motion is

$$m\ddot{y} + b\dot{y} + ky = f(t) \quad (\text{ii})$$

The displacement transfer function is

$$\frac{y}{f} = \frac{1}{(ms^2 + bs + k)} \quad (\text{iii})$$

Note that, for notational convenience, the same lowercase letters are used to represent the Laplace transforms as well as the original time-domain variables (y and f). The acceleration transfer function is obtained by multiplying Equation iii by s^2 . (From Table 2.1, the Laplace transform of d/dt is s , with zero initial conditions). Hence

$$\frac{a}{f} = \frac{s^2}{(ms^2 + bs + k)} = G(s) \quad (\text{iv})$$

FIGURE 2.8 Free-body diagram.

In the frequency domain, the corresponding frequency-response function is obtained by substituting $j\omega$ for s . Hence,

$$G(j\omega) = \frac{-\omega^2}{(-m\omega^2 + bj\omega + k)} \quad (\text{v})$$

Divide throughout by m and use $b/m = 2\zeta\omega_n$ and $k/m = \omega_n^2$, where ω_n = undamped natural frequency and ζ = damping ratio.

Then,

$$G(j\omega) = \frac{-\omega^2/m}{(\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega)} = \frac{-r^2/m}{1 - r^2 + 2j\zeta rr} \quad (\text{vi})$$

where $r = \omega/\omega_n$. The magnitude of $G(j\omega)$ gives the amplification of the acceleration signal with respect to the forcing excitation:

$$|G(j\omega)| = \frac{r^2/m}{\sqrt{(1 - r^2)^2 + (2\zeta r)^2}} \quad (\text{vii})$$

Its peak value corresponds to the peak value of

$$p(r) = \frac{r^4}{(1 - r^2)^2 + (2\zeta r)^2} \quad (\text{viii})$$

and gives the resonance. This occurs when $dp/dr = 0$. Hence,

$$[(1 - r^2)^2 + (2\zeta r)^2]4r^3 - r^4[2(1 - r^2)(-2r) + 8\zeta^2 r] = 0$$

The solution is

$$r = 0 \quad \text{or} \quad [(1 - r^2)^2 + 4\zeta^2 r^2] + r^2[1 - r^2 - 2\zeta^2] = 0$$

The first result ($r = 0$) corresponds to static conditions and is ignored. Hence, the resonant peak occurs when

$$(1 - r^2)^2 + 4\zeta^2 r^2 + r^2 - r^4 - 2\zeta^2 r^2 = 0$$

which has the valid root

$$r = \frac{1}{\sqrt{1 - 2\zeta^2}} \quad (\text{ix})$$

Note that r has to be real and positive. It follows that, for a resonance to occur we need

$$0 < \zeta < \frac{1}{\sqrt{2}}$$

Substitute in (vii), the resonant value of r , to obtain

$$|G|_{\text{peak}} = \frac{\frac{1}{m(1 - 2\zeta^2)}}{\sqrt{\left(1 - \frac{1}{1 - 2\zeta^2}\right)^2 + \frac{4\zeta^2}{1 - 2\zeta^2}}}$$

or

$$|G|_{\text{peak}} = \frac{1}{2m\zeta\sqrt{1 - \zeta^2}} \quad (\text{x})$$

2.4 Mechanical Impedance Approach

Any type of force or motion variable may be used as input and output variables in defining a system transfer function. In vibration studies, three particular choices are widely used. The corresponding

frequency transfer functions are named impedance functions, mobility functions, and transmissibility functions. These are described in the present section and in the subsequent section, and their use is illustrated.

Through variables (force) and across variables (velocity), when expressed in the frequency domain (as Fourier spectra), are used in defining the two important frequency transfer functions: mechanical impedance and mobility. In the case of impedance functions, velocity is considered the input variable and the force is the output variable; whereas in the case of mobility functions, the converse applies. Specifically,

$$M = \frac{1}{Z} \quad (2.82)$$

It is clear that mobility (M) is the inverse of impedance (Z). Either transfer function may be used in a given problem. One can define several other versions of frequency transfer functions that might be useful in the modeling and analysis of mechanical systems. Some of the relatively common ones are listed in Table 2.2.

Note that in the frequency domain, since $\text{acceleration} = j\omega \times \text{velocity}$; and $\text{displacement} = \text{velocity}/(j\omega)$, the alternative types of transfer functions as defined in Table 2.2, are related to mechanical impedance and mobility through a factor of $j\omega$; specifically,

$$\begin{aligned} \text{dynamic inertia} &= \text{force/acceleration} = \text{impedance}/(j\omega) \\ \text{acceleration} &= \text{acceleration/force} = \text{mobility} \times (j\omega) \\ \text{dynamic stiffness} &= \text{force/displacement} = \text{impedance} \times j\omega \\ \text{receptance} &= \text{displacement} = \text{mobility}/(j\omega) \end{aligned}$$

In these definitions, the variable (force, acceleration, and displacement) should be interpreted as the corresponding Fourier spectra.

The time-domain constitutive relations for the mass, spring, and the damper elements are well known. The corresponding transfer relations are obtained by replacing the derivative operator d/dt by the Laplace operator s . The frequency transfer functions are obtained by substituting $j\omega$ or $j2\pi$ for s . These results are derived below.

Mass Element:

$$m \frac{dv}{dt} = f$$

In the frequency domain,

$$mj\omega v = f \quad \text{or} \quad \frac{f}{v} = mj\omega$$

Hence,

$$Z_m = mj\omega \quad (2.83a)$$

and

$$M_m = \frac{1}{mj\omega} \quad (2.83b)$$

TABLE 2.2 Definitions of Useful Mechanical Transfer Functions

Transfer Function	Definition (in the Frequency Domain)
Dynamic stiffness	Force/displacement
Receptance, dynamic flexibility, or compliance	Displacement/force
Impedance (Z)	Force/velocity
Mobility (M)	Velocity/force
Dynamic inertia	Force/acceleration
Accelerance	Acceleration/force
Force transmissibility (T_f)	Transmitted force/applied force
Motion transmissibility (T_m)	Transmitted velocity/applied velocity

TABLE 2.3 Impedance and Mobility Functions of Basic Mechanical Elements

Element	Frequency Transfer Function (Set $s = j\omega = j2\pi f$)		
	Impedance	Mobility	Receptance
Mass, m	$Z_m = ms$	$M_m = \frac{1}{ms}$	$R_m = \frac{1}{ms^2}$
Spring, k	$Z_k = \frac{k}{s}$	$M_k = \frac{s}{k}$	$R_k = \frac{1}{k}$
Damper, b	$Z_b = b$	$M_b = \frac{1}{b}$	$R_b = \frac{1}{bs}$

Spring Element:

$$f = kx \quad \text{or} \quad \frac{df}{dt} = kv$$

In the frequency domain,

$$j\omega f = kv \quad \text{or} \quad \frac{f}{v} = \frac{k}{j\omega}$$

Hence,

$$Z_k = \frac{k}{j\omega} \tag{2.84a}$$

and

$$M_k = \frac{j\omega}{k} \tag{2.84b}$$

Damper Element:

$$f = bv \quad \text{or} \quad \frac{f}{v} = b$$

Then,

$$Z_b = b \tag{2.85a}$$

or

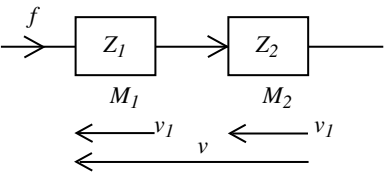

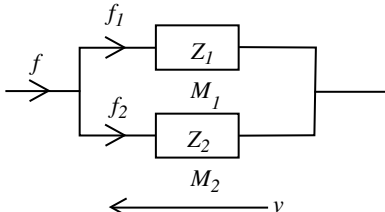

$$M_b = \frac{1}{b} \tag{2.85b}$$

These results are summarized in Table 2.3.

2.4.1 Interconnection Laws

Any general impedance element or a mobility element may be interpreted as a *two-port element* in which, under steady conditions, energy (or power) transfer into the device takes place at the *input port* and energy (or power) transfer out of the device takes place at the output port. Each port of a two-port element has a *through variable*, such as force or current, and an *across variable*, such as velocity or voltage, associated with it. Through variables are called *flux variables*, and across variable are called *potential variables*. Through variables are not always the same as *flow variables* (velocity and current). Similarly, across variables are not the same as *effort variables* (force and voltage). For example, force is an effort variable, but it is also a through variable. Similarly, velocity is a flow variable and is also an across variable. The concept of effort and flow variables is useful in giving unified definitions for electrical and mechanical impedance. However, in component interconnecting and circuit analysis, mechanical impedance is not analogous to electrical impedance. The definition of mechanical impedance is force/velocity in the frequency domain. This is a ratio of (through variable)/(across variable); whereas electrical impedance, defined as voltage/current in the frequency domain, is a ratio of

TABLE 2.4 Interconnection Laws for Impedance and Mobility

Series Connections	Parallel Connections
 <div>$v = v_1 + v_2$$\frac{v}{f} = \frac{v_1}{f} + \frac{v_2}{f}$$M = M_1 + M_2$$\frac{1}{Z} = \frac{1}{Z_1} + \frac{1}{Z_2}$</div>	 <div>$f = f_1 + f_2$$\frac{f}{v} = \frac{f_1}{v} + \frac{f_2}{v}$$Z = Z_1 + Z_2$$\frac{1}{M} = \frac{1}{M_1} + \frac{1}{M_2}$</div>

(across variable)/(through variable). Since both force and voltage are “effort” variables, and velocity and current are “flow” variables, it is then convenient to use the definition

$$\text{Impedance (electrical or mechanical)} = \frac{\text{Effort}}{\text{Flow}}$$

In other words, impedance measures how much effort is needed to drive a system at unity flow. Nevertheless, this definition does not particularly help us to analyze interconnected systems with mechanical impedance, because mechanical impedance cannot be manipulated using the rules for electrical impedance. For example, if two electric components are connected in series, the current (through variable) will be the same for both components, and the voltage (across variable) will be additive. Accordingly, the impedance of a series-connected electrical system is just the sum of the impedances of the individual components. Now consider two mechanical components connected in series. Here the force (through variable) will be the same for both components, and velocity (across variable) will be additive. Hence, it is mobility, not impedance, that is additive in the case of series-connected mechanical components. It can be concluded that, in circuit analysis, mobility behaves like electrical impedance and mechanical impedance behaves like electrical admittance. Hence, the “generalized series element” is electrical impedance or mechanical mobility, and the “generalized parallel element” is electrical admittance or mechanical impedance. The corresponding interconnection laws are summarized in Table 2.4.

Now, two examples are given to demonstrate the use of impedance and mobility methods in frequency-domain problems.

Example 2.5

Consider the simple oscillator shown in Figure 2.9(a). A schematic mechanical circuit is given in Figure 2.9(b). Note here that in this circuit, the broken line from the mass to the ground represents how the inertia force of the mass is felt by, or virtually transmitted to, the ground. This is the case because the net force that generates the acceleration in the mass (i.e., the inertia force) has to be transmitted to the ground at the reference point of the force source. This is the same reference with respect to which the velocity of the mass is expressed. If the input is the force $f(t)$, the source element is a force source. The corresponding response is the velocity v , and in this situation, the transfer function $V(f)/F(f)$ is a mobility function. On the other hand, if the input is the velocity $v(t)$, the source element is a velocity source. Then, f is the output, and the transfer function $F(f)/V(f)$ is an impedance function.

FIGURE 2.9 (a) A ground-based mechanical oscillator; (b) schematic mechanical circuit; (c) impedance circuit.

Suppose that a known forcing function is applied to this system (with zero initial conditions) using a force source, and the velocity is measured. Now, if we were to move the mass exactly at this predetermined velocity (using a velocity source), the force generated at the source will be identical to the originally applied force. In other words, mobility is the reciprocal (inverse) of impedance, as noted earlier. This reciprocity should be intuitively clear because we are dealing with the same system and same initial conditions. Owing to this property, we may use either the impedance representation or the mobility representation, depending on whether the elements are connected in parallel or in series, and irrespective of whether the input is a force or a velocity. Once the transfer function is determined in one form, its reciprocal gives the other form.

In the present example, the three elements are connected in parallel, as is clear from the mechanical circuit shown in Figure 2.9(c). Hence, the impedance representation is appropriate. The overall impedance function of the system is

$$Z(f) = \frac{F(f)}{V(f)} = Z_m + Z_k + Z_b = ms + \frac{k}{s} + b \Big|_{s=j2\pi f} = \frac{ms^2 + bs + k}{s} \Big|_{s=j2\pi f} \quad (2.86)$$

Then, the mobility function is

$$M(f) = \frac{V(f)}{F(f)} = \frac{s}{ms^2 + bs + k} \Big|_{s=j2\pi f} \quad (2.87)$$

Note that, if in fact the input is the force, the mobility function will govern the system behavior. In this case, the characteristic polynomial of the system is $s^2 + bs + k$, which corresponds to a simple oscillator, and accordingly the (dependent) velocity response of the system would be governed by this. If, on the other hand, the input is the velocity, the impedance function will govern the system behavior. The characteristic polynomial of the system, in this case, is s , which corresponds to a simple integrator. The (dependent) force response of the system would be governed by an integrator-type behavior. To explore

this behavior further, suppose that the velocity source has a constant value. The inertia force will be zero. The damping force will be constant. The spring force will increase linearly. Hence, the net force will have an integration (linearly increasing) effect. If the velocity source provides a linearly increasing velocity (constant acceleration), the inertia force will be constant, the damping force will increase linearly, and the spring force will increase quadratically.

Example 2.6

Consider the system shown in Figure 2.10(a). In this example, the motion of the mass, m , is not associated with an external force. The support motion, v , however, is associated with a force, f .

The schematic mechanical circuit representation shown in Figure 2.10(b), and the corresponding impedance circuit shown in Figure 2.10(c), indicate that the spring and the damper are connected in parallel and that the mass is connected in series with this pair. By impedance addition for parallel elements and mobility addition for series elements, it follows that the mobility function is

$$\frac{V(f)}{F(f)} = M_m + \frac{1}{(Z_k + Z_b)} = \frac{1}{ms} + \frac{1}{(k/s + b)} \Big|_{s=j2\pi f} = \frac{ms^2 + bs + k}{ms(bs + k)} \Big|_{s=j2\pi f} \quad (2.88)$$

It follows that, when the support force is the input (force source) and the support velocity is the output, the system characteristic polynomial is $ms(bs + k)$, which is known to be inherently unstable due to the presence of a free integrator, and has a non-oscillatory transient response.

The impedance function that corresponds to support velocity input (velocity source) is the reciprocal of the previous mobility function; thus,

$$\frac{F(f)}{V(f)} = \frac{ms(bs + k)}{ms^2 + bs + k} \Big|_{s=j2\pi f} \quad (2.89)$$

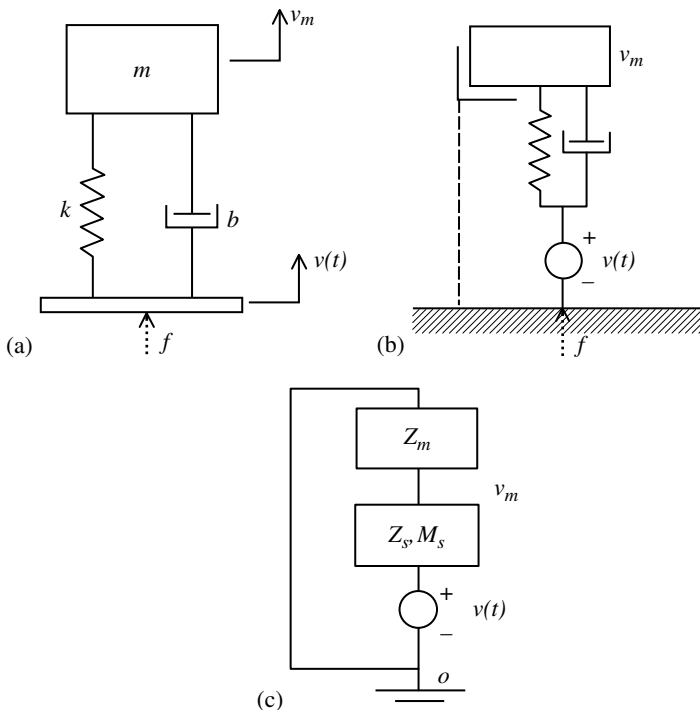

FIGURE 2.10 (a) An oscillator with support motion; (b) schematic mechanical circuit; (c) impedance circuit.

and

$$\frac{V_m(f)}{F(f)} = \frac{1}{ms} \Big|_{s=j2\pi f} \quad (2.90)$$

The resulting impedance function $F(f)/V_m(f)$ is not admissible and is physically non-realizable because V_m cannot be an input as there is no associated force. This is confirmed by the fact that the corresponding transfer function is a differentiator, which is not physically realizable. The mobility function $V_m(f)/F(f)$ corresponds to a simple integrator. Physically, when a force, f , is applied to the support, it is transmitted to the mass, unchanged, through the parallel spring–damper unit. Accordingly, when f is constant, a constant acceleration is produced at the mass causing its velocity to increase linearly (an integration behavior).

Maxwell's principle of reciprocity can be demonstrated by noting that the mobility function $V_m(f)/F(f)$, obtained in this example, will be identical to the mobility function when the locations of f and V_m are reversed (i.e., when a force, f , is applied to the mass m and the resulting motion, V_m , of the support, which is not restrained by a force, is measured), with the same initial conditions. The reciprocity property is valid for linear, constant-parameter systems in general and is particularly useful in vibration analysis and the testing of multi-DoF systems; for example, to determine a transfer function that is difficult to measure, by measuring its symmetrical counterpart in the transfer function matrix.

2.5 Transmissibility Functions

Transmissibility functions are transfer functions that are particularly useful in the analysis of vibration isolation in machinery and other mechanical systems. Two types of transmissibility function, force transmissibility and motion transmissibility, can be defined (see Table 2.2). Due to a reciprocity characteristic in linear systems, it can be shown that these two transfer functions are equal and, consequently, it is sufficient to consider only one of them. Let us, however, consider both types first and show their equivalence.

2.5.1 Force Transmissibility

Consider a mechanical system that is supported on a rigid foundation through a suspension system. If a forcing excitation is applied to the system, the force is not directly transmitted to the foundation. The suspension system acts as a vibration isolation device. Force transmissibility determines the fraction of the forcing excitation that is transmitted to the support structure (foundation) through the suspension, at different excitation frequencies, and is defined as

$$\text{Force Transmissibility, } T_f = \frac{\text{Force Transmitted to Support, } F_s}{\text{Applied Force, } F} \quad (2.91)$$

Note that this is defined in the frequency domain, and that accordingly F_s and F should be interpreted as the Fourier spectra of the corresponding forces.

A schematic representation of the force transmissibility mechanism is shown in Figure 2.11(a). The reason for the suspension force f_s being not equal to the applied force f is attributed to the inertia paths (broken line in the figure) that are present in a mechanical system.

2.5.2 Motion Transmissibility

Consider a mechanical system that is supported by suspension on a structure that may be subjected to undesirable motions (e.g., guideway deflections, vehicle motions, seismic disturbances). Motion transmissibility determines the fraction of the support motion that is transmitted to the system through

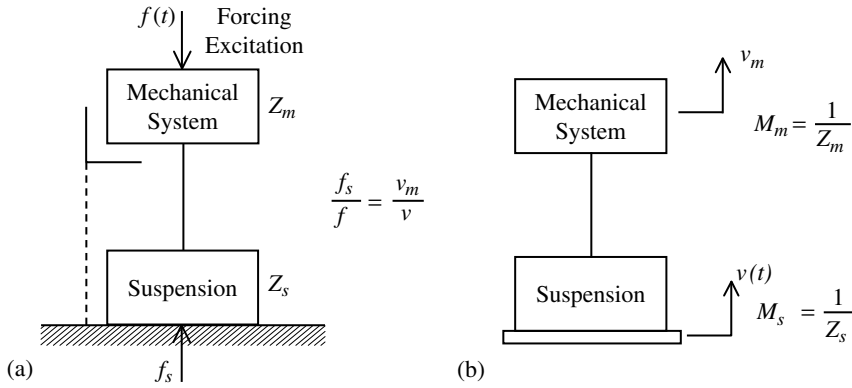

FIGURE 2.11 (a) An inertial system with ground-based suspension; (b) the counterpart (complementary) system with support motion.

its suspension at different frequencies. It is defined as

$$\text{Motion Transmissibility, } T_m = \frac{\text{System Motion, } V_m}{\text{Support Motion, } V} \quad (2.92)$$

The velocities V_m and V are expressed in the frequency domain, as Fourier spectra.

A schematic representation of the motion transmissibility mechanism is shown in Figure 2.11(b). Typically, the motion of the system is taken as the velocity of one of its critical masses. Different transmissibility functions are obtained when different mass points (or DoFs) of the system are considered.

Next, two examples are given to show a reciprocity property that makes the force transmissibility and the motion transmissibility functions identical in complementary (reciprocal) systems.

System Suspended on a Rigid Base (Force Transmissibility)

Consider the system suspended on a rigid base and excited by force $f(t)$, as shown earlier in Figure 2.9(a). Here the system is the inertia element m , and the suspension is the parallel spring and damper combination. We have noted that the three elements m , k , and b are all in parallel.

Here, $Z_m = m j \omega$; $Z_b = b$; and $Z_k = k / j \omega$, as given in Table 2.3. Now, because the elements are connected in parallel, we have (see Table 2.4)

$$\frac{f}{v} = Z_m + Z_b + Z_k \quad (2.93)$$

Hence,

$$\frac{v}{f} = \frac{1}{Z_m + Z_b + Z_d} \quad (2.94)$$

Also, suspension impedance is

$$\frac{f_s}{v} = Z_b + Z_k = Z_s \quad (2.95)$$

where f_s is the force transmitted to the support structure (foundation). Then,

$$\frac{f_s}{f} = \frac{Z_b + Z_k}{Z_m + Z_b + Z_k} = \frac{Z_s}{Z_m + Z_s} \quad (2.96)$$

FIGURE 2.12 Transmissibility curve for a simple mechanical oscillator.

This result should be immediately clear since force is divided among parallel branches in proportion to their impedance values (because the velocity is common). Now,

$$\text{Force Transmissibility Magnitude, } |T_f| = \left| \frac{\text{Force Transmitted to Support}}{\text{Applied Force to System}} \right| = \left| \frac{Z_s}{Z_m + Z_s} \right| \quad (2.97)$$

Substitute parameters

$$\begin{aligned} |T_f| &= \left| \frac{f_s}{f} \right| = \left| \frac{b + \frac{k}{j\omega}}{mj\omega + b + \frac{k}{j\omega}} \right| = \left| \frac{bj\omega + k}{k - m\omega^2 + bj\omega} \right| = \sqrt{\frac{b^2\omega^2 + k^2}{(k - m\omega^2)^2 + b^2\omega^2}} \\ &= \sqrt{\frac{(2\zeta\omega_n\omega)^2 + \omega_n^4}{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}} \end{aligned}$$

On simplification, we obtain

$$|T_f| = \sqrt{\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2}} \quad (2.98)$$

where the normalized frequency is

$$\frac{\omega}{\omega_n} = r$$

At $r = 0$, we have $|T_f| = 1$.

At $r = 1$,

$$|T_f| = \sqrt{1 + \frac{1}{4\zeta^2}} \quad (2.99)$$

This transmissibility magnitude curve is shown in Figure 2.12.

System with Support Motion (Motion Transmissibility)

Consider again the system suspended on a moving platform as shown in Figure 2.10(a). For this system, we have $Z_m = mj\omega$ and $M_m = 1/mj\omega$ for the mass element. Since the damper and the spring are

connected in parallel, the corresponding impedances are additive. Hence, we have

$$Z_s = Z_b + Z_k = b + \frac{k}{j\omega} \quad \text{and} \quad M_s = \frac{1}{b + \frac{k}{j\omega}}$$

$$\text{Motion Transmissibility Magnitude, } T_m = \left| \frac{\text{Motion of system inertia}}{\text{Applied support motion}} \right| = \left| \frac{M_m}{M_m + M_s} \right| \quad (2.100)$$

This directly follows from the fact that the velocity is divided among series elements in proportion to their mobilities (because the force is common).

However,

$$\frac{M_m}{M_m + M_s} = \frac{1}{1 + \frac{M_s}{M_m}} = \frac{1}{1 + \frac{Z_m}{Z_s}} = \frac{Z_s}{Z_m + Z_s} \quad (2.101)$$

Hence,

$$|T_m| = \left| \frac{Z_s}{Z_m + Z_s} \right| \quad (2.102)$$

It follows that

$$T_f = T_m \quad (2.103)$$

This establishes the reciprocity property.

2.5.3 General Case

Consider an inertial system with a ground-based suspension, as shown in Figure 2.11(a), and its counterpart with a moving support, as shown in Figure 2.11(b).

The corresponding impedance circuits are shown in Figure 2.13.

For system (a), we have

$$\frac{f_s}{f} = \frac{Z_s}{Z_m + Z_s}$$

For system (b), we have

$$\frac{V_m}{v} = \frac{M_m}{M_m + M_s} = \frac{1}{1 + \frac{M_s}{M_m}} = \frac{1}{1 + \frac{Z_m}{Z_s}} = \frac{Z_s}{Z_s + Z_m}$$

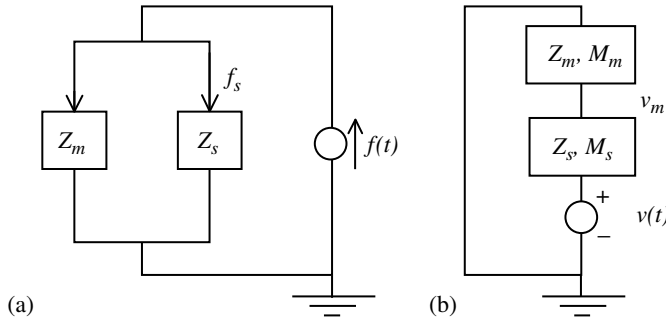

FIGURE 2.13 Impedance circuits: (a) inertial system with ground-based suspension; (b) system and suspension with support motion.

FIGURE 2.14 (a) Schematic mechanical circuit of the fluid coupling system; (b) impedance circuit.

It follows that

$$\frac{f_s}{f} = \frac{V_m}{v} \quad \text{and} \quad T_f = T_m \quad (2.104)$$

for this more general situation.

Example 2.7

Consider again the problem of a fluid coupling system shown in Figure 2.5 and studied in Example 2.1. A schematic mechanical circuit for the system is shown in Figure 2.14(a). The corresponding impedance circuit is shown in Figure 2.14(b). Let us use the impedance method to solve the same problem.

For this problem, we have: input angular velocity = $\dot{\alpha}(t)$; angular velocity of the load = $\dot{\theta}$; and load impedance $Z_l = Z_m + Z_k$. In view of the series connection of Z_b and Z_l , we have

$$\frac{\dot{\theta}}{\dot{\alpha}} = \frac{M_l}{M_l + M_b} = \frac{1/M_b}{1/M_b + 1/M_l} = \frac{Z_b}{Z_b + Z_m + Z_k} \quad (i)$$

For the torsional spring,

$$\frac{\tau}{\dot{\theta}} = Z_k \quad (ii)$$

Multiply Equation (i) and Equation (ii) together.

$$\frac{\tau}{\dot{\alpha}} = \frac{Z_k Z_b}{(Z_b + Z_m + Z_k)} \quad (iii)$$

Since the time derivative corresponds to multiplication by $j\omega$ in the frequency domain, we can write (iii) in the form

$$\frac{\tau}{\alpha} = j\omega \frac{Z_k Z_b}{(Z_b + Z_m + Z_k)} \quad (iv)$$

Substitute $Z_b = b$, $Z_m = j\omega J$, and $Z_k = k/j\omega$. We obtain $\tau/\alpha = kbj\omega/((k - J\omega^2) + bj\omega)$, which is identical to what we obtained in Example 2.1.

2.5.4 Peak Values of Frequency-Response Functions

The peak values of a frequency transfer function correspond to the resonances. The frequencies at these points are called resonant frequencies. Since a transfer function is the ratio of a response variable to an input variable, it is reasonable to obtain different peak frequencies for the same excitation input, if the response variable that is considered is different. Some results obtained for a damped oscillator model are summarized in Table 2.5.

TABLE 2.5 Some Practical Frequency-Response Functions and Their Peaks

System	Response/Excitation	Frequency-Response Function (Normalized)	Normalized Frequency (r_p)	Peak Magnitude (Normalized)
Simple oscillator	Displacement/force	$\frac{1}{(1 - r^2) + 2j\zeta r}$	$\sqrt{1 - 2\zeta^2}$	$\frac{1}{2\zeta\sqrt{1 - \zeta^2}}$
Simple oscillator with velocity response	Velocity/force	$\frac{j r}{(1 - r^2) + 2j\zeta r}$	1	$\frac{1}{2\zeta}$
Simple oscillator with acceleration response	Acceleration/force	$\frac{-r^2}{(1 - r^2) + 2j\zeta r}$	$\frac{1}{\sqrt{1 - 2\zeta^2}}$	$\frac{1}{2\zeta\sqrt{1 - \zeta^2}}$
Fluid coupling system	Torque/displacement	$\frac{2j\zeta r}{(1 - r^2) + 2j\zeta r}$	1	1
Force transmissibility	Force/force	$\frac{1 + 2j\zeta r}{(1 - r^2) + 2j\zeta r}$	$\frac{\sqrt{\sqrt{1 + 8\zeta^2} - 1}}{2\zeta}$	$\sqrt{1 + \frac{1}{4\zeta^2}}$ (for small ζ)
Motion transmissibility	Velocity/velocity	Same	Same	Same

2.6 Receptance Method

Receptance is another name for dynamic flexibility or compliance, and is given by the transfer function (output displacement)/(input force) in the frequency domain (see Table 2.2). Also, as has been mentioned previously, it is directly related to mobility through

$$\text{Receptance} = \frac{\text{Mobility}}{j\omega} \quad (2.105)$$

and this relationship should be clear due to the fact that velocity = $j\omega \times$ displacement, with zero initial conditions, in the frequency domain. Hence, the receptance functions for the basic elements mass (m), spring (k), and damper (b) can be derived from the mobility functions of these elements, as given in Table 2.3. As a result, the interconnection laws given for mobility (M) will be valid for receptance (R) as well. Specifically, for two receptance elements R_1 and R_2 connected in series, we have the combined receptance

$$\text{Series: } R = R_1 + R_2 \quad (2.106)$$

because the displacement is additive and the force is common. For two receptance elements connected in parallel, the combined receptance R is given by

$$\text{Parallel: } \frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} \quad (2.107)$$

because the forces are additive and the displacement is common. The inverse of receptance is dynamic stiffness.

2.6.1 Application of Receptance

The receptance method is widely used in the frequency-domain analysis of multi-DoF systems. This is true particularly because the receptance of a multicomponent system can be expressed in a convenient form in terms of the receptances of its constituent components. In deriving such relations, we use the conditions of continuity (forces balance at points of interconnection, or nodes) and compatibility (relative displacements in a loop add to zero). In fact, Equation 2.106 and Equation 2.107 are special cases of receptance relations for multicomponent systems.

It should be clear from Table 2.3 that the receptance R_m of an inertia element ($-1/(\omega^2 m)$), and the receptance R_k of a spring element ($1/k$), are real quantities, unlike the corresponding mobility functions. The receptance R_b of a damper ($1/(bj\omega)$) is imaginary, however. It follows that receptance functions of undamped systems are real, and we will have to deal with real quantities only in the receptance analysis of undamped systems. This makes the analysis quite convenient. Also, since the displacement response of an undamped system becomes infinite when excited by a harmonic force at its natural frequency, we see that the receptance function of an undamped system goes to infinity (or its inverse becomes zero) at its natural frequencies. This property can be utilized in determining an undamped natural frequency (say, the fundamental natural frequency) of a system using the receptance method. In particular, the characteristic equations for a system with two interconnected components are

$$\text{Series: } \frac{1}{R_1 + R_2} = 0 \quad (2.108)$$

$$\text{Parallel: } R_1 + R_2 = 0 \quad (2.109)$$

and their solutions will give the undamped natural frequencies of the combined system. Now, we will consider two examples to illustrate the application of receptance techniques.

Undamped Simple Oscillator

Consider the simple oscillator shown in Figure 2.9, but assume that the damper is not present. As was noted earlier, the mass and the spring elements are connected in parallel. Hence, the characteristic

equation of the undamped system is

$$R_m + R_k = 0 \quad (2.110)$$

or

$$-\frac{1}{\omega^2 m} + \frac{1}{k} = 0 \quad (2.111)$$

or

$$-k + \omega^2 m = 0$$

whose positive solution is

$$\omega = \omega_n = \sqrt{\frac{k}{m}}$$

which gives the undamped natural frequency.

Dynamic Absorber

Dynamic absorbers are commonly used for vibration suppression in machinery over narrow frequency ranges. Specifically, a dynamic absorber can “absorb” the vibration energy from the main system (machine) at a specific frequency (the tuned frequency) and thereby completely balance the vibration excitation in the system.

Consider a machine of equivalent mass M and equivalent stiffness K that is mounted on a rigid foundation, as modeled in Figure 2.15(a). A dynamic absorber, which is a lightly damped oscillator, of mass m and stiffness k is mounted on the machine. The damping is neglected in the model. The machine receives a vibration excitation $f(t)$, and the objective of the absorber is to counteract this excitation. A schematic mechanical circuit of the system is shown in Figure 2.15(b). The overall system can be considered to consist of two subsystems: the subsystem a , representing the machine, has M and K connected in parallel with the excitation source; and the subsystem b , representing the vibrating absorber,

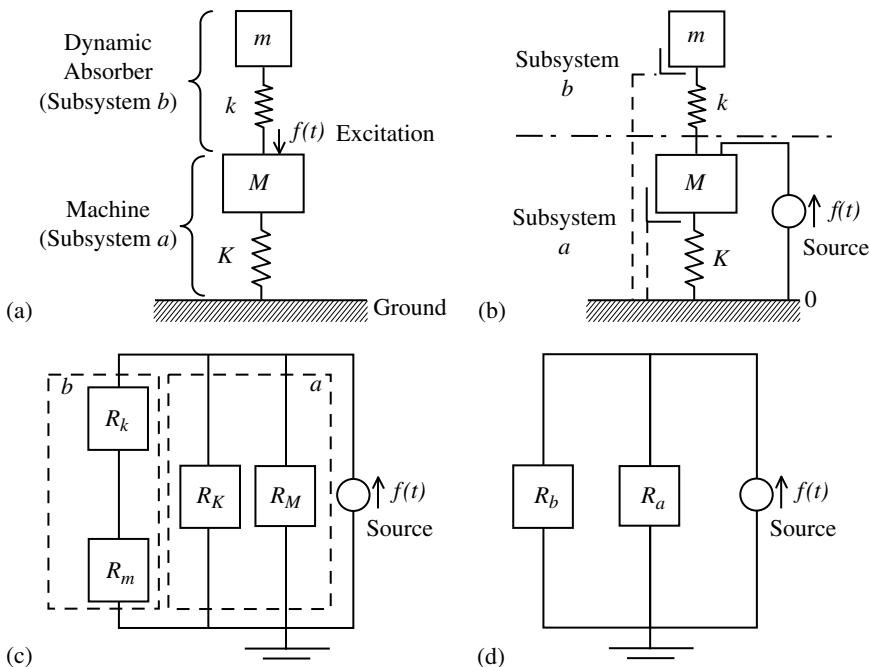

FIGURE 2.15 (a) A machine with a vibration absorber; (b) schematic mechanical circuit; (c) component receptance circuit; and (d) subsystem receptance circuit.

Box 2.3

CONCEPTS OF RECEPTION

$$\text{Receptance, } R \quad = \quad \frac{\text{Displacement}}{\text{Force}}$$

(Compliance, Dynamic Flexibility)

Receptance = Mobility/ $j\omega$

Series Connection: $R = R_1 + R_2$

Parallel Connection: $1/R = 1/R_1 + 1/R_2$

Note: R is real for undamped systems.

Natural Frequency: $R \rightarrow \infty$ (undamped case)

Characteristic Equation:

For system with series components: $1/\sum R_i = 0$

For system with parallel components: $\sum 1/R_i = 0$

has m and k connected in series, as is clear from Figure 2.15(b). The corresponding receptance circuit, indicating the two subsystems with receptances R_a and R_b , is shown in Figure 2.15(d).

Since M and K are connected in parallel, from Equation 2.107 we have

$$\frac{1}{R_a} = -\omega^2 M + K \quad (2.112)$$

Since m and k are connected in series, from Equation 2.106 we have

$$R_b = -\frac{1}{\omega^2 m} + \frac{1}{k} \quad (2.113)$$

Now, since the subsystems a and b are connected in parallel, from Equation 2.109, the characteristic equation of the overall system is given by

$$R_a + R_b = 0 \quad (2.114)$$

Substitute Equations 2.112 and 2.113 in Equation 2.114. We obtain

$$\frac{1}{-\omega^2 M + K} + \frac{1}{-\omega^2 m} + \frac{1}{k} = 0 \quad (2.115)$$

On simplification, after multiplying throughout by the common denominator, we obtain the characteristic equation

$$mM\omega^4 - (kM + Km + km)\omega^2 + kK = 0 \quad (2.116)$$

This will give two positive roots for ω , which are the two undamped natural frequencies of the system. Typically, the natural frequency of the vibration absorber has to be tuned to the frequency of excitation in order to achieve effective vibration suppression, as discussed in Chapter 12 (Enunciations 1–26).

Here, we have only considered *direct receptance* functions, where the considered excitation and response are both for the same node. For more complex, multicomponent, multi-DoF systems, we will need to consider *cross receptance* functions, where the response is considered at a node other than where the excitation force is applied. Such situations are beyond the scope of the present, introductory material. Some concepts of receptance are summarized in Box 2.3.

Transform Techniques

2A.1 Introduction

Many people use “transforms” without even knowing it. A transform is simply a number, variable, or function in a different form. For example, since $10^2 = 100$, one can use the exponent (2) to represent the number 100. Doing this for all numbers (i.e., using their exponent to the base 10) results in a “table of logarithms.” One can perform mathematical computations using only logarithms. The logarithm transforms all numbers into their exponential equivalents; a table of such transforms (i.e., a log table) enables a user to quickly transform any number into its exponent, do the computations using exponents (where a product becomes an addition and a division becomes a subtraction), and transform the result back into the original form (i.e., by an inverse logarithm). It is seen that the computations become simpler by using logarithms, but at the cost of the time and effort for transformation and inverse transformation.

Other common transforms include the Laplace transform, Fourier transform, and Z transform. In particular, the Laplace transform provides a simple, algebraic way to solve (i.e., integrate) a linear differential equation. Most functions that we use are of the form t^n , $\sin \omega t$, or e^t , or some combination of them. Thus, in the expression

$$y = f(t)$$

the function y is quite likely to be a power, a sine, or an exponential function. Also, often, we must work with derivatives and integrals of these functions and differential equations containing these functions. These tasks can be greatly simplified by the use of the Laplace transform.

Concepts of frequency-response analysis originate from the nature of the response of a dynamic system to a sinusoidal (i.e., harmonic) excitation. These concepts can be generalized because the time-domain analysis, where the independent variable is time (t), and the frequency-domain analysis, where the independent variable is frequency (ω), are linked through the Fourier transformation. Analytically, it is more general and versatile to use the Laplace transformation, where the independent variable is the Laplace variable (s), which is complex (nonreal). This is true because analytical Laplace transforms may exist even for time functions that do not have “analytical” Fourier transforms. However, with compatible definitions, the Fourier transform results can be obtained from the Laplace transform results simply by setting $s = j\omega$. In the present appendix, we will formally introduce the Laplace transformation and the

Fourier transformation, and will illustrate how these techniques are useful in the analysis of mechatronic systems. The preference of one domain over another will depend on such factors as the nature of the excitation input, the type of the analytical model available, the time duration of interest, and the quantities that need to be determined.

2A.2 Laplace Transform

The Laplace transformation relates the time domain to the *Laplace domain* (also called *s-domain* or complex frequency domain). The Laplace transform, $Y(s)$, of a piecewise-continuous function or signal, $y(t)$, is given, by definition, as

$$Y(s) = \int_0^{\infty} y(t) \exp(-st) dt \quad (2A.1)$$

and is denoted using the Laplace operator, \mathcal{L} , as

$$Y(s) = \mathcal{L}y(t) \quad (2A.1)^*$$

Here, s is a complex independent variable known as the Laplace variable, defined by

$$s = \sigma + j\omega \quad (2A.2)$$

where σ is a real-valued constant that will make the transform (Equation 2A.1) finite, ω is simply frequency, and $j = \sqrt{-1}$. The real value (σ) can be chosen sufficiently large so that the integral in Equation 2A.1 is finite even when the integral of the signal itself (i.e., $\int y(t) dt$) is not finite. This is the reason, for example, the Laplace transform functions better than the Fourier transform, which will be defined later, from the analytical point of view. The symbol s can be considered to be a constant, when integrating with respect to t , in Equation 2A.1.

The inverse relation (i.e., obtaining y from its Laplace transform) is

$$y(t) = \frac{1}{2\pi j} \int_{\sigma-j\omega}^{\sigma+j\omega} Y(s) \exp(st) ds \quad (2A.3)$$

and is denoted using the inverse Laplace operator, \mathcal{L}^{-1} , as

$$y(t) = \mathcal{L}^{-1}Y(s) \quad (2A.3)^*$$

The integration in Equation 2A.3 is performed along a vertical line parallel to the imaginary (vertical) axis, located at σ from the origin in the complex Laplace plane (the s -plane). For a given piecewise-continuous function, $y(t)$, the Laplace transform exists if the integral in Equation 2A.1 converges. A sufficient condition for this is

$$\int_0^{\infty} |y(t)| \exp(-\sigma t) dt < \infty \quad (2A.4)$$

Convergence is guaranteed by choosing a sufficiently large and positive σ . This property is an advantage of the Laplace transformation over the Fourier transformation.

2A.2.1 Laplace Transforms of Some Common Functions

Now we determine the Laplace transform of some useful functions using the definition (Equation 2A.1). Usually, however, we use Laplace transform tables to obtain these results.

Laplace Transform of a Constant

Suppose our function $y(t)$ is a constant, B . Then the Laplace transform is

$$\mathcal{L}(B) = Y(s) = \int_0^{\infty} B e^{-st} dt = B \left. \frac{e^{-st}}{-s} \right|_0^{\infty} = \frac{B}{s}$$

Laplace Transform of the Exponential

If $y(t)$ is e^{at} , its Laplace transform is

$$\mathcal{L}(e^{at}) = \int_0^{\infty} e^{-st} e^{at} dt = \int_0^{\infty} e^{(a-s)t} dt = \frac{1}{(a-s)} e^{(a-s)t} \Big|_0^{\infty} = \frac{1}{s-a}$$

Note: If $y(t)$ is e^{-at} , it is obvious that the Laplace transform is

$$\mathcal{L}(e^{-at}) = \int_0^{\infty} e^{-st} e^{-at} dt = \int_0^{\infty} e^{-(a+s)t} dt = \frac{-1}{(a+s)} e^{-(a+s)t} \Big|_0^{\infty} = \frac{1}{s+a}$$

This result can be obtained from the previous result simply by replacing a with $-a$.

Laplace Transform of Sine and Cosine

In the following, the letter $j = \sqrt{-1}$. If $y(t)$ is $\sin \omega t$, the Laplace transform is

$$\mathcal{L}(\sin \omega t) = \int_0^{\infty} e^{-st} (\sin \omega t) dt$$

Consider the identities:

$$e^{j\omega t} = \cos \omega t + j \sin \omega t$$

$$e^{-j\omega t} = \cos \omega t - j \sin \omega t$$

If we add and subtract these two equations, respectively, we obtain the expressions for the sine and the cosine in terms of $e^{j\omega t}$ and $e^{-j\omega t}$:

$$\cos \omega t = \frac{1}{2} (e^{j\omega t} + e^{-j\omega t})$$

$$\sin \omega t = \frac{1}{2j} (e^{j\omega t} - e^{-j\omega t})$$

$$\mathcal{L}(\cos \omega t) = \frac{1}{2} \mathcal{L}(e^{j\omega t}) + \frac{1}{2} \mathcal{L}(e^{-j\omega t})$$

$$\mathcal{L}(\sin \omega t) = \frac{1}{2} \mathcal{L}(e^{j\omega t}) - \frac{1}{2} \mathcal{L}(e^{-j\omega t})$$

We have just seen that

$$\mathcal{L}(e^{at}) = \frac{1}{s-a}, \quad \mathcal{L}(e^{-at}) = \frac{1}{s+a}$$

Hence,

$$\mathcal{L}(e^{j\omega t}) = \frac{1}{s-j\omega}, \quad \mathcal{L}(e^{-j\omega t}) = \frac{1}{s+j\omega}$$

Substituting these expressions, we obtain:

$$\mathcal{L}(\cos \omega t) = \frac{1}{2} \left[\frac{1}{s-j\omega} \right] + \frac{1}{2} \left[\frac{1}{s+j\omega} \right] = \frac{1}{2} \left[\frac{s+j\omega}{s^2-(j\omega)^2} + \frac{s-j\omega}{s^2-(j\omega)^2} \right] = \frac{s}{s^2+\omega^2}$$

$$\begin{aligned} \mathcal{L}(\sin \omega t) &= \frac{1}{2j} \mathcal{L}(e^{j\omega t} - e^{-j\omega t}) = \frac{1}{2j} \left[\frac{1}{s-j\omega} \right] - \frac{1}{2j} \left[\frac{1}{s+j\omega} \right] = \frac{1}{2j} \left[\frac{s+j\omega}{s^2-(j\omega)^2} + \frac{s-j\omega}{s^2-(j\omega)^2} \right] \\ &= \frac{1}{2j} \left[\frac{2j\omega}{s^2+\omega^2} \right] = \frac{\omega}{s^2+\omega^2} \end{aligned}$$

Transform of a Derivative

Let us transform a derivative of a function. Specifically, the derivative of a function y of t is denoted by $\dot{y} = dy/dt$. Its Laplace transform is given by

$$\mathcal{L}(\dot{y}) = \int_0^{\infty} e^{-st} \dot{y} dt = \int_0^{\infty} e^{-st} \frac{dy}{dt} dt \quad (2A.5)$$

Now, we integrate by parts, to eliminate the derivative within the integrand.

Integration by parts: From calculus we know that $d(uv) = u dv + v du$.

By integrating we obtain $uv = \int u dv + \int v du$

Hence,

$$\int u dv = uv - \int v du \quad (2A.6)$$

This is known as integration by parts.

In Equation 2A.5, let

$$u = e^{-st} \quad \text{and} \quad v = y$$

Then,

$$dv = dy = \frac{dy}{dt} dt = \dot{y} dt$$

$$du = \frac{du}{dt} dt = -s e^{-st} dt.$$

Substitute in Equation 2A.5 to integrate by parts:

$$\begin{aligned} \mathcal{L}(\dot{y}) &= \int_0^{\infty} e^{-st} dy = \int u dv = uv - \int v du = e^{-st} y(t) \Big|_0^{\infty} - \int_0^{\infty} -s e^{-st} y(t) dt = -y(0) + s\mathcal{L}[y(t)] \\ &= s\mathcal{L}(y) - y(0) \end{aligned}$$

where $y(0)$ = initial value of y . This says that the Laplace transform of a first derivative, \dot{y} , equals s times the Laplace transform of the function y minus the initial value of the function (the initial condition).

Note: We can determine the Laplace transforms of the second and higher derivatives by repeated application of the result for the first derivative. For example, the transform of the second derivative is given by

$$\mathcal{L}[\ddot{y}(t)] = \mathcal{L}\left[\frac{d\dot{y}(t)}{dt}\right] = s\mathcal{L}[\dot{y}(t)] - \dot{y}(0) = s\{s\mathcal{L}[y(t)] - y(0)\} - \dot{y}(0) \quad \text{or}$$

$$\mathcal{L}[\ddot{y}(t)] = s^2\mathcal{L}[y(t)] - sy(0) - \dot{y}(0)$$

2A.2.2 Table of Laplace Transforms

Table 2A.1 shows the Laplace transforms of some common functions. Specifically, the table lists functions as $y(t)$, and their Laplace transforms (on the right) as $Y(s)$ or $\mathcal{L}y(t)$. If one is given a function, one can obtain its Laplace transform from the table. Conversely, if one is given the transform, one can obtain the function from the table.

Some general properties and results of the Laplace transform are given in **Table 2A.2**.

In particular, note that with zero initial conditions, differentiation can be interpreted as multiplication by s . Also, integration can be interpreted as division by s .

TABLE 2A.1 Laplace Transform Pairs

$y(t) = \mathcal{L}^{-1}[Y(s)]$	$\mathcal{L}[y(t)] = Y(s)$
B	B/s
e^{-at}	$\frac{1}{s+a}$
e^{at}	$\frac{1}{s-a}$
$\sinh at$	$\frac{a}{s^2 - a^2}$
$\cosh at$	$\frac{s}{s^2 - a^2}$
$\sin \omega t$	$\frac{\omega}{s^2 + \omega^2}$
$\cos \omega t$	$\frac{s}{s^2 + \omega^2}$
$e^{-at} \sin \omega t$	$\frac{\omega}{(s+a)^2 + \omega^2}$
$e^{-at} \cos \omega t$	$\frac{s+a}{(s+a)^2 + \omega^2}$
Ramp t	$\frac{1}{s^2}$
$e^{-at}(1-at)$	$\frac{s}{(s+a)^2}$
$y(t)$	$Y(s)$
$\frac{dy}{dt} = \dot{y}$	$sY(s) - y(0)$
$\frac{d^2y}{dt^2} = \ddot{y}$	$s^2Y(s) - sy(0) - \dot{y}(0)$
$\frac{d^3y}{dt^3} = \dddot{y}$	$s^3Y(s) - s^2y(0) - s\dot{y}(0) - \ddot{y}(0)$
$\int_a^t y(t)dt$	$\frac{1}{s}Y(s) - \frac{1}{s} \int_0^a y(t)dt$
$af(t) + bg(t)$	$aF(s) + bG(s)$
Unit step $U(t) = \begin{cases} 1 & \text{for } t \geq 0 \\ 0 & \text{for otherwise} \end{cases}$	$\frac{1}{s}$
Delayed step $cU(t-b)$	$\frac{c}{s}e^{-bs}$
Pulse $c[U(t) - U(t-b)]$	$c\left(\frac{1 - e^{-bs}}{s}\right)$
Impulse function $\delta(t)$	1
Delayed impulse $\delta(t-b) = \dot{U}(t-b)$	e^{-bs}
Sine pulse	$\left(\frac{\omega}{s^2 + \omega^2}\right)(1 + e^{-(\pi s/\omega)})$

TABLE 2A.2 Important Laplace Transform Relations

$\mathcal{L}^{-1}F(s) = f(t)$	$\mathcal{L}f(t) = F(s)$
$\frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} F(s)\exp(st)ds$	$\int_0^\infty f(t)\exp(-st)dt$
$k_1f_1(t) + k_2f_2(t)$	$k_1F_1(s) + k_2F_2(s)$
$\exp(-at)f(t)$	$F(s + a)$
$f(t - \tau)$	$\exp(-\tau s)F(s)$
$f^{(n)}(t) = \frac{d^n f(t)}{dt^n}$	$s^n F(s) - s^{n-1}f(0^+) - s^{n-2}f'(0^+) - \dots - f^{(n-1)}(0^+)$
$\int_{-\infty}^t f(t)dt$	$\frac{F(s)}{s} + \frac{\int_{-\infty}^0 f(t)dt}{s}$
t^n	$\frac{n!}{s^{n+1}}$
$t^n e^{-at}$	$\frac{n!}{(s + a)^{n+1}}$

2A.3 Response Analysis

The Laplace transform method can be used in the response analysis of dynamic systems, mechatronic and control systems in particular. We will give examples for the approach.

Example 2A.1

The capacitor–charge equation of the RC circuit shown in Figure 2A.1 is

$$e = iR + v \quad (\text{i})$$

For the capacitor,

$$i = C \frac{dv}{dt} \quad (\text{ii})$$

Substitute Equation (ii) in (i) to get the circuit equation

$$e = RC \frac{dv}{dt} + v \quad (\text{iii})$$

FIGURE 2A.1 An RC circuit with applied voltage, e , and voltage, v , across the capacitor.

Take the Laplace transform of each term in Equation (iii), with all initial conditions = 0

$$E(s) = RCsV(s) + V(s)$$

The transfer function expressed as the output/input ratio (in the transform form) is

$$\frac{V(s)}{E(s)} = \frac{V(s)}{sRCV(s) + V(s)} = \frac{1}{sRC + 1} = \frac{1}{\tau s + 1} \quad (\text{iv})$$

where $\tau = RC$.

The actual response can now be found from Table 2A.1 for a given input E . The first step is to get the transform into proper form (like Line 2)

$$\frac{1}{\tau s + 1} = \frac{1/\tau}{s + (1/\tau)} = \frac{a}{s + a} = a \left(\frac{1}{s + a} \right)$$

where $a = 1/\tau$. Suppose that input (excitation), e , is a unit impulse. Its Laplace transform (see Table 2A.1)

is $E = 1$. Then from Equation (iv)

$$V(s) = \frac{1}{\tau s + 1}$$

From Line 2 of Table 2A.1, the response is

$$v = a e^{-at} = \frac{1}{\tau} e^{-t/\tau} = \frac{1}{RC} e^{-t/RC}$$

A common transfer function for an overdamped second-order system (e.g., one with two RC circuit components of Figure 2A.1) would be

$$\frac{V(s)}{E(s)} = \frac{1}{(1 + \tau_1 s)(1 + \tau_2 s)}$$

This can be expressed as “partial fractions” in the form

$$\frac{A}{1 + \tau_1 s} + \frac{B}{1 + \tau_2 s}$$

and solved in the usual manner.

Example 2A.2

The transfer function of a thermal system is given by

$$G(s) = \frac{2}{(s + 1)(s + 3)}$$

If a unit-step input is applied to the system, with zero initial conditions, what is the resulting response?

Solution

Input: $U(s) = 1/s$ (for a unit step)

Since

$$\frac{Y(s)}{U(s)} = \frac{2}{(s + 1)(s + 3)}$$

the output (response) is

$$Y(s) = \frac{2}{s(s + 1)(s + 3)}$$

Its inverse Laplace transform gives the time response. For this, first convert the expression into partial fractions as

$$\frac{2}{s(s + 1)(s + 3)} = \frac{A}{s} + \frac{B}{(s + 1)} + \frac{C}{(s + 3)} \quad (i)$$

The unknown, A , is determined by multiplying Equation (i) throughout by s and then setting $s = 0$. We obtain

$$A = \frac{2}{(0 + 1)(0 + 3)} = \frac{2}{3}$$

Similarly, B is obtained by multiplying Equation (i) throughout by $(s + 1)$ and then setting $s = -1$. We obtain

$$B = \frac{2}{(-1)(-1 + 3)} = -1$$

Next, C is obtained by multiplying Equation (i) throughout by $(s + 3)$ and then setting $s = -3$. We obtain

$$C = \frac{2}{(-3)(-3 + 1)} = \frac{1}{3}$$

Hence,

$$Y(s) = \frac{2}{3s} - \frac{1}{(s + 1)} + \frac{1}{3(s + 3)}$$

Take the inverse transform using Line 2 of [Table 2A.1](#)

$$y(t) = \frac{2}{3} - e^{-t} + \frac{1}{3}e^{-3t}$$

Example 2A.3

The transfer function of a damped simple oscillator is known to be of the form

$$\frac{Y(s)}{U(s)} = \frac{\omega_n^2}{(s^2 + 2\zeta\omega_n s + \omega_n^2)}$$

where ω_n is the undamped natural frequency and ζ the damping ratio.

Suppose that a unit step input (i.e., $U(s) = 1/s$) is applied to the system. Using Laplace transform tables, determine the resulting response with zero initial conditions.

Solution

$$Y(s) = \frac{1}{s} \frac{\omega_n^2}{(s^2 + 2\zeta\omega_n s + \omega_n^2)}$$

The corresponding partial fractions are of the form:

$$Y(s) = \frac{A}{s} + \frac{Bs + C}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} = \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)} \quad (\text{i})$$

We need to determine A , B , and C .

Multiply Equation (i) throughout by s and set $s = 0$. We obtain:

$$A = 1$$

Next, note that the roots of the characteristic equation,

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = 0$$

are

$$s = -\zeta\omega_n \pm \sqrt{\zeta^2 - 1}\omega_n = -\zeta\omega_n \pm j\omega_d$$

These are the poles of the system and are complex conjugates. Two equations for B and C are obtained by multiplying Equation (i) by $s + \zeta\omega_n - \sqrt{\zeta^2 - 1}\omega_n$ and setting $s = -\zeta\omega_n + \sqrt{\zeta^2 - 1}\omega_n$, and by multiplying Equation (i) by $s + \zeta\omega_n + \sqrt{\zeta^2 - 1}\omega_n$ and setting $s = -\zeta\omega_n - \sqrt{\zeta^2 - 1}\omega_n$. We obtain $B = -1$ and $C = 0$. Consequently,

$$Y(s) = \frac{1}{s} - \frac{s}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} = \frac{1}{s} - \frac{s + \zeta\omega_n}{[(s + \zeta\omega_n)^2 + \omega_d^2]} + \frac{\zeta}{\sqrt{1 - \zeta^2}} \frac{\omega_d}{[(s + \zeta\omega_n)^2 + \omega_d^2]}$$

where $\omega_d = \sqrt{1 - \zeta^2}\omega_n$ is the damped natural frequency.

Now, use Table 2A.1 to obtain the inverse Laplace transform:

$$\begin{aligned}
 y_{\text{step}}(t) &= 1 - e^{-\zeta\omega_n t} \cos \omega_d t - \frac{\zeta}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} \sin \omega_d t = 1 - \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} [\sin \phi \cos \omega_d t + \cos \phi \sin \omega_d t] \\
 &= 1 - \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \sin(\omega_d t + \phi)
 \end{aligned}$$

where

$$\cos \phi = \zeta = \text{damping ratio}, \quad \sin \phi = \sqrt{1-\zeta^2}$$

Example 2A.4

The open-loop response of a plant to a unit impulse input, with zero initial conditions, was found to be $2 e^{-t} \sin t$. What is the transfer function of the plant?

Solution

By linearity, since a unit impulse is the derivative of a unit step, the response to a unit impulse is given by the derivative of the result given in the previous example; thus,

$$\begin{aligned}
 y_{\text{impulse}}(t) &= \frac{\zeta\omega_n}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} \sin(\omega_d t + \phi) - \frac{\omega_d}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} \cos(\omega_d t + \phi) \\
 &= \frac{\omega_n}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} [\cos \phi \sin(\omega_d t + \phi) - \sin \phi \cos(\omega_d t + \phi)]
 \end{aligned}$$

or

$$y_{\text{impulse}}(t) = \frac{\omega_n}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} \sin \omega_d t$$

Compare this with the given expression. We have

$$\frac{\omega_n}{\sqrt{1-\zeta^2}} = 2, \quad \zeta\omega_n = 1, \quad \omega_d = 1$$

However,

$$\omega_n^2 = (\zeta\omega_n)^2 + \omega_d^2 = 1 + 1 = 2$$

Hence,

$$\omega_n = \sqrt{2}$$

Hence,

$$\zeta = \frac{1}{\sqrt{2}}$$

The system transfer function is

$$\frac{\omega_n^2}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} = \frac{2}{s^2 + 2s + 2}$$

Example 2A.5

Express the Laplace transformed expression

$$X(s) = \frac{s^3 + 5s^2 + 9s + 7}{(s+1)(s+2)}$$

as partial fractions. From the result, determine the inverse Laplace function, $x(t)$.

Solution

$$X(s) = s + 2 + \frac{2}{s+1} - \frac{1}{s+2}$$

From Table 2A.1, we get the inverse Laplace transform

$$x(t) = \frac{d}{dt}\delta(t) + 2\delta(t) + 2e^{-t} - e^{-2t}$$

where $\delta(t)$ is the unit impulse function.

2A.4 Transfer Function

By the use of Laplace transformation, a *convolution integral* equation can be converted into an algebraic relationship. To illustrate this, consider the convolution integral which gives the response, $y(t)$, of a dynamic system to an excitation input, $u(t)$, with zero initial conditions, as discussed in Chapter 2. By definition (Equation 2A.1), its Laplace transform is written as

$$Y(s) = \int_0^\infty \int_0^\infty h(\tau)u(t-\tau)d\tau \exp(-st)dt \quad (2A.7)$$

Note that $h(t)$ is the *impulse response function* of the system. Since integration with respect to t is performed while keeping τ constant, we have $dt = d(t-\tau)$. Consequently,

$$Y(s) = \int_{-\tau}^\infty u(t-\tau)\exp[-s(t-\tau)]d(t-\tau) \int_0^\infty h(\tau)\exp(-s\tau)d\tau$$

The lower limit of the first integration can be made equal to zero, in view of the fact that $u(t) = 0$ for $t < 0$. Again, by using the definition of Laplace transformation, the foregoing relation can be expressed as

$$Y(s) = H(s)U(s) \quad (2A.8)$$

in which

$$H(s) = Lh(t) = \int_0^\infty h(t)\exp(-st)dt \quad (2A.9)$$

Note that, by definition, the transfer function of a system, denoted by $H(s)$, is given by Equation 2A.8. More specifically, the system transfer function is given by the ratio of the Laplace-transformed output and the Laplace-transformed input with zero initial conditions. In view of Equation 2A.9, it is clear that the system transfer function can be expressed as the Laplace transform of the impulse-response function of the system. The transfer function of a linear and constant-parameter system is a unique function that completely represents the system. A physically realizable, linear, constant-parameter system possesses a unique transfer function, even if the Laplace transforms of a particular input and the corresponding output do not exist. This is clear from the fact that the transfer function is a system model and does not depend on the system input itself.

Note: The transfer function is also commonly denoted by $G(s)$. However, in the present context, we use $H(s)$ in view of its relation to $h(t)$.

Consider the n th-order linear, constant-parameter dynamic system given by

$$a_n \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_0 y = b_0 u + b_1 \frac{du(t)}{dt} + \cdots + b_m \frac{d^m u(t)}{dt^m} \quad (2A.10)$$

for a physically realizable system, $m \leq n$. By applying Laplace transformation and then integrating by parts, it may be verified that

$$L \frac{d^k f(t)}{dt^k} = s^k \hat{F}(s) - s^{k-1} f(0) - s^{k-2} \frac{df(0)}{dt} - \cdots + \frac{d^{k-1} f(0)}{dt^{k-1}} \quad (2A.11)$$

By definition, the initial conditions are set to zero in obtaining the transfer function. This results in

$$H(s) = \frac{b_0 + b_1 s + \cdots + b_m s^m}{a_0 + a_1 s + \cdots + a_n s^n} \quad (2A.12)$$

for $m \leq n$. Note that Equation 2A.12 contains all the information that is contained in Equation 2A.10. Consequently, transfer function is an analytical model of a system. The transfer function may be employed to determine the total response of a system for a given input, even though it is defined in terms of the response under zero initial conditions. This is logical because the analytical model of a system is independent of the initial conditions of the system.

2A.5 Fourier Transform

The Fourier transform, $Y(f)$, of a signal, $y(t)$, relates the time domain to the frequency domain. Specifically,

$$Y(f) = \int_{-\infty}^{+\infty} y(t) \exp(-j2\pi ft) dt = \int_{-\infty}^{+\infty} y(t) e^{-j\omega t} dt \quad (2A.13)$$

Using the Fourier operator, F , terminology:

$$Y(f) = Fy(t) \quad (2A.14)$$

Note that if $y(t) = 0$ for $t < 0$, as in the conventional definition of system excitations and responses, the Fourier transform is obtained from the Laplace transform by simply changing the variable according to $s = j2\pi f$ or $j\omega$. The Fourier is a special case of the Laplace, where, in Equation 2A.2, $\sigma = 0$:

$$Y(f) = Y(s)|_{s=j2\pi f} \quad (2A.15)$$

or

$$Y(\omega) = Y(s)|_{s=j\omega} \quad (2A.16)$$

The (complex) function $Y(f)$ is also termed the (continuous) *Fourier spectrum* of the (real) signal, $y(t)$. The inverse transform is given by:

$$y(t) = \int_{-\infty}^{+\infty} Y(f) \exp(j2\pi ft) df \quad (2A.17)$$

or

$$y(t) = F^{-1}Y(f)$$

Note that according to the definition given by Equation 2A.13, the Fourier spectrum, $Y(f)$, is defined for the entire frequency range $f(-\infty, +\infty)$ which includes negative values. This is termed the *two-sided spectrum*. Since, in practical applications it is not possible to have “negative frequencies,” the *one-sided spectrum* is usually defined only for the frequency range $f(0, \infty)$.

In order that a two-sided spectrum has the same amount of *power* as a one-sided spectrum, it is necessary to make the one-sided spectrum double the two-sided spectrum for $f > 0$.

If the signal is not sufficiently transient (fast-decaying or damped), the infinite integral given by Equation 2A.13 might not exist, but the corresponding Laplace transform might still exist.

2A.5.1 Frequency-Response Function (Frequency Transfer Function)

The Fourier integral transform of the impulse-response function is given by

$$H(f) = \int_{-\infty}^{\infty} h(t) \exp(-j2\pi ft) dt \quad (2A.18)$$

where f is the *cyclic frequency* (measured in cycles/sec or hertz). This is known as the frequency-response function (or frequency transfer function) of a system. Fourier transform operation is denoted as $Fh(t) = H(f)$. In view of the fact that $h(t) = 0$ for $t < 0$, the lower limit of integration in Equation 2A.18 can be made zero. Then, from Equation 2A.9, it is clear that $H(f)$ is obtained simply by setting $s = j2\pi f$ in $H(s)$. Hence, strictly speaking, we should use the notation $H(j2\pi f)$ and not $H(f)$. However, for notational simplicity, we denote $H(j2\pi f)$ by $H(f)$. Furthermore, since the angular frequency $\omega = 2\pi f$, we can express the frequency-response function as $H(j\omega)$, or simply by $H(\omega)$ for notational convenience. It should be noted that the frequency-response function, like the Laplace transfer function, is a complete representation of a linear, constant-parameter system. In view of the fact that both $u(t) = 0$ and $y(t) = 0$ for $t < 0$, we can write the Fourier transforms of the input and the output of a system directly by setting $s = j2\pi f = j\omega$ in the corresponding Laplace transforms.

Then, from Equation 2A.8, we have

$$Y(f) = H(f)U(f) \quad (2A.19)$$

Note: Sometimes, for notational convenience, the same lowercase letters are used to represent the Laplace and Fourier transforms as well as the original time-domain variables.

If the Fourier integral transform of a function exists, then its Laplace transform also exists. The converse is not generally true, however, because of the poor convergence of the Fourier integral in comparison to the Laplace integral. This arises from the fact that the factor $\exp(-\sigma t)$ is not present in the Fourier integral. For a physically realizable, linear, constant-parameter system, $H(f)$ exists even if $U(f)$ and $Y(f)$ do not exist for a particular input. The experimental determination of $H(f)$, however, requires system stability. For the n th-order system given by Equation 2A.10, the frequency-response function is determined by setting $s = j2\pi f$ in Equation 2A.12 as

$$H(f) = \frac{b_0 + b_1 j2\pi f + \cdots + b_m (j2\pi f)^m}{a_0 + a_1 j2\pi f + \cdots + a_n (j2\pi f)^n} \quad (2A.20)$$

This, generally, is a complex function of f , which has a magnitude denoted by $|H(f)|$ and a phase angle denoted by $\angle H(f)$.

2A.6 The s -Plane

We have noted that the Laplace variable s is a complex variable, with a real part and an imaginary part. Hence, to represent it we will need two axes at right angles to each other—the real axis and the imaginary axis. These two axes form a plane, which is called the s -plane. Any general value of s (or any variation or trace of s) may be marked on the s -plane.

2A.6.1 An Interpretation of Laplace and Fourier Transforms

In the Laplace transformation of a function, $f(t)$, we multiply the function by e^{-st} and integrate with respect to t . This process may be interpreted as determining the “components” $F(s)$ of $f(t)$ in the “direction” e^{-st} , where s is a complex variable. All such components $F(s)$ should be equivalent to the original function, $f(t)$.

In the Fourier transformation of $f(t)$ we multiply it by $e^{-j\omega t}$ and integrate with respect to t . This is the same as setting $s = j\omega$. Hence, the Fourier transform of $f(t)$ is $F(j\omega)$. Furthermore, $F(j\omega)$ represents the components of $f(t)$ that are in the direction of $e^{-j\omega t}$. Since $e^{-j\omega t} = \cos \omega t - j \sin \omega t$, in the Fourier transformation we determine the sinusoidal components of frequency ω , of a time

function $f(t)$. Since s is complex, $F(s)$ is also complex and so is $F(j\omega)$. Hence, they all will have a real part and an imaginary part.

2A.6.2 Application in Circuit Analysis

The fact that $\sin \omega t$ and $\cos \omega t$ are 90° out of phase is further confirmed in view of

$$e^{j\omega t} = \cos \omega t + j \sin \omega t \quad (2A.21)$$

Consider the R – L – C circuit shown in Figure 2A.2. For the capacitor, the current, i , and the voltage, v , are related through

$$i = C \frac{dv}{dt} \quad (2A.22)$$

If the voltage $v = v_0 \sin \omega t$, the current $i = v_0 \omega C \cos \omega t$. Note that the magnitude of v/i is $1/\omega C$ (or $1/2\pi fC$ where $\omega = 2\pi f$; f is the cyclic frequency and ω is the angular frequency). But v and i are out of phase by 90° . In fact, in the case of a capacitor, i leads v by 90° . The equivalent circuit resistance of a capacitance is called *reactance*, and is given by

$$X_C = \frac{1}{2\pi fC} \quad (2A.23)$$

$$= \frac{1}{\omega C} \quad (2A.24)$$

Note that this parameter changes with the frequency.

We cannot add the reactance of the capacitor and the resistance of the resistor algebraically; we must add them vectorially because the voltages across a capacitor and resistor in series are not in phase, unlike in the case of a resistor. Also, the resistance in a resistor does not change with frequency. In a series circuit, as in Figure 2A.2, the current is identical in each element, but the voltages differ in both amplitude and phase; in a parallel circuit, the voltages are identical, but the currents differ in amplitude and phase.

Similarly, for an inductor,

$$v = L \frac{di}{dt} \quad (2A.25)$$

The corresponding reactance is

$$X_L = \omega L = 2\pi fL \quad (2A.26)$$

If the voltage (E) across R in Figure 2A.2(a) is in the direction shown in Figure 2A.2(b) (i.e., pointing to the right), then the voltage across the inductor, L , must point up (90° leading) and the voltage across the capacitor, C , must point down (90° lagging). Since the current (I) is identical in each component of a

FIGURE 2A.2 (a) Series RLC circuit; (b) phases of voltage drops; (c) impedance triangle.

series circuit, we see the directions of IR , IX_L and IX_C as in [Figure 2A.2\(b\)](#), giving the impedance triangle shown in [Figure 2A.2\(c\)](#).

To express these reactances in the s -domain, we simply substitute s for $j\omega$:

$$\begin{aligned} -jX_C &= \frac{1}{sC} \\ jX_L &= sL \end{aligned}$$

The series impedance of the RLC circuit can be expressed as

$$Z = R + jX_L - jX_C = R + sL + \frac{1}{sC}$$

In this discussion, note the use of $\sqrt{-1}$ or j to indicate a 90° phase change.

Summary

This chapter presents the modal analysis of lumped-parameter mechanical vibrating systems. In the considered systems, inertia, flexibility, and damping characteristics are lumped at a finite number of discrete points in the system. Techniques for determining the natural frequencies and mode shapes of vibration are given. The orthogonality of mode shapes is established. The existence of natural modes in damped systems is investigated. Proportional damping is discussed. Both free vibration and forced vibration of multi-degree-of-freedom (multi-DoF) systems are analyzed.

3.1 Introduction

Complex vibrating systems usually consist of components that possess distributed energy-storage and energy-dissipative characteristics. In these systems, inertial, stiffness, and damping properties vary (piecewise) continuously with respect to the spatial location. Consequently, partial differential equations, with spatial coordinates (e.g., Cartesian coordinates x , y , z) and time t as independent variables are necessary to represent their vibration response.

A distributed (continuous) vibrating system may be approximated (modeled) by an appropriate set of lumped masses properly interconnected using discrete spring and damper elements. Such a model is termed *lumped-parameter model* or *discrete model*. An immediate advantage resulting from this lumped-parameter representation is that the system equations become ordinary differential equations. Often, linear springs and linear viscous damping elements are used in these models. The resulting linear ordinary differential equations can be solved by the modal analysis method. The method is based on the fact that these idealized systems (models) have preferred frequencies and geometric configurations (or *natural modes*) in which they tend to execute free vibration. An arbitrary response of the system can be interpreted as a linear combination of these *modal vibrations*, and as a result its analysis may be conveniently done using modal techniques.

Modal analysis is an important tool in vibration analysis, diagnosis, design, and control. In some systems, mechanical malfunction or failure can be attributed to the excitation of their preferred motion such as modal vibrations and resonances. By modal analysis, it is possible to establish the extent and location of severe vibrations in a system. For this reason, it is an important diagnostic tool. For the same reason, modal analysis is also a useful method for predicting impending malfunctions or other mechanical problems. Structural modification and substructuring are techniques of vibration analysis and design that are based on modal analysis. By sensitivity analysis methods using a modal model, it is possible to determine which degrees of freedom (DoFs) of a mechanical system are most sensitive to addition or removal of mass and stiffness elements. In this manner, a convenient and systematic method can be established for making structural modifications to eliminate an existing vibration problem, or to verify the effects of a particular modification. A large and complex system can be divided into several subsystems which can be independently analyzed. By modal analysis techniques, the dynamic characteristics of the overall system can be determined from the subsystem information. This approach has several advantages, including: (1) subsystems can be developed by different methods such as experimentation, finite element method, or other modeling techniques and assembled to obtain the overall model; (2) the analysis of a high order system can be reduced to several lower order analyses; and (3) the design of a complex system can be carried out by designing and developing its subsystems separately. These capabilities of structural modification and substructure analysis which are possessed by the modal analysis method make it a useful tool in the design development process of mechanical systems. Modal control, a technique that employs modal analysis, is quite effective in the vibration control of complex mechanical systems.

3.2 Degrees of Freedom and Independent Coordinates

The geometric configuration of a vibrating system can be completely determined by a set of independent coordinates. This number of independent coordinates, for most systems, is termed the number of DoFs of the system. For example, a particle freely moving on a plane requires two independent coordinates to completely locate it (e.g., x and y Cartesian coordinates or r and θ polar coordinates); its motion has two DoF. A rigid body that is free to take any orientation in (three-dimensional) space needs six independent coordinates to completely define its position. For instance, its centroid is positioned using three independent Cartesian coordinates (x, y, z). Any axis fixed in the body and passing through its centroid can be oriented by two independent angles (θ, ϕ). The orientation of the body about this body axis can be fixed by a third independent angle (ψ). Altogether, six independent coordinates have been utilized; the system has six DoF.

Strictly speaking, the number of DoF is equal to the number of independent, incremental, generalized coordinates that are needed to represent a general motion. In other words, it is the number of incremental independent motions that are possible. For holonomic systems (i.e., systems possessing holonomic constraints only), the number of independent incremental generalized coordinates is equal to the number of independent generalized coordinates; hence, either definition may be used for the number of DoF. If, on the other hand, the system has nonholonomic

constraints, the definition based on incremental coordinates should be used, because in these systems the number of independent incremental coordinates is in general less than the number of independent coordinates that are required to completely position the system.

3.2.1 Nonholonomic Constraints

Constraints of a system that cannot be represented by purely algebraic equations in its generalized coordinates and time are termed nonholonomic constraints. For a nonholonomic system, more coordinates than the number of DoF are required to completely define the position of the system. The number of excess coordinates is equal to the number of nonalgebraic relations that define the nonholonomic constraints in the system. Examples for nonholonomic systems are afforded by bodies rolling on surfaces and bodies whose velocities are constrained in some manner.

Example 3.1

A good example for a nonholonomic system is provided by a sphere rolling, without slipping, on a plane surface. In Figure 3.1, the point O denotes the center of the sphere at a given instant, and P is an arbitrary point within the sphere. The instantaneous point of contact with the plane surface is denoted by Q , so that the radius of the sphere is $OQ = a$. This system requires five independent generalized coordinates to position it. For example, the center O is fixed by the Cartesian coordinates x and y . Since the sphere is free to roll along any arbitrary path on the plane and return to the starting point, the line OP can assume any arbitrary orientation for any given position for the center O . This line can be oriented by two independent coordinates θ and ϕ , defined as in Figure 3.1. Furthermore, since the sphere is free to spin about the z -axis and is also free to roll on any trajectory (and return to its starting point), it follows that the sphere can take any orientation about the line OP (for a specific location of point O and line OP). This position can be oriented by the angle ψ . These five generalized coordinates x , y , θ , ϕ , and ψ are independent. The corresponding incremental coordinates δx , δy , $\delta \theta$, $\delta \phi$, and $\delta \psi$ are, however, not independent, as a result of the constraint of rolling without slipping. It can be shown that two independent differential equations can be written for this constraint, and that consequently there exist only three independent incremental coordinates; the system actually has only three DoF.

To establish the equations for the two nonholonomic constraints note that the incremental displacements δx and δy of the center O about the instantaneous point of contact Q can be written

$$\delta x = a \delta \beta, \quad \delta y = -a \delta \alpha$$

FIGURE 3.1 Rolling sphere on a plane (an example of a nonholonomic system).

in which the rotations of α and β are taken as positive about the positive directions of x and y , respectively (Figure 3.1). Next, we will express $\delta\alpha$ and $\delta\beta$ in terms of the generalized coordinates. Note that $\delta\theta$ is directed along the z direction and has no components along the x and y directions. On the other hand, $\delta\phi$ has the components $\delta\phi \cos \theta$ in the positive y direction and $\delta\phi \sin \theta$ in the negative x direction. Furthermore, the horizontal component of $\delta\psi$ is $\delta\psi \sin \phi$. This in turn has the components $(\delta\psi \sin \phi) \cos \theta$ and $(\delta\psi \sin \phi) \sin \theta$ in the positive x and y directions, respectively. It follows that

$$\delta\alpha = -\delta\phi \sin \theta + \delta\psi \sin \phi \cos \theta$$

$$\delta\beta = \delta\phi \cos \theta + \delta\psi \sin \phi \sin \theta$$

Consequently, the two nonholonomic constraint equations are

$$\delta x = a(\delta\phi \cos \theta + \delta\psi \sin \phi \sin \theta)$$

$$\delta y = a(\delta\phi \sin \theta - \delta\psi \sin \phi \cos \theta)$$

Note that these are differential equations that cannot be directly integrated to give algebraic equations. A particular choice for the three independent incremental coordinates associated with the three DoF in the present system of a rolling sphere would be $\delta\theta$, $\delta\phi$, and $\delta\psi$. The incremental variables $\delta\alpha$, $\delta\beta$, and $\delta\theta$ will form another choice. The incremental variables δx , δy , and $\delta\theta$ will also form a possible choice. Once three incremented displacements are chosen in this manner, the remaining two incremental generalized coordinates are not independent and can be expressed in terms of these three incremented variables using the constraint differential equations.

Example 3.2

A relatively simple example for a nonholonomic system is a single-dimensional rigid body (a straight line) moving on a plane such that its velocity is always along the body axis. The idealized motion of a ship in calm water is a practical situation representing such a system. This body needs three independent coordinates to completely define all possible configurations that it can take. For example, the centroid of the body can be fixed by two Cartesian coordinates x and y on the plane, and the orientation of the axis through the centroid may be fixed by a single angle θ . Note that, for a given location (x, y) of the centroid, any arbitrary orientation (θ) for the body axis is feasible, because, as in the previous example, any arbitrary trajectory can be followed by this body and return the centroid to the starting point, but with a different orientation of the axis of the body. Since the velocity is always directed along the body axis, a nonholonomic constraint exists and it is expressed as

$$\frac{dy}{dx} = \tan \theta$$

It follows that there are only two independent incremental variables; the system has only two DoF. Some useful definitions and properties that were discussed in this section are summarized in Box 3.1.

3.3 System Representation

Some damped systems do not possess real modes. If a system does not possess real modes, modal analysis could still be used, but the results would only be approximately valid. In modal analysis it is convenient to first neglect damping and develop the fundamental results, and then subsequently extend the results to damped systems, for example, by assuming a suitable damping model that possesses real modes. Since damping is an energy dissipation phenomenon, it is usually possible to determine a model that possesses real modes and also has an energy dissipation capacity equivalent to that of the actual system.

Box 3.1

SOME DEFINITIONS AND PROPERTIES OF MECHANICAL SYSTEMS

Holonomic constraints	Constraints that can be represented by purely algebraic relations
Nonholonomic constraints	Constraints that require differential relations for their representation
Holonomic system	A system that possesses holonomic constraints only
Nonholonomic system	A system that possesses one or more nonholonomic constraints
Number of DoFs	The number of independent incremental coordinates that are needed to represent general incremental motion of a system = number of independent incremental motions = $2 \times$ number of DoF (typically)
Order of a system	
For a holonomic system	
Number of independent incremental coordinates	= Number of independent coordinates = number of DoF
For a nonholonomic system	
Number of independent incremental coordinates	< Number of independent coordinates

Consider the three undamped system representations (models) shown in Figure 3.2. The motion of system (a) consists of the *translatory* displacements y_1 and y_2 of the lumped masses m_1 and m_2 . The masses are subjected to the external excitation forces (inputs) $f_1(t)$ and $f_2(t)$ and the restraining forces of the discrete, tensile-compressive stiffness (spring) elements k_1 , k_2 , and k_3 . Only two independent

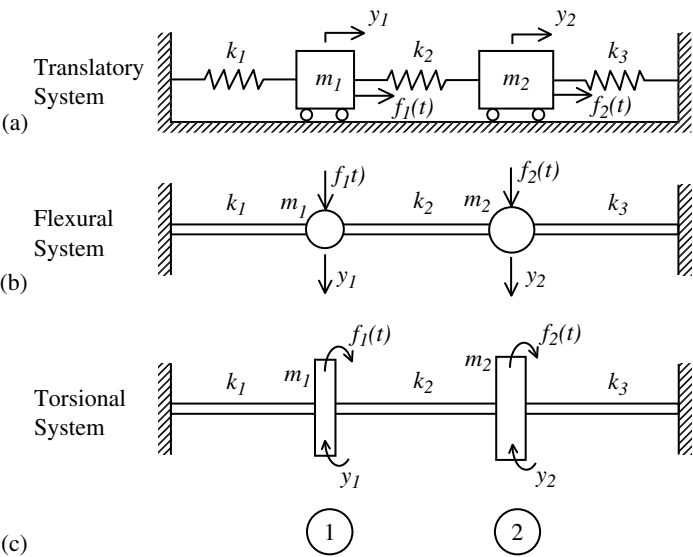

FIGURE 3.2 Three types of two-DoF systems.

incremental coordinates (δy_1 and δy_2) are required to completely define the incremental motion of the system subject to its inherent constraints. It follows that the system has two DoF.

In system (b), shown in Figure 3.2, the elastic stiffness to the *transverse* displacements y_1 and y_2 of the lumped masses is provided by three bending (*flexural*) springs that are considered massless. This flexural system is very much analogous to the translatory system (a) even though the physical construction and the motion itself are quite different. System (c) in Figure 3.2 is the analogous *torsional* system. In this case, the lumped elements m_1 and m_2 should be interpreted as polar moments of inertia about the shaft axis, and k_1 , k_2 , and k_3 as the torsional stiffness in the connecting shafts. Furthermore, the motion coordinates y_1 and y_2 are rotations and the external excitations $f_1(t)$ and $f_2(t)$ are torques applied at the inertia elements. Practical examples where these three types of vibration system models may be useful are: (a) a two-car train, (b) a bridge with two separate vehicle loads, and (c) an electric motor and pump combination.

The three systems shown in Figure 3.2 are analogous to each other in the sense that the dynamics of all three systems can be represented by similar equations of motion. For modal analysis, it is convenient to express the system equations as a set of coupled second-order differential equations in terms of the displacement variables (coordinates) of the inertia elements. Since in modal analysis we are concerned with linear systems, the system parameters can be given by a mass matrix and a stiffness matrix, or by a flexibility matrix. Lagrange's equations of motion directly yield these matrices; however, we will now present an intuitive method for identifying the stiffness and mass matrices.

The linear, lumped-parameter, undamped systems shown in Figure 3.2 satisfy the set of dynamic equations

$$\begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix} \begin{bmatrix} \ddot{y}_1 \\ \ddot{y}_2 \end{bmatrix} + \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \end{bmatrix}$$

or

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f} \quad (3.1)$$

Here, \mathbf{M} is the inertia matrix which is the generalized case of mass matrix, and \mathbf{K} is the stiffness matrix. There are many ways to derive Equation 3.1. Below, we will describe an approach, termed the *influence coefficient method*, which accomplishes the task by separately determining \mathbf{K} and \mathbf{M} .

3.3.1 Stiffness and Flexibility Matrices

In the systems shown in Figure 3.2 suppose the accelerations \ddot{y}_1 and \ddot{y}_2 are both zero at a particular instant, so that the inertia effects are absent. The stiffness matrix \mathbf{K} is given under these circumstances by the constitutive relation for the spring elements:

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$$

or

$$\mathbf{f} = \mathbf{K}\mathbf{y} \quad (3.2)$$

in which \mathbf{f} is the force vector $[f_1, f_2]^T$ and \mathbf{y} is the displacement vector $[y_1, y_2]^T$. Both are column vectors. The elements of the stiffness matrix, in this two-DoF case, are explicitly given by

$$\mathbf{K} = \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix}$$

Suppose that $y_1 = 1$ and $y_2 = 0$ (i.e., give a unit displacement to m_1 while holding m_2 at its original position). Then k_{11} and k_{21} are the forces needed at location 1 and location 2, respectively, to maintain this static configuration. For this condition it is clear that $f_1 = k_1 + k_2$ and $f_2 = -k_2$. Accordingly,

$$k_{11} = k_1 + k_2, \quad k_{21} = -k_2$$

Similarly, suppose that $y_1 = 0$ and $y_2 = 1$. Then k_{12} and k_{22} are the forces needed at location 1 and location 2, respectively, to maintain the corresponding static configuration. It follows that

$$k_{12} = -k_2, \quad k_{22} = k_2 + k_3$$

Consequently, the complete stiffness matrix can be expressed in terms of the stiffness elements in the system as

$$\mathbf{K} = \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 + k_3 \end{bmatrix}$$

From the foregoing development, it should be clear that the stiffness parameter k_{ij} represents the force that is needed at the location i to obtain a unit displacement at location j . Hence, these parameters are termed *stiffness influence coefficients*.

Observe that the stiffness matrix is symmetric. Specifically,

$$k_{ij} = k_{ji} \quad \text{for } i \neq j$$

or

$$\mathbf{K}^T = \mathbf{K} \quad (3.3)$$

Note, however, that \mathbf{K} is not diagonal in general ($k_{ij} \neq 0$ for at least two values of $i \neq j$). This means that the system is statically coupled (or *flexibly coupled*).

Flexibility matrix \mathbf{L} is the inverse of the stiffness matrix

$$\mathbf{L} = \mathbf{K}^{-1} \quad (3.4)$$

To determine the flexibility matrix using the influence coefficient approach, we have to start with a constitutive relation of the form

$$\mathbf{y} = \mathbf{L}\mathbf{f} \quad (3.5)$$

Assuming that there are no inertia forces at a particular instant, we then proceed as before. For the systems in Figure 3.2, for example, we start with $f_1 = 1$ and $f_2 = 0$. In this manner, we can determine the elements l_{11} and l_{21} of the flexibility matrix

$$\mathbf{L} = \begin{bmatrix} l_{11} & l_{12} \\ l_{21} & l_{22} \end{bmatrix}$$

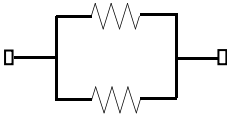

However, here, the result is not as straightforward as in the previous case. For example, to determine l_{11} , we will have to find the flexibility contributions from either side of m_1 . The flexibility of the stiffness element k_1 is $1/k_1$. The combined flexibility of k_2 and k_3 , which are connected in series, is $1/k_2 + 1/k_3$ because the displacements (*across variables*) are additive in series. The two flexibilities on either side of m_1 are applied in parallel at m_1 . Since the forces (*through variables*) are additive in parallel, the stiffness will also be additive. Consequently,

$$\frac{1}{l_{11}} = \frac{1}{(1/k_1)} + \frac{1}{(1/k_2 + 1/k_3)}$$

After some algebraic manipulation we get

$$l_{11} = \frac{k_2 + k_3}{k_1 k_2 + k_2 k_3 + k_3 k_1}$$

TABLE 3.1 Combination Rules for Stiffness and Flexibility Elements

Connection	Graphical Representation	Combined Stiffness	Combined Flexibility
Series		$\frac{1}{(1/k_1 + 1/k_2)}$	$l_1 + l_2$
Parallel		$k_1 + k_2$	$\frac{1}{(1/l_1 + 1/l_2)}$

Since there is no external force at m_2 in the assumed loading configuration, the deflections at m_2 and m_1 are proportioned according to the flexibility distribution along the path. Accordingly,

$$l_{21} = \left[\frac{1/k_3}{1/k_3 + 1/k_2} \right] l_{11}$$

or

$$l_{21} = \frac{k_2}{k_1 k_2 + k_2 k_3 + k_3 k_1}$$

Similarly, we can obtain

$$l_{12} = \frac{k_2}{k_1 k_2 + k_2 k_3 + k_3 k_1}$$

and

$$l_{22} = \frac{k_1 + k_2}{k_1 k_2 + k_2 k_3 + k_3 k_1}$$

Note that these results confirm the symmetry of flexibility matrices

$$l_{ij} = l_{ji} \quad \text{for } i \neq j$$

or

$$\mathbf{L}^T = \mathbf{L} \tag{3.6}$$

Also, we can verify the fact that \mathbf{L} is the inverse of \mathbf{K} . The series–parallel combination rules for stiffness and flexibility that are useful in the present approach are summarized in Table 3.1.

The flexibility parameters l_{ij} represent the displacement at the location i when a unit force is applied at location j . Hence, these parameters are termed *flexibility influence coefficients*.

3.3.2 Inertia Matrix

The mass matrix, which is used in the case of translatory motions, can be generalized as inertia matrix \mathbf{M} in order to include rotatory motions as well. To determine \mathbf{M} for the systems shown in Figure 3.2, suppose the deflections y_1 and y_2 are both zero at a particular instant so that the springs are in their static equilibrium configuration. Under these conditions, the equation of motion 3.1 becomes

$$\mathbf{f} = \mathbf{M}\ddot{\mathbf{y}} \tag{3.7}$$

For the present two-DoF case, the elements of \mathbf{M} are denoted by

$$\mathbf{M} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

To identify these elements, first set $\ddot{y}_1 = 1$ and $\ddot{y}_2 = 0$. Then, m_{11} and m_{21} are the forces needed at the locations 1 and 2, respectively, to sustain the given accelerations; specifically, $f_1 = m_1$ and $f_2 = 0$. It follows that

$$m_{11} = m_1, \quad m_{21} = 0$$

Similarly, by setting $\ddot{y}_1 = 0$ and $\ddot{y}_2 = 1$, we get

$$m_{12} = 0, \quad m_{22} = m_2$$

Then, the mass matrix is obtained as

$$\mathbf{M} = \begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix}$$

It should be clear now that the inertia parameter m_{ij} represents the force that should be applied at the location i in order to produce a unit acceleration at location j . Consequently, these parameters are called *inertia influence coefficients*.

Note that the mass matrix is symmetric in general; specifically

$$m_{ij} = m_{ji} \quad \text{for } i \neq j$$

or

$$\mathbf{M}^T = \mathbf{M} \tag{3.8}$$

Furthermore, when the independent displacements of the lumped inertia elements are chosen as the motion coordinates, as is typical, the inertia matrix becomes diagonal. If not, it can be made diagonal by using straightforward algebraic substitutions so that each equation contains the second derivative of just one displacement variable. Hence, we may assume

$$m_{ij} = 0 \quad \text{for } i \neq j \tag{3.9}$$

Then the system is said to be inertially uncoupled. This approach to finding \mathbf{K} and \mathbf{M} is summarized in Box 3.2. It can be conveniently extended to damped systems for determining the damping matrix \mathbf{C} .

FIGURE 3.3 Free-body diagram of the two-DoF system.

3.3.3 Direct Approach for Equations of Motion

The influence coefficient approach that was described in the previous section is a rather indirect way of obtaining the equations of motion 3.1 for a multi-DoF system. The most straightforward approach, however, is to sketch a free-body diagram for the system, mark the forces or torques on each inertia element, and finally, apply Newton's Second Law. This approach is now illustrated for the system shown in Figure 3.2(a). The equations of motion for the systems in Figures 3.2(b) and (c) will follow analogously.

The free-body diagram of the system in Figure 3.2(a) is sketched in Figure 3.3. Note that all the forces on each inertia element are marked.

Application of Newton's Second Law to the two mass elements separately gives

$$m_1 \ddot{y}_1 = -k_1 y_1 + k_2 (y_2 - y_1) + f_1(t)$$

$$m_2 \ddot{y}_2 = -k_2 (y_2 - y_1) - k_3 y_2 + f_2(t)$$

The terms can be rearranged to obtain the following two coupled, second order, linear, ordinary differential equations:

$$m_1 \ddot{y}_1 + (k_1 + k_2) y_1 - k_2 y_2 = f_1(t)$$

$$m_2 \ddot{y}_2 - k_2 y_1 + (k_2 + k_3) y_2 = f_2(t)$$

which may be expressed in the vector-matrix form as

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{bmatrix} \ddot{y}_1 \\ \ddot{y}_2 \end{bmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 + k_3 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} f_1(t) \\ f_2(t) \end{bmatrix}$$

Observe that this result is identical to what we obtained by the influence coefficient approach.

Another convenient approach that would provide essentially the same result is the energy method through the application of Lagrange's equations. Two common types of models used in vibration analysis and applications are summarized in Box 3.3.

3.4 Modal Vibrations

Among the infinite number of relative geometric configurations the lumped masses in a multi-DoF system could assume under free motion (i.e., with $\mathbf{f}(t) = 0$), when excited by an arbitrary initial state, there is a finite number of configurations that are naturally preferred by the system. Each of these configurations will have an associated frequency of motion. These motions are termed *modal motions*. By choosing the initial displacement $\mathbf{y}(0)$ proportional to a particular modal configuration, with zero initial velocity, $\dot{\mathbf{y}}(0) = 0$, that particular mode can be excited at the associated natural frequency of motion. The displacements of different DoF retain this initial proportion at all times. This constant proportion in displacement can be expressed as a vector $\boldsymbol{\psi}$ for that mode, and represents the mode shape. Note that each modal motion is a harmonic motion executed at a specific frequency ω known as the *natural frequency* (undamped). In view of these general properties of modal motions,

Linear	Nonlinear
Coupled second-order equations	
$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t)$	$\mathbf{M}\ddot{\mathbf{y}} = \mathbf{h}(\mathbf{y}, \dot{\mathbf{y}}, \mathbf{f}(t))$
Response vector:	
$\mathbf{y} = [y_1, y_2, \dots, y_p]^T$; p = number of DoF	
Excitation vector: $\mathbf{f}(t) = [f_1, f_2, \dots, f_p]^T$	
\mathbf{M} = mass matrix	
\mathbf{C} or \mathbf{B} = damping matrix	
\mathbf{K} = stiffness matrix	
Coupled first-order equations (state-space models)	
$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$	$\dot{\mathbf{x}} = \mathbf{a}(\mathbf{x}, \mathbf{u})$
$\mathbf{y} = \mathbf{C}\mathbf{x}$	$\mathbf{y} = \mathbf{y}(\mathbf{x})$
State vector $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$; n = order of the system	
Input (excitation) vector $\mathbf{u} = [u_1, u_2, \dots, u_m]^T$	
Output (response) vector $\mathbf{y} = [y_1, y_2, \dots, y_p]^T$	
Notes:	
1. Definition of state: If $\mathbf{x}(t_0)$, and \mathbf{u} from t_0 to t_1 , are known, $\mathbf{x}(t_1)$ can be determined completely	
2. State vector \mathbf{x} contains a minimum number (n) of elements	
3. State model is not unique (different state models are possible for the same system)	
4. One approach to obtaining a state model is to use $\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{bmatrix}$	

$$\mathbf{y} = \boldsymbol{\Psi} \cos \omega t \quad (3.10)$$
$$\mathbf{y} = \boldsymbol{\psi} e^{j\omega t} \quad (3.11)$$
$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{0} \quad (3.12)$$
$$[\omega^2 \mathbf{M} - \mathbf{K}] \boldsymbol{\Psi} = 0 \quad (3.13)$$
$$\det[\omega^2 \mathbf{M} - \mathbf{K}] = 0 \quad (3.14)$$

results a mode shape vector Ψ_i that determines up to one unknown parameter which can be used as a scaling parameter. Extra care should be exercised, however, when determining mode shapes for zero natural frequencies (i.e., rigid-body modes) and repeated natural frequencies (i.e., for systems with a dynamic symmetry). We shall return to these considerations in later sections.

Example 3.3

Consider a mechanical system modeled as in Figure 3.4. This is obtained from the systems in Figure 3.2 by setting $m_1 = m$, $m_2 = \alpha m$, $k_1 = k$, $k_2 = \beta k$, and $k_3 = 0$. The corresponding mass matrix and the stiffness matrix are

FIGURE 3.4 A modal vibration example.

$$\mathbf{M} = \begin{bmatrix} m & 0 \\ 0 & \alpha m \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} (1 + \beta)k & -\beta k \\ -\beta k & \beta k \end{bmatrix}$$

The natural frequencies are given by the roots of the characteristic equation

$$\det \begin{bmatrix} \omega^2 m - (1 + \beta)k & \beta k \\ \beta k & \omega^2 \alpha m - \beta k \end{bmatrix} = 0$$

By expanding the determinant, this can be expressed as

$$[\omega^2 m - (1 + \beta)k][\omega^2 \alpha m - \beta k] - \beta^2 k^2 = 0$$

or

$$\omega^4 \alpha m^2 - \omega^2 km[\beta + \alpha(1 + \beta)] + \beta k^2 = 0$$

Let us define a frequency parameter $\omega_0 = \sqrt{k/m}$. This parameter is identified as the natural frequency of an undamped simple oscillator (single-DoF mass-spring system) with mass m and stiffness k . Consequently, the characteristic equation of the given 2 DoF system can be written as

$$\alpha \left(\frac{\omega}{\omega_0} \right)^4 - (\alpha + \beta + \alpha\beta) \left(\frac{\omega}{\omega_0} \right)^2 + \beta = 0$$

whose roots are

$$\left(\frac{\omega_1}{\omega_0} \right)^2, \left(\frac{\omega_2}{\omega_0} \right)^2 = \frac{1}{2\alpha} \{ \alpha + \beta + \alpha\beta \} \left\{ 1 \mp \sqrt{1 - \frac{4\alpha\beta}{(\alpha + \beta + \alpha\beta)^2}} \right\}$$

The mode shapes are obtained by solving for Ψ in

$$\begin{bmatrix} \omega^2 m - (1 + \beta)k & \beta k \\ \beta k & \omega^2 \alpha m - \beta k \end{bmatrix} \Psi = 0$$

or

$$\begin{bmatrix} \left(\frac{\omega}{\omega_0} \right)^2 - (1 + \beta) & \beta \\ \beta & \alpha \left(\frac{\omega}{\omega_0} \right)^2 - \beta \end{bmatrix} \Psi = 0$$

In a mode shape vector, only the ratio of the elements is needed. This is because, in determining a mode shape, we are concerned about the relative motions of the lumped masses, not the absolute motions.

FIGURE 3.5 Dependence of natural frequencies (ω/ω_0) on mass ratio (α) and stiffness ratio (β) .

From the above equation, it is clear that this ratio is given by

$$\frac{\psi_2}{\psi_1} = \frac{(1 + \beta) - \left(\frac{\omega}{\omega_0}\right)^2}{\beta} = \frac{\beta}{\beta - \alpha\left(\frac{\omega}{\omega_0}\right)^2}$$

which is evaluated by substituting the appropriate value for (ω/ω_0) , depending on the mode, into any one of the right-hand-side expressions above.

The dependence of the natural frequencies on the parameters α and β is illustrated by the curves in Figure 3.5. Some representative values of the natural frequencies and mode shape ratios are listed in Table 3.2.

Note that, when $\beta = 0$, the spring connecting the two masses does not exist and the system reduces to two separate systems: a simple oscillator of natural frequency ω_0 and a single mass particle (of zero natural frequency). It is clear that in this case $\omega_1/\omega_0 = 0$ and $\omega_2/\omega_0 = 1$. This fact can be established from the expressions for natural frequencies of the original system by setting $\beta = 0$. The mode corresponding to $\omega_1/\omega_0 = 0$ is a rigid-body mode in which the free mass moves indefinitely (zero frequency) and the other mass (restrained mass) stands still. It follows that the mode shape ratio $(\psi_2/\psi_1)_1 \rightarrow \infty$. In the second mass, the free mass stands still and the restrained mass moves. Hence, $(\psi_2/\psi_1)_1 = 0$. These results are also obtained from the general expressions for the mode shape ratios of the original system.

TABLE 3.2 The Dependence of Natural Frequencies and Mode Shapes on Inertia and Stiffness

α	0.5				1.0				2.0			
β	ω_1/ω_0	ω_2/ω_0	$(\psi_2/\psi_1)_1$	$(\psi_2/\psi_1)_2$	ω_1/ω_0	ω_2/ω_0	$(\psi_2/\psi_1)_1$	$(\psi_2/\psi_1)_2$	ω_1/ω_0	ω_2/ω_0	$(\psi_2/\psi_1)_1$	$(\psi_2/\psi_1)_2$
0	0	1.0	∞	0	0	1.0	∞	0	0	1.0	∞	0
0.5	0.71	1.41	2.0	-1.0	0.54	1.31	2.41	-0.41	0.40	1.26	2.69	-0.19
1.0	0.77	1.85	1.41	-1.41	0.62	1.62	1.62	-0.62	0.47	1.51	1.78	-0.28
2.0	0.79	2.52	1.19	-1.69	0.66	2.14	1.28	-0.78	0.52	1.93	1.37	-0.37
5.0	0.81	3.92	1.07	-1.87	0.69	3.24	1.10	-0.91	0.55	2.86	1.14	-0.44
∞	0.82	∞	1.0	-2.0	0.71	∞	1.0	-1.0	0.57	∞	1.0	-0.5

When $\beta \rightarrow \infty$, the spring connecting the two masses becomes rigid and the two masses act as a single mass $(1 + \alpha)m$ restrained by a spring of stiffness k . This simple oscillator has a squared natural frequency of $\omega_0^2/(1 + \alpha)$. This is considered the smaller natural frequency of the corresponding system: $(\omega_1/\omega_0)^2 = 1/(1 + \alpha)$. The larger natural frequency ω_2 approaches ∞ in this case and it corresponds to the natural frequency of a massless spring. These limiting results can be derived from the general expressions for the natural frequencies of the original system by using the fact that for small $|x| \ll 1$, the expression $\sqrt{1 - x}$ is approximately equal to $1 - (1/2)x$. (Proof: Use the Taylor series expansion.) In the first mode, the two masses move as one unit and hence the mode shape ratio $(\psi_2/\psi_1)_1 = 1$. In the second mode, the two masses move in opposite directions restrained by an infinitely stiff spring. This is considered the static mode which results from the redundant situation of associating two DoF to a system that actually has only one lumped mass $(1 + \alpha)m$. In this case, the mode shape ratio is obtained from the general result as follows: For large β , we can neglect α in comparison. Hence,

$$\left(\frac{\omega_2}{\omega_0}\right)^2 = \frac{1}{2\alpha} \{\beta + \alpha\beta\} \{1 + 1\} = (1 + \alpha) \frac{\beta}{\alpha}$$

By substituting this result in the expression for the mode shape ratio, we obtain

$$\left(\frac{\psi_2}{\psi_1}\right)_2 = \frac{\beta}{\beta - \alpha\left(\frac{\omega_2}{\omega_0}\right)^2} = \frac{\beta}{\beta - \alpha(1 + \alpha)\frac{\beta}{\alpha}} = -\frac{1}{\alpha}$$

Finally, consider the case $\alpha = 0$ (with $\beta \neq 0$). In this case, only one mass m restrained by a spring of stiffness k is present. The spring of stiffness βk has an open end. The first mode corresponds to a simple oscillator of natural frequency ω_0 . Hence, $\omega_1/\omega_0 = 1$. The open end has the same displacement as the point mass. Consequently, $(\psi_2/\psi_1)_1 = 1$. These results can be derived from the general expressions for the original system. In the second mode the simple oscillator stands still and the open-ended spring oscillates (at an infinite frequency). Hence $\omega_2/\omega_0 = \infty$, and this again corresponds to a static mode situation which arises by assigning two DoF to a system that has only one DoF associated with its inertia elements. Since the lumped mass stands still, we have $(\psi_2/\psi_1)_2 = \infty$.

Note that, when $\alpha = 0$ and $\beta = 0$, the system reduces to a simple oscillator and the second mode is completely undefined. Hence, the corresponding results cannot be derived from the general results for the original system.

3.5 Orthogonality of Natural Modes

Let us write Equation 3.13 explicitly for the two distinct modes i and j . Distinct modes are defined as those having distinct natural frequencies (i.e., $\omega_i \neq \omega_j$).

$$\omega_i^2 \mathbf{M} \boldsymbol{\psi}_i - \mathbf{K} \boldsymbol{\psi}_i = 0 \quad (3.15)$$

$$\omega_j^2 \mathbf{M} \boldsymbol{\psi}_j - \mathbf{K} \boldsymbol{\psi}_j = 0 \quad (3.16)$$

Premultiply Equation 3.15 by $\boldsymbol{\psi}_j^T$ and Equation 3.16 by $\boldsymbol{\psi}_i^T$

$$\omega_i^2 \boldsymbol{\psi}_j^T \mathbf{M} \boldsymbol{\psi}_i - \boldsymbol{\psi}_j^T \mathbf{K} \boldsymbol{\psi}_i = 0 \quad (3.17)$$

$$\omega_j^2 \boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_j - \boldsymbol{\psi}_i^T \mathbf{K} \boldsymbol{\psi}_j = 0 \quad (3.18)$$

Take the transpose of Equation 3.18, which is a scalar:

$$\omega_j^2 \boldsymbol{\psi}_j^T \mathbf{M}^T \boldsymbol{\psi}_i - \boldsymbol{\psi}_j^T \mathbf{K}^T \boldsymbol{\psi}_i = 0$$

This, in view of the symmetry of \mathbf{M} and \mathbf{K} as expressed in Equation 3.8 and Equation 3.3, becomes

$$\omega_j^2 \boldsymbol{\psi}_j^T \mathbf{M} \boldsymbol{\psi}_i - \boldsymbol{\psi}_j^T \mathbf{K} \boldsymbol{\psi}_i = 0$$

By subtracting this result from Equation 3.17, we get

$$(\omega_i^2 - \omega_j^2)\boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_j = 0$$

Now, because $\omega_i \neq \omega_j$, it follows that

$$\boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_j = \begin{cases} 0 & \text{for } i \neq j \\ M_i & \text{for } i = j \end{cases} \quad (3.19)$$

Equation 3.19 is a useful *orthogonality condition* for natural modes.

Even though the foregoing condition of **M**-orthogonality was proved for distinct (unequal) natural frequencies it is generally true, even if two or more modes have repeated (equal) natural frequencies. Indeed, if a particular natural frequency is repeated r times, there will be r arbitrary elements in the modal vector. As a result, we are able to determine r independent mode shapes that are orthogonal with respect to the **M** matrix. An example is given later in the problem of Figure 3.6. Note further that any such mode shape vector corresponding to a repeated natural frequency will also be **M**-orthogonal to the mode shape vector corresponding to any of the remaining distinct natural frequencies. Consequently, we conclude that the entire set of n mode shape vectors is **M**-orthogonal even in the presence of various combinations of repeated natural frequencies.

FIGURE 3.6 A simplified vehicle model for heave and pitch motions.

3.5.1 Modal Mass and Normalized Modal Vectors

Note that, in Equation 3.19, a parameter M_i has been defined to denote $\boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_i$. This parameter is termed the *generalized mass* or *modal mass* for the i th mode. Since the modal vectors $\boldsymbol{\psi}_i$ are determined for up to one unknown parameter, it is possible to set the value of M_i arbitrarily. The process of specifying the unknown scaling parameter in the modal vector, according to some convenient rule, is called the *normalization* of modal vectors. The resulting modal vectors are termed *normal modes*. A particularly useful method of normalization is to set each modal mass to unity ($M_i = 1$). The corresponding normal modes are said to be *normalized with respect to the mass matrix*, or **M**-normal. Note that, if $\boldsymbol{\psi}_i$ is normal with respect to **M**, then it follows from Equation 3.18 that $-\boldsymbol{\psi}_i$ is also normal with respect to **M**. Specifically,

$$(-\boldsymbol{\psi}_i)^T \mathbf{M} (-\boldsymbol{\psi}_i) = \boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_i = 1 \quad (3.20)$$

It follows that **M**-normal modal vectors are still arbitrary up to a multiplier of -1 . A convenient practice for eliminating this arbitrariness is to make the first element of each normalized modal vector positive.

3.6 Static Modes and Rigid-Body Modes

3.6.1 Static Modes

Modes corresponding to infinite natural frequencies are known as static modes. For these modes, the modal mass is zero; in the normalization process with respect to **M** static modes cannot be included. If we assign a DoF for a massless location, the resulting mass matrix **M** becomes singular ($\det \mathbf{M} = 0$) and a static mode arises. We have come across two similar situations in a previous example; in one case the stiffness of the spring connecting two masses is made infinite so that they act as a single mass in the limit, and in the other case one of the two masses is made equal to zero so that only one mass is left. We should take extra precautions to avoid such situations by using proper modeling practices; the presence of a static mode amounts to assigning a DoF to a system that it does not actually possess. In a static mode, the system behaves like a simple massless spring.

In the literature of experimental modal analysis, the static modes are represented by a *residual flexibility* term in the transfer functions. Note that, in this case, modes of natural frequencies that are

higher than the analysis bandwidth or the maximum frequency of interest are considered static modes. Such issues of experimental modal analysis will be discussed in [Chapter 18](#).

3.6.2 Linear Independence of Modal Vectors

In the absence of static modes (i.e., modal masses $M_i \neq 0$), the inertia matrix \mathbf{M} will be nonsingular. Then the orthogonality condition 3.19 implies that the modal vectors are *linearly independent*, and consequently, they will form a *basis* for the n -dimensional space of all possible displacement trajectories \mathbf{y} for the system. Any vector in this *configuration space* (or displacement space), therefore, can be expressed as a linear combination of the modal vectors.

Note that we have assumed in the earlier development that the natural frequencies are distinct (or unequal). Nevertheless, linearly independent modal vectors are possessed by modes of equal natural frequencies as well. An example is the situation where these modes are physically uncoupled. These modal vectors are not unique, however; there will be arbitrary elements in the modal vector equal in number to the repeated natural frequencies. Any linear combination of these modal vectors can also serve as a modal vector at the same natural frequency. To explain this point further, without loss of generality suppose that $\omega_1 = \omega_2$. Then, from Equation 3.15, we have

$$\omega_1^2 \mathbf{M} \boldsymbol{\psi}_1 - \mathbf{K} \boldsymbol{\psi}_1 = 0$$

$$\omega_1^2 \mathbf{M} \boldsymbol{\psi}_2 - \mathbf{K} \boldsymbol{\psi}_2 = 0$$

Multiply the first equation by α , the second equation by β , and add the resulting equations. We get

$$\omega_1^2 \mathbf{M}(\alpha \boldsymbol{\psi}_1 + \beta \boldsymbol{\psi}_2) - \mathbf{K}(\alpha \boldsymbol{\psi}_1 + \beta \boldsymbol{\psi}_2) = 0$$

This verifies that any linear combination $\alpha \boldsymbol{\psi}_1 + \beta \boldsymbol{\psi}_2$ of the two modal vectors $\boldsymbol{\psi}_1$ and $\boldsymbol{\psi}_2$ will also serve as a modal vector for the natural frequency ω_1 . The physical significance of this phenomenon should be clear in Example 3.4.

3.6.3 Modal Stiffness and Normalized Modal Vectors

It is possible to establish an alternative version of the orthogonality condition given as Equation 3.19 by substituting it into Equation 3.18. This gives

$$\boldsymbol{\psi}_i^T \mathbf{K} \boldsymbol{\psi}_j = \begin{cases} 0 & \text{for } i \neq j \\ K_i & \text{for } i = j \end{cases} \quad (3.21)$$

This condition is termed **K-orthogonality**.

Since the **M-orthogonality** condition (Equation 3.19) is true even for the case of repeated natural frequencies, it should be clear that the **K-orthogonality** condition (Equation 3.21) is also true, in general, even with repeated natural frequencies. The newly defined parameter K_i represents the value of $\boldsymbol{\psi}_i^T \mathbf{K} \boldsymbol{\psi}_i$ and is known as the *generalized stiffness* or *modal stiffness* corresponding to the i th mode.

Another useful way to *normalize* modal vectors is to choose their unknown parameters so that all modal stiffnesses are unity ($K_i = 1$ for all i). This process is known as normalization with respect to the stiffness matrix. The resulting normal modes are said to be **K-normal**. These normal modes are still arbitrary up to a multiplier of -1 . This can be eliminated by assigning positive values to the first element of all modal vectors.

Note that it is not possible to normalize a modal vector simultaneously with respect to both \mathbf{M} and \mathbf{K} , in general. To understand this further, we may observe that $\omega_i^2 = K_i/M_i$ and consequently we are unable to pick both K_i and M_i arbitrarily. In particular, for the **M-normal** case $K_i = \omega_i^2$ and for the **K-normal** case $M_i = 1/\omega_i^2$.

3.6.4 Rigid-Body Modes

Rigid-body modes are those for which the natural frequency is zero. Modal stiffness is zero for rigid-body modes, and as a result it is not possible to normalize these modes with respect to the stiffness matrix. Note that when rigid-body modes are present the stiffness matrix becomes *singular* ($\det \mathbf{K} = 0$). Physically, removal of a spring that connects two DoF results in a rigid-body mode. In Example 3.3 we came across a similar situation. In experimental modal analysis applications, low-stiffness connections or restraints, which might be present in a test object, could result in approximate rigid-body modes that would become prominent at low frequencies.

Some important results of modal analysis that we have discussed thus far are summarized in Table 3.3.

Example 3.4

Consider a light rod of length l having equal masses m attached to its ends. Each end is supported by a spring of stiffness k as shown in Figure 3.6. Note that this system may represent a simplified model of a vehicle in heave and pitch motions. Gravity effects can be eliminated by measuring the displacements y_1 and y_2 of the two masses about their respective static equilibrium positions. Assume small front-to-back rotations θ in the pitch motion and small up-and-down displacements $(1/2)(y_1 + y_2)$ of the centroid in its heave motion.

3.6.4.1 Equation of Heave Motion

From Newton's Second Law for rigid-body motion, we get

$$2m \frac{1}{2}(\ddot{y}_1 + \ddot{y}_2) = -ky_1 - ky_2$$

3.6.4.2 Equation of Pitch Motion

Note that, for small angles of rotation, $\theta = (y_1 - y_2)/l$. The moment of inertia of the system about the centroid is $2m(l/2)^2 = (1/2)ml^2$. Hence, by Newton's Second Law for rigid-body rotation, we have

$$\frac{1}{2}ml^2 \left(\frac{\ddot{y}_1 - \ddot{y}_2}{l} \right) = -\frac{l}{2}ky_1 + \frac{l}{2}ky_2$$

These two equations of motion can be written as

$$\ddot{y}_1 + \ddot{y}_2 + \omega_0^2(y_1 + y_2) = 0$$

$$\ddot{y}_1 - \ddot{y}_2 + \omega_0^2(y_1 - y_2) = 0$$

TABLE 3.3 Some Important Results of Modal Analysis

System	$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t)$
Symmetry	$\mathbf{M}^T = \mathbf{M}$ and $\mathbf{K}^T = \mathbf{K}$
Modal problem	$[\omega^2 \mathbf{M} - \mathbf{K}]\boldsymbol{\psi} = 0$
Characteristic equation (gives natural frequencies)	$\det[\omega^2 \mathbf{M} - \mathbf{K}] = 0$
\mathbf{M} -orthogonality	$\boldsymbol{\psi}_i^T \mathbf{M} \boldsymbol{\psi}_j = \begin{cases} 0 & \text{for } i \neq j \\ M_i & \text{for } i = j \end{cases}$
\mathbf{K} -orthogonality	$\boldsymbol{\psi}_i^T \mathbf{K} \boldsymbol{\psi}_j = \begin{cases} 0 & \text{for } i \neq j \\ K_i & \text{for } i = j \end{cases}$
Modal mass (generalized mass)	M_i
Modal stiffness (generalized stiffness)	K_i
Natural frequency	$\omega_i = \sqrt{K_i/M_i}$
\mathbf{M} -normal case	$M_i = 1, K_i = \omega_i^2$
\mathbf{K} -normal case	$K_i = 1, M_i = 1/\omega_i^2$
Presence of rigid-body modes	$\det \mathbf{K} = 0, K_i = 0$, and $\omega_i = 0$
Presence of static modes	$\det \mathbf{M} = 0, M_i = 0$, and $\omega_i \rightarrow \infty$

in which $\omega_0 = \sqrt{k/m}$. By straightforward algebraic manipulation, a pair of completely uncoupled equations of motion are obtained; thus

$$\ddot{y}_1 + \omega_0^2 y_1 = 0$$

$$\ddot{y}_2 + \omega_0^2 y_2 = 0$$

It follows that the resulting mass matrix and the stiffness matrix are both diagonal. In this case, there is an infinite number of choices for mode shapes, and any two linearly independent second-order vectors can serve as modal vectors for the system. Two particular choices are shown in Figure 3.7. Any of these mode shapes will correspond to the same natural frequency ω_0 .

In each of these two choices, the mode shapes have been chosen so that they are orthogonal with respect to both \mathbf{M} and \mathbf{K} . This fact is verified below. Note that, in the present example

$$\mathbf{M} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad \mathbf{K} = \begin{bmatrix} \omega_0^2 & 0 \\ 0 & \omega_0^2 \end{bmatrix}$$

For Case 1:

$$[1 \quad 1]\mathbf{M} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 0 \quad \text{and} \quad [1 \quad 1]\mathbf{K} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 0$$

For Case 2:

$$[1 \quad 0]\mathbf{M} \begin{bmatrix} 0 \\ 1 \end{bmatrix} = 0 \quad \text{and} \quad [1 \quad 0]\mathbf{K} \begin{bmatrix} 0 \\ 1 \end{bmatrix} = 0$$

In general, since both elements of each eigenvector can be picked arbitrarily, we can write

$$\boldsymbol{\psi}_1 = \begin{bmatrix} 1 \\ a \end{bmatrix} \quad \text{and} \quad \boldsymbol{\psi}_2 = \begin{bmatrix} 1 \\ b \end{bmatrix}$$

where a and b are arbitrary, limited only by the orthogonality requirement for $\boldsymbol{\psi}_1$ and $\boldsymbol{\psi}_2$. The \mathbf{M} -orthogonality requires

$$[1 \quad a] \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ b \end{bmatrix} = 0$$

and \mathbf{K} -orthogonality requires

$$[1 \quad a] \begin{bmatrix} \omega_0^2 & 0 \\ 0 & \omega_0^2 \end{bmatrix} \begin{bmatrix} 1 \\ b \end{bmatrix} = 0$$

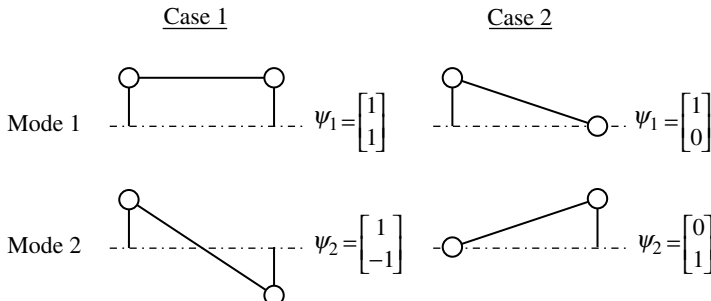

FIGURE 3.7 Two possibilities of mode shapes for the symmetric heave-pitch vehicle.

Both conditions give $1 + ab = 0$, which corresponds to $ab = -1$. Note that Case 1 corresponds to $a = 1$ and $b = -1$ and Case 2 corresponds to $a = 0$ and $b \rightarrow \infty$. More generally, we can pick as modal vectors

$$\psi_1 = \begin{bmatrix} 1 \\ a \end{bmatrix} \quad \text{and} \quad \psi_2 = \begin{bmatrix} 1 \\ -1/a \end{bmatrix}$$

such that the two mode shapes are both **M**-orthogonal and **K**-orthogonal. In fact, if this particular system is excited by an arbitrary initial displacement, it will undergo free vibrations at frequency ω_0 while maintaining the initial displacement ratio. Hence, if **M**-orthogonality and **K**-orthogonality are not required, any arbitrary second-order vector may serve as a modal vector to this system.

Example 3.5

An example for a system possessing a rigid-body mode is shown in Figure 3.8. This system, a crude model of a two-car train, can be derived from the system shown in Figure 3.4 by removing the end spring (inertia restraint) and setting $\alpha = 1$ and $\beta = 1$. The equation for unforced motion of this system is

FIGURE 3.8 A simplified model of a two-car train.

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{bmatrix} \ddot{y}_1 \\ \ddot{y}_2 \end{bmatrix} + \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

Note that $\det \mathbf{M} = m^2 \neq 0$ and hence the system does not possess static modes. This should also be obvious from the fact that each DoF (y_1 and y_2) has an associated, independent mass element. On the other hand, $\det \mathbf{K} = k^2 - k^2 = 0$ which signals the presence of rigid-body modes.

The characteristic equation of the system is

$$\det \begin{bmatrix} \omega^2 m - k & k \\ k & \omega^2 m - k \end{bmatrix} = 0$$

or

$$(\omega^2 m - k)^2 - k^2 = 0$$

The two natural frequencies are given by the roots: $\omega_1 = 0$ and $\omega_2 = \sqrt{2k/m}$. Note that the zero natural frequency corresponds to the rigid body mode. The mode shapes can reveal further interesting facts.

3.6.4.3 First Mode (Rigid-Body Mode)

In this case, we have $\omega = 0$. Consequently, from Equation 3.15, the mode shape is given by

$$\begin{bmatrix} -k & k \\ k & -k \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

which has the general solution $\psi_1 = \psi_2$, or

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} a \\ a \end{bmatrix}$$

The parameter a can be chosen arbitrarily. The corresponding modal mass is

$$M_1 = [a \quad a] \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{bmatrix} a \\ a \end{bmatrix} = 2ma^2$$

If the modal vector is normalized with respect to \mathbf{M} , we have $M_1 = 2ma^2 = 1$. Then, $a = \pm 1/\sqrt{2m}$ and the corresponding normal mode vector would be

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_1 = \begin{bmatrix} \frac{1}{\sqrt{2m}} \\ \frac{1}{\sqrt{2m}} \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} -\frac{1}{\sqrt{2m}} \\ -\frac{1}{\sqrt{2m}} \end{bmatrix}$$

which is arbitrary up to a multiplier of -1 . If the first element of the normal mode is restricted to be positive, the former vector (one with positive elements) should be used.

We have already noted that it is not possible to normalize a rigid-body mode with respect to \mathbf{K} . Specifically, the modal stiffness for the rigid-body mode is

$$K_1 = \begin{bmatrix} a & a \end{bmatrix} \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} a \\ a \end{bmatrix} = 0$$

for any choice for a , as expected.

3.6.4.4 Second Mode

For this mode, $\omega_2 = \sqrt{2k/m}$. By substituting into Equation 3.15 we get

$$\begin{bmatrix} k & k \\ k & k \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

the solution of which gives the corresponding modal vector (mode shape).

The general solution is $\psi_2 = -\psi_1$, or

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} a \\ -a \end{bmatrix}$$

in which a is arbitrary. The corresponding modal mass is given by

$$M_2 = \begin{bmatrix} a & -a \end{bmatrix} \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{bmatrix} a \\ -a \end{bmatrix} = 2ma^2$$

and the modal stiffness is given

$$K_2 = \begin{bmatrix} a & -a \end{bmatrix} \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} a \\ -a \end{bmatrix} = 4ka^2$$

Then, for \mathbf{M} -normality we must have $2ma^2 = 1$ or $a = \pm 1/\sqrt{2m}$.

It follows that the \mathbf{M} -normal mode vector would be

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_1 = \begin{bmatrix} \frac{1}{\sqrt{2m}} \\ -\frac{1}{\sqrt{2m}} \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} -\frac{1}{\sqrt{2m}} \\ \frac{1}{\sqrt{2m}} \end{bmatrix}$$

The corresponding value of the modal stiffness is $K_2 = 2k/m$, which is equal to ω_2^2 , as expected. Similarly, for \mathbf{K} -normality we must have $4Ka^2 = 1$, or $a = \pm 1/\sqrt{4K}$. Hence, the \mathbf{K} -normal modal vector would be

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} \frac{1}{\sqrt{4k}} \\ -\frac{1}{\sqrt{4k}} \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} -\frac{1}{\sqrt{4k}} \\ \frac{1}{\sqrt{4k}} \end{bmatrix}$$

The corresponding value of the modal mass is $M_2 = m/(2k)$ which is equal to $1/\omega_2^2$, as expected.

The mode shapes of the system are shown in Figure 3.9. Note that in the rigid-body mode both masses move in the same direction through the same distance, with the connecting spring maintained in the unstretched configuration. In the second mode, the two masses move in opposite directions with equal amplitudes. This results in a *node point* halfway along the spring. A node is a point in the system that remains stationary under a modal motion. It follows that, in the second mode, the system behaves like an identical pair of simple oscillators, each possessing twice the stiffness of the original spring (see Figure 3.10). The corresponding natural frequency is $\sqrt{2k/m}$, which is equal to ω_2 .

Orthogonality of the two modes may be verified with respect to the mass matrix as

$$\begin{bmatrix} 1 & 1 \end{bmatrix} \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 0$$

and, with respect to the stiffness matrix, as

$$\begin{bmatrix} 1 & 1 \end{bmatrix} \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 0$$

Since \mathbf{K} is singular, due to the presence of the rigid-body mode, the first orthogonality condition (Equation 3.19), and not the second (Equation 3.21), is the useful result for this system. In particular, since \mathbf{M} is nonsingular, the orthogonality of the modal vectors with respect to the mass matrix implies that they are linearly independent vectors by themselves. This is further verified by the nonsingularity of the *modal matrix*; specifically

$$\det[\boldsymbol{\psi}_1, \boldsymbol{\psi}_2] = \det \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \neq 0$$

Since \mathbf{M} is a scalar multiple of the identity matrix, we note that the modal vectors are in fact orthogonal, as is clear from

$$\boldsymbol{\psi}_1^T \boldsymbol{\psi}_2 = \begin{bmatrix} 1 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 0$$

3.6.5 Modal Matrix

An n -DoF system has n modal vectors $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n$, which are independent. The $n \times n$ square matrix $\boldsymbol{\Psi}$ whose columns are the modal vectors is known as the modal matrix

$$\boldsymbol{\Psi} = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n] \quad (3.22)$$

Since the mass matrix \mathbf{M} can always be made nonsingular through proper modeling practices (in choosing the DoF), it can be concluded that the modal matrix is nonsingular

$$\det \boldsymbol{\Psi} \neq 0 \quad (3.23)$$

FIGURE 3.9 Mode shapes of the two-car train example.

FIGURE 3.10 Equivalent system for mode 2 of the two-car train example.

and the inverse Ψ^{-1} exists. Before showing this fact, note that the orthogonality conditions (Equation 3.19 and Equation 3.21) can be written in terms of the modal matrix as

$$\Psi^T \mathbf{M} \Psi = \text{diag}[M_1, M_2, \dots, M_n] = \bar{\mathbf{M}} \quad (3.24)$$

$$\Psi^T \mathbf{K} \Psi = \text{diag}[K_1, K_2, \dots, K_n] = \bar{\mathbf{K}} \quad (3.25)$$

in which $\bar{\mathbf{M}}$ and $\bar{\mathbf{K}}$ are the *diagonal* matrices of modal masses and modal stiffnesses, respectively.

Next, we use the result from linear algebra, which states that the determinant of the product of two square matrices is equal to the product of the determinants. Also, a square matrix and its transpose have the same determinant. Then, by taking the determinant of both sides of Equation 3.24, it follows that

$$\det \Psi^T \mathbf{M} \Psi = (\det \Psi)^2 \det \mathbf{M} = \det \bar{\mathbf{M}} = M_1, M_2, \dots, M_n \quad (3.26)$$

Here, we have also used the fact that in Equation 3.24 the RHS matrix is diagonal. Now, $M_i \neq 0$ for all i since there are no static modes in a well-posed modal problem. It follows that

$$\det \Psi \neq 0 \quad (3.27)$$

which implies that Ψ is nonsingular.

3.6.6 Configuration Space and State Space

All solutions of the displacement response \mathbf{y} span a Euclidean space known as the *configuration space*. This is an n -Euclidean space (L^n). This is also the *displacement space*.

The trace of the displacement vector \mathbf{y} is not a complete representation of the dynamic response of a vibrating system because the same \mathbf{y} can correspond to more than one *dynamic state* of the system. Hence, \mathbf{y} is not a state vector. However,

$$\begin{bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{bmatrix}_{2n}$$

is a state vector, because it includes both displacement and velocity and completely represents the state of the system. This *state vector* spans the *state space* (L^{2n}) which is a $2n$ -Euclidean space.

3.6.6.1 State Vector

This is a vector \mathbf{x} consisting of a minimal set of response variables of a dynamic system such that, with knowledge of the initial state $\mathbf{x}(t_0)$ and the subsequent input $\mathbf{u}[t_0, t_1]$ to the system over a finite time interval $[t_0, t_1]$, the end state $\mathbf{x}(t_1)$ can be *uniquely* determined. Each point in a state space uniquely (and completely) determines the state of the dynamic system under these conditions.

Note: Configuration space can be thought of as a subspace of the state space, which is obtained by projecting the state space into the subspace formed by the axes of the \mathbf{y} vector.

For an n -DoF vibrating system (see Equation 3.1), the displacement response vector \mathbf{y} is of order n . If we know the initial condition $\mathbf{y}(0)$ and the forcing excitation $\mathbf{f}(t)$, it is not possible to completely determine $\mathbf{y}(t)$ in general. However, if we know $\mathbf{y}(0)$ and $\dot{\mathbf{y}}(0)$ as well as $\mathbf{f}(t)$, then it is possible to completely determine $\mathbf{y}(t)$ and $\dot{\mathbf{y}}(t)$. This says what we have noted before; \mathbf{y} alone does not constitute a state vector, but \mathbf{y} and $\dot{\mathbf{y}}$ together do. In this case, the order of the state space is $2n$, which is twice the number of DoF.

3.7 Other Modal Formulations

The modal problem (eigenvalue problem) studied in the previous sections consists of the solution of

$$\omega^2 \mathbf{M} \boldsymbol{\psi} = \mathbf{K} \boldsymbol{\psi} \quad (3.28)$$

which is identical to Equation 3.13. The natural frequencies (eigenvalues) are given by solving the characteristic equation 3.14. The corresponding mode shape vectors (eigenvectors) $\boldsymbol{\psi}_i$ are determined by

substituting each natural frequency ω_i into Equation 3.13 and solving for a nontrivial solution. This solution will have at least one arbitrary parameter. Hence, $\boldsymbol{\psi}$ represents the relative displacements at the various DoF of the vibrating system and not the absolute displacements. Now, two other formulations are given for the modal problem.

The first alternative formulation given below involves the solution of the eigenvalue problem of a nonsymmetric matrix ($\mathbf{M}^{-1}\mathbf{K}$). The other formulation given consists of first transforming the original problem into a new set of motion coordinates, then solving the eigenvalue problem of a symmetric matrix ($\mathbf{M}^{-1/2}\mathbf{K}\mathbf{M}^{-1/2}$), and then transforming the resulting modal vectors back to the original motion coordinates. Of course, all three of these formulations will give the same end result for the natural frequencies and mode shapes of the system, because the physical problem would remain the same regardless of what formulation and solution approach are employed. This fact will be illustrated using an example.

3.7.1 Nonsymmetric Modal Formulation

Consider the original modal formulation given by Equation 3.28 that we have studied. Since the inertia matrix \mathbf{M} is nonsingular, its inverse \mathbf{M}^{-1} exists. The premultiplication of Equation 3.28 by \mathbf{M}^{-1} gives

$$\omega^2 \boldsymbol{\psi} = \mathbf{M}^{-1} \mathbf{K} \boldsymbol{\psi} \quad (3.29)$$

This vector–matrix equation is of the form

$$\lambda \boldsymbol{\psi} = \mathbf{S} \boldsymbol{\psi} \quad (3.30)$$

where $\lambda = \omega^2$ and $\mathbf{S} = \mathbf{M}^{-1}\mathbf{K}$. Equation 3.30 represents the standard matrix eigenvalue problem for matrix \mathbf{S} . It follows that

Squared natural frequencies = eigenvalues of $\mathbf{M}^{-1}\mathbf{K}$

Mode shape vectors = eigenvectors of $\mathbf{M}^{-1}\mathbf{K}$

3.7.2 Transformed Symmetric Modal Formulation

Now consider the free (unforced) system equations

$$\mathbf{M} \ddot{\mathbf{y}} + \mathbf{K} \mathbf{y} = \mathbf{0} \quad (3.31)$$

whose modal problem needs to be solved. First, we define the square root of matrix \mathbf{M} , as denoted by $\mathbf{M}^{1/2}$, such that

$$\mathbf{M}^{1/2} \mathbf{M}^{1/2} = \mathbf{M} \quad (3.32)$$

Since \mathbf{M} is symmetric, $\mathbf{M}^{1/2}$ also has to be symmetric. Next, we define $\mathbf{M}^{-1/2}$ as the inverse of $\mathbf{M}^{1/2}$. Specifically,

$$\mathbf{M}^{-1/2} \mathbf{M}^{1/2} = \mathbf{M}^{1/2} \mathbf{M}^{-1/2} = \mathbf{I} \quad (3.33)$$

where \mathbf{I} is the identity matrix. Note that $\mathbf{M}^{-1/2}$ is also symmetric.

Once $\mathbf{M}^{-1/2}$ is defined in this manner, we transform the original problem 3.31 using the coordinate transformation

$$\mathbf{y} = \mathbf{M}^{-1/2} \mathbf{q} \quad (3.34)$$

Here, \mathbf{q} denotes the transformed displacement vector, which is related to the actual displacement vector \mathbf{y} through the matrix transformation using $\mathbf{M}^{-1/2}$.

By differentiating Equation 3.34 twice, we get

$$\ddot{\mathbf{y}} = \mathbf{M}^{-1/2} \ddot{\mathbf{q}} \quad (3.35)$$

Substitute Equation 3.34 and Equation 3.35 into Equation 3.31. This gives

$$\mathbf{M}\mathbf{M}^{-1/2} \ddot{\mathbf{q}} + \mathbf{K}\mathbf{M}^{-1/2} \mathbf{q} = 0$$

Premultiply this result by $\mathbf{M}^{-1/2}$ and use the fact that

$$\mathbf{M}^{-1/2} \mathbf{M} \mathbf{M}^{-1/2} = \mathbf{M}^{-1/2} \mathbf{M}^{1/2} \mathbf{M}^{1/2} \mathbf{M}^{-1/2} = \mathbf{I}$$

which follows from Equation 3.32 and Equation 3.33. We get

$$\ddot{\mathbf{q}} + \mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2} \mathbf{q} = 0 \quad (3.36)$$

Equation 3.36 is the transformed problem, whose modal response may be given by

$$\mathbf{q} = e^{j\omega t} \phi \quad (3.37)$$

where ω represents a natural frequency and ϕ represents the corresponding modal vector, as usual. Then, in view of Equation 3.34, we have

$$\mathbf{y} = e^{j\omega t} \mathbf{M}^{-1/2} \phi = e^{j\omega t} \boldsymbol{\psi} \quad (3.38)$$

It follows that the natural frequencies of the original problem 3.31 are identical to the natural frequencies of the transformed problem 3.36, and the modal vectors $\boldsymbol{\psi}$ of the original problem are related to the modal vectors ϕ of the transformed problem through

$$\boldsymbol{\psi} = \mathbf{M}^{-1/2} \phi \quad (3.39)$$

Substitute the modal response 3.37 into Equation 3.36. We get

$$\lambda \phi = \mathbf{P} \phi \quad (3.40)$$

where $\lambda = \omega^2$ and $\mathbf{P} = \mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2}$.

Equation 3.40, just like Equation 3.30, represents a standard matrix eigenvalue problem. But now matrix \mathbf{P} is symmetric. As a result, its eigenvectors ϕ will not only be real but also orthogonal.

The solution steps for the present, transformed, and symmetric modal problem are:

1. Determine $\mathbf{M}^{-1/2}$.
2. Solve for eigenvalues λ and eigenvectors ϕ of $\mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2}$. Eigenvalues are squares of the natural frequencies of the original system.
3. Determine the modal vectors $\boldsymbol{\psi}$ of the original system by using $\boldsymbol{\psi} = \mathbf{M}^{-1/2} \phi$.

The three approaches of modal analysis which we have studied are summarized in Table 3.4.

TABLE 3.4 Three Approaches of Modal Analysis

Approach	Standard	Nonsymmetric Matrix Eigenvalue	Symmetric Matrix Eigenvalue
Modal formulation	$[\omega^2 \mathbf{M} - \mathbf{K}] \boldsymbol{\psi} = 0$	$\omega^2 \boldsymbol{\psi} = \mathbf{M}^{-1} \mathbf{K} \boldsymbol{\psi}$	$\omega^2 \phi = \mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2} \phi$
Squared natural frequencies (ω_i^2)	Roots of $\det[\omega^2 \mathbf{M} - \mathbf{K}] = 0$	Eigenvalues of $\mathbf{M}^{-1} \mathbf{K}$	Eigenvalues of $\mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2}$
Mode-shape vectors ($\boldsymbol{\psi}_i$)	Nontrivial solutions of $[\omega_i^2 \mathbf{M} - \mathbf{K}] \boldsymbol{\psi} = 0$	Eigenvectors of $\mathbf{M}^{-1} \mathbf{K}$	Determine eigenvectors ϕ_i of $\mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2}$. Then $\boldsymbol{\psi}_i = \mathbf{M}^{-1/2} \phi_i$

Example 3.6

We will use the 2-DoF vibration problem given in [Figure 3.4](#) (Example 3.3) to demonstrate the fact that all three approaches summarized in [Table 3.4](#) will lead to the same results.

Consider the special case of $\alpha = 0.5$ and $\beta = 0.5$. Then we have

$$\mathbf{M} = \begin{bmatrix} m & 0 \\ 0 & \frac{m}{2} \end{bmatrix} \quad \text{and} \quad \mathbf{K} = \begin{bmatrix} \frac{3}{2}k & -\frac{k}{2} \\ -\frac{k}{2} & \frac{k}{2} \end{bmatrix}$$

Approach 1

Using the standard approach, we obtain the modal results given in [Table 3.3](#). Specifically, we get the natural frequencies (normalized with respect to $\omega_0 = \sqrt{k/m}$)

$$\frac{\omega_1}{\omega_0} = \frac{1}{\sqrt{2}} \quad \text{and} \quad \frac{\omega_2}{\omega_0} = \sqrt{2}$$

and the mode shapes

$$\left(\frac{\psi_2}{\psi_1} \right)_1 = 2 \quad \text{and} \quad \left(\frac{\psi_2}{\psi_1} \right)_2 = -1$$

Let us now obtain these results using the other two approaches of modal analysis.

Approach 2

$$\mathbf{M}^{-1} = \begin{bmatrix} \frac{1}{m} & 0 \\ 0 & \frac{2}{m} \end{bmatrix},$$

$$\mathbf{M}^{-1}\mathbf{K} = \begin{bmatrix} \frac{1}{m} & 0 \\ 0 & \frac{2}{m} \end{bmatrix} \begin{bmatrix} \frac{3}{2}k & -\frac{k}{2} \\ -\frac{k}{2} & \frac{k}{2} \end{bmatrix} = \begin{bmatrix} \frac{3}{2}\frac{k}{m} & -\frac{1}{2}\frac{k}{m} \\ -\frac{k}{m} & \frac{k}{m} \end{bmatrix} = \omega_0^2 \begin{bmatrix} \frac{3}{2} & -\frac{1}{2} \\ -1 & 1 \end{bmatrix}$$

Note that this is not a symmetric matrix. We solve the eigenvalue problem of

$$\begin{bmatrix} \frac{3}{2} & -\frac{1}{2} \\ -1 & 1 \end{bmatrix}$$

Eigenvalues λ are given by

$$\det \begin{bmatrix} \lambda - \frac{3}{2} & \frac{1}{2} \\ 1 & \lambda - 1 \end{bmatrix} = 0$$

or

$$\left(\lambda - \frac{3}{2} \right) (\lambda - 1) - \frac{1}{2} = 0$$

or

$$\lambda^2 - \frac{5}{2}\lambda + 1 = 0$$

the roots of which are

$$\lambda_1, \lambda_2 = \frac{1}{2}, 2$$

It follows that $\omega_1/\omega_0 = 1/\sqrt{2}$ and $\omega_2/\omega_0 = \sqrt{2}$ as before.

The eigenvector corresponding to λ_1 (mode 1) is given by

$$\begin{bmatrix} \frac{1}{2} & -\frac{3}{2} & \frac{1}{2} \\ 1 & \frac{1}{2} & -1 \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_1 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

The solution is $(\psi_2/\psi_1)_1 = 2$ as before.

The eigenvector corresponding to λ_2 (mode 2) is given by

$$\begin{bmatrix} 2 & -\frac{3}{2} & \frac{1}{2} \\ 1 & 2 & -1 \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

The solution is $(\psi_2/\psi_1)_2 = -1$ as before.

Approach 3

Since \mathbf{M} is diagonal, it is easy to obtain $\mathbf{M}^{1/2}$. We simply take the square root of the diagonal elements; thus,

$$\mathbf{M}^{1/2} = \begin{bmatrix} \sqrt{m} & 0 \\ 0 & \sqrt{\frac{m}{2}} \end{bmatrix}$$

Its inverse is given by inverting the diagonal elements; thus

$$\mathbf{M}^{-1/2} = \begin{bmatrix} \frac{1}{\sqrt{m}} & 0 \\ 0 & \sqrt{\frac{2}{m}} \end{bmatrix}$$

Now,

$$\begin{aligned} \mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2} &= \begin{bmatrix} \frac{1}{\sqrt{m}} & 0 \\ 0 & \sqrt{\frac{2}{m}} \end{bmatrix} \begin{bmatrix} \frac{3}{2}k & -\frac{k}{2} \\ -\frac{k}{2} & \frac{k}{2} \end{bmatrix} \begin{bmatrix} \frac{1}{\sqrt{m}} & 0 \\ 0 & \sqrt{\frac{2}{m}} \end{bmatrix} = \begin{bmatrix} \frac{3}{2} \frac{k}{m} & -\frac{1}{\sqrt{2}} \frac{k}{m} \\ -\frac{1}{\sqrt{2}} \frac{k}{m} & \frac{k}{m} \end{bmatrix} \\ &= \omega_0^2 \begin{bmatrix} \frac{3}{2} & -\frac{1}{\sqrt{2}} \\ -\frac{1}{\sqrt{2}} & 1 \end{bmatrix} \end{aligned}$$

Note that, as expected, this is a symmetric matrix. We solve for eigenvalues and eigenvectors of

$$\begin{bmatrix} \frac{3}{2} & -\frac{1}{\sqrt{2}} \\ -\frac{1}{\sqrt{2}} & 1 \end{bmatrix}$$

Eigenvalues are given by

$$\det \begin{bmatrix} \lambda - \frac{3}{2} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & \lambda - 1 \end{bmatrix} = 0$$

or

$$\left(\lambda - \frac{3}{2}\right)(\lambda - 1) - \frac{1}{2} = 0$$

or

$$\lambda^2 - \frac{5}{2}\lambda + 1 = 0$$

which is identical to the characteristic equation obtained in the first two approaches. It follows that the same two natural frequencies are obtained by this method. The eigenvector ϕ_1 for mode 1 is given by

$$\begin{bmatrix} \frac{1}{2} - \frac{3}{2} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & \frac{1}{2} - 1 \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \end{bmatrix}_1 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

which gives $(\phi_2/\phi_1)_1 = [\sqrt{2}]$.

Accordingly, we may use

$$\begin{bmatrix} \phi_1 \\ \phi_2 \end{bmatrix}_1 = \begin{bmatrix} 1 \\ \sqrt{2} \end{bmatrix}$$

The eigenvector ϕ_2 for mode 2 is given by

$$\begin{bmatrix} 2 - \frac{3}{2} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & 2 - 1 \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \end{bmatrix}_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

which gives $(\phi_2/\phi_1)_2 = -1/\sqrt{2}$.

Accordingly, we use

$$\begin{bmatrix} \phi_1 \\ \phi_2 \end{bmatrix}_2 = \begin{bmatrix} 1 \\ -\frac{1}{\sqrt{2}} \end{bmatrix}$$

Now, we transform these eigenvectors back to the original coordinate system using Equation 3.39. We get

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_1 = \begin{bmatrix} \frac{1}{\sqrt{m}} & 0 \\ 0 & \sqrt{\frac{2}{m}} \end{bmatrix} \begin{bmatrix} 1 \\ \sqrt{2} \end{bmatrix} = \begin{bmatrix} \frac{1}{\sqrt{m}} \\ \frac{2}{\sqrt{m}} \end{bmatrix}$$

which gives $(\psi_2/\psi_1)_1 = 2$ as before.

Also,

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} \frac{1}{\sqrt{m}} & 0 \\ 0 & \sqrt{\frac{2}{m}} \end{bmatrix} \begin{bmatrix} 1 \\ -\frac{1}{\sqrt{2}} \end{bmatrix} = \begin{bmatrix} \frac{1}{\sqrt{m}} \\ -\frac{1}{\sqrt{m}} \end{bmatrix}$$

which gives $(\psi_2/\psi_1)_2 = -1$ as before.

3.8 Forced Vibration

The forced motion of a linear, n -DoF, undamped system is given by the nonhomogeneous equation of motion 3.1:

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) \quad (3.41)$$

Even though the following discussion is based on this undamped model, the results can be easily extended to the damped case.

We have observed that the modal vectors form a basis for the *configuration space*. In other words, it is possible to express the response \mathbf{y} as a linear combination of the modal vectors $\boldsymbol{\psi}_i$:

$$\mathbf{y} = q_1\boldsymbol{\psi}_1 + q_2\boldsymbol{\psi}_2 + \cdots + q_n\boldsymbol{\psi}_n \quad (3.42)$$

The parameters q_i are a set of *generalized coordinates* and are functions of time t . Equation 3.42 is written in the vector–matrix form

$$\mathbf{y} = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n] \begin{bmatrix} q_1 \\ q_2 \\ \vdots \\ q_n \end{bmatrix}$$

or

$$\mathbf{y} = \boldsymbol{\Psi}\mathbf{q} \quad (3.43)$$

and can be viewed as a coordinate transformation from the trajectory space to the *canonical space* of generalized coordinates (principal coordinates or natural coordinates). Note that the inverse transformation exists because the modal matrix $\boldsymbol{\Psi}$ is nonsingular. On substituting Equation 3.43 into Equation 3.41, we obtain

$$\mathbf{M}\boldsymbol{\Psi}\ddot{\mathbf{q}} + \mathbf{K}\boldsymbol{\Psi}\mathbf{q} = \mathbf{f}(t)$$

This result is premultiplied by $\boldsymbol{\Psi}^T$ and the orthogonality conditions (Equation 3.24 and Equation 3.25) are substituted to obtain the canonical form of the system equation:

$$\bar{\mathbf{M}}\ddot{\mathbf{q}} + \bar{\mathbf{K}}\mathbf{q} = \bar{\mathbf{f}}(t) \quad (3.44)$$

in which $\bar{\mathbf{M}}$ and $\bar{\mathbf{K}}$ are the diagonal matrices given by Equation 3.24 and Equation 3.25, and the transformed forcing vector is given by

$$\bar{\mathbf{f}}(t) = \boldsymbol{\Psi}^T \mathbf{f}(t) \quad (3.45)$$

Since $\bar{\mathbf{M}}$ and $\bar{\mathbf{K}}$ are diagonal matrices, Equation 3.44 corresponds to the set of n uncoupled *simple oscillator* equations:

$$M_i \ddot{q}_i + K_i q_i = \bar{f}_i(t) \quad \text{for } i = 1, 2, \dots, n \quad (3.46)$$

In other words, the coordinate transformation 3.43 using the modal matrix has uncoupled the equations of forced motion. It follows from Equation 3.46 that the natural frequencies of the system are given by

$$\omega_i^2 = K_i/M_i \quad \text{for } i = 1, 2, \dots, n \quad (3.47)$$

as we have noted before.

It is particularly convenient to employ \mathbf{M} -normal modal vectors. In this case, $\bar{\mathbf{M}}$ becomes the n th order identity matrix, and $\bar{\mathbf{K}}$ the diagonal matrix having ω_i^2 as its diagonal elements; thus

$$\bar{\mathbf{M}} = \mathbf{I} \quad (3.48)$$

$$\bar{\mathbf{K}} = \text{diag}[\omega_1^2, \omega_2^2, \dots, \omega_n^2] \quad (3.49)$$

The corresponding uncoupled equations 3.46 take the form

$$\ddot{q}_i + \omega_i^2 q_i = \bar{f}_i(t) \quad \text{for } i = 1, 2, \dots, n \quad (3.50)$$

in which the forcing terms $\bar{f}_i(t)$ are given by Equation 3.45, Ψ being \mathbf{M} -normal.

Typically, the initial conditions for the original system are provided as the initial position $\mathbf{y}(0)$ and the initial velocity $\dot{\mathbf{y}}(0)$. The corresponding initial conditions for the transformed equations of motion are obtained using Equation 3.43 as

$$\mathbf{q}(0) = \Psi^{-1} \mathbf{y}(0) \quad (3.51)$$

$$\dot{\mathbf{q}}(0) = \Psi^{-1} \dot{\mathbf{y}}(0) \quad (3.52)$$

The complete response of the original system can be conveniently obtained by first solving the simple oscillator equation 3.50 and then transforming the results back into the trajectory space using Equation 3.43.

The complete solution to this linear system can be viewed as the sum of the initial condition response in the absence of the forcing function and the forced response with zero initial conditions, as discussed in [Chapter 2](#). For the simple oscillator equation 3.50, the initial condition response q_{iI} is given by

$$q_{iI} = q_i(0) \cos \omega_i t + \frac{\dot{q}_i(0)}{\omega_i} \sin \omega_i t \quad (3.53)$$

The impulse response function (i.e., response to a unit impulse excitation) for the undamped oscillator equation is

$$h_i(t) = \frac{1}{\omega_i} \sin \omega_i t \quad \text{for } t \geq 0 \quad (3.54)$$

The forced response q_{iF} , with zero initial conditions, is obtained using the *convolution integral* method; specifically

$$q_{iF} = \int_0^t \bar{f}_i(\tau) h_i(t - \tau) d\tau \quad (3.55)$$

The complete solution in the canonical domain is

$$q_i = q_{iI} + q_{iF} = q_i(0) \cos \omega_i t + \frac{\dot{q}_i(0)}{\omega_i} \sin \omega_i t + \frac{1}{\omega_i} \int_0^t \bar{f}_i(\tau) \sin \omega_i(t - \tau) d\tau \quad i = 1, 2, \dots, n \quad (3.56)$$

Each of the n responses is a modal response that is the contribution from that mode to the actual response \mathbf{y} . This approach is summarized in Box 3.4. Next, we will illustrate this approach of solving for the forced vibration by means of an example.

Box 3.4

MODAL APPROACH TO FORCED RESPONSE

Forced system: $\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t)$

Number of DoFs = n

Modal transformation: $\mathbf{y} = \mathbf{\Psi}\mathbf{q}$

where modal matrix $\mathbf{\Psi} = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n]$ = matrix of mode shape vectors.

We obtain the diagonalized system

$$\bar{\mathbf{M}}\ddot{\mathbf{q}} + \bar{\mathbf{K}}\mathbf{q} = \bar{\mathbf{f}}(t)$$

or

$$M_i\ddot{q}_i + K_i q_i = f_i(t); \quad i = 1, 2, \dots, n$$

where

$$\bar{\mathbf{M}} = \mathbf{\Psi}^T \mathbf{M} \mathbf{\Psi} = \text{diag}[M_1, M_2, \dots, M_n]$$

$$\bar{\mathbf{K}} = \mathbf{\Psi}^T \mathbf{K} \mathbf{\Psi} = \text{diag}[K_1, K_2, \dots, K_n]$$

$$\bar{\mathbf{f}}(t) = \mathbf{\Psi}^T \mathbf{f}(t) = [\bar{f}_1, \bar{f}_2, \dots, \bar{f}_n]^T$$

Initial conditions:

$$\mathbf{q}(0) = \mathbf{\Psi}^{-1} \mathbf{y}(0)$$

$$\dot{\mathbf{q}}(0) = \mathbf{\Psi}^{-1} \dot{\mathbf{y}}(0)$$

Steps: Use \mathbf{M} -normal case: $M_i = 1$, $K_i = \omega_i^2$

Then,

$$\ddot{q}_i + \omega_i^2 q_i = \bar{f}_i(t); \quad i = 1, 2, \dots, n$$

1. Free, initial-condition response (zero-input response)

$$q_{iF} = q_i(0) \cos \omega_i t + \frac{\dot{q}_i(0)}{\omega_i} \sin \omega_i t$$

2. Forced, zero initial-condition response

$$q_{iF} = \frac{1}{\omega_i} \int_0^t \bar{f}_i(\tau) \sin \omega_i(t - \tau) d\tau$$

3. $q_i = q_{iF} + q_{iF}$

4. Transform back to \mathbf{y} using $\mathbf{y} = \mathbf{\Psi}\mathbf{q}$

Example 3.7

Let us consider again the system shown in Figure 3.8. A step-input force $f(t)$ given by

$$f(t) = \begin{cases} f_0 & \text{for } t \geq 0 \\ 0 & \text{for } t < 0 \end{cases}$$

is applied to the left-hand mass (DoF y_1). Assume that the system starts from rest ($\mathbf{y}(0) = 0$ and $\dot{\mathbf{y}}(0) = 0$).

As before, the \mathbf{M} -normal modal matrix of the system is

$$\mathbf{\Psi} = \begin{bmatrix} \frac{1}{\sqrt{2m}} & \frac{1}{\sqrt{2m}} \\ \frac{1}{\sqrt{2m}} & -\frac{1}{\sqrt{2m}} \end{bmatrix} = \frac{1}{\sqrt{2m}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

No forcing input is applied to the second DoF (y_2). Hence, the overall forcing input vector is

$$\mathbf{f}(t) = \begin{bmatrix} f_0 \\ 0 \end{bmatrix} \quad \text{for } t \geq 0$$

From Equation 3.45, the transformed forcing input vector is obtained as

$$\tilde{\mathbf{f}}(t) = \mathbf{\Psi}^T \mathbf{f}(t) = \frac{1}{\sqrt{2m}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} f_0 \\ 0 \end{bmatrix} = \frac{f_0}{\sqrt{2m}} \begin{bmatrix} 1 \\ 1 \end{bmatrix} \quad \text{for } t \geq 0$$

From Equation 3.51 and Equation 3.52, the initial conditions for the modal (canonical) variables are obtained as $\dot{\mathbf{q}}(0) = 0$ and $\mathbf{q}(0) = 0$. The modal responses $q_1(t)$ and $q_2(t)$ are obtained using Equation 3.56.

3.8.1 First Mode (Rigid-Body Mode)

Note that

$$\lim_{\omega_i \rightarrow 0} \frac{\sin \omega_i(t - \tau)}{\omega_i} = t - \tau$$

It follows that

$$q_1(t) = \int_0^t \frac{f_0(t - \tau)}{\sqrt{2m}} d\tau = \frac{f_0 t^2}{2\sqrt{2m}}$$

3.8.2 Second Mode (Oscillatory Mode)

$$q_2(t) = \frac{1}{\omega_2} \int_0^t \frac{f_0}{\sqrt{2m}} \sin \omega_2(t - \tau) d\tau = \frac{f_0}{\omega_2^2 \sqrt{2m}} (1 - \cos \omega_2 t)$$

The overall response in the physical trajectory space is obtained by transforming the modal responses using Equation 3.43; thus

$$\mathbf{y} = \frac{1}{\sqrt{2m}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} \frac{f_0 t^2}{2\sqrt{2m}} \\ \frac{f_0 (1 - \cos \omega_2 t)}{\omega_2^2 \sqrt{2m}} \end{bmatrix} = \frac{f_0}{2m} \begin{bmatrix} \frac{t^2}{2} + \frac{1}{\omega_2^2} (1 - \cos \omega_2 t) \\ \frac{t^2}{2} - \frac{1}{\omega_2^2} (1 - \cos \omega_2 t) \end{bmatrix}$$

FIGURE 3.11 Forced response obtained through modal analysis.

with $\omega_2^2 = 2k/m$. The response of both masses grows (unstable) quadratically in an oscillatory manner, as shown in Figure 3.11.

3.9 Damped Systems

Let us examine the possibility of extending the modal analysis results to damped systems. Damping is an energy dissipation phenomenon. In lumped-parameter models of vibrating systems, damping force can be represented by a resisting force at each lumped mass. In view of Equation 3.1, then, the system equations for a damped system can be written as

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) - \mathbf{d} \quad (3.57)$$

in which \mathbf{d} is the damping force vector. Modeling of damping is usually quite complicated. Often, a linear model, whose energy dissipation capacity is equivalent to that of the actual system, is employed. Such a model is termed as an *equivalent damping* model. The most popular model for damping is the *linear viscous model*, in which the damping force is proportional to the relative velocity. In lumped-parameter dynamic models, (linear) viscous damping elements may be assigned across pairs of DoF or across a DoF and a fixed reference. The damping force for such a model may be expressed as

$$\mathbf{d} = \mathbf{C}\dot{\mathbf{y}} \quad (3.58)$$

in which \mathbf{C} is the *damping matrix*. The resulting damped system equation is

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) \quad (3.59)$$

To determine the elements of \mathbf{C} for a given system model by the influence coefficient approach, the same procedure outlined previously for obtaining the elements of \mathbf{K} may be used, except that the velocities \dot{y}_i should be used in place of the displacements y_i . The coefficients c_{ij} are termed as *damping influence coefficients*.

3.9.1 Proportional Damping

Because the modal vectors are orthogonal with respect to both \mathbf{M} and \mathbf{K} , the transformation 3.43 will decouple the undamped system equation 3.41. It should be clear, however, that the same transformation will not diagonalize the \mathbf{C} matrix in general. As we have observed in the previous section, decoupling or *modal decomposition*, is a convenient tool in response analysis. This is because each uncoupled modal equation is a simple oscillator equation with a well-known solution that can be transformed back (or, recombined) to obtain the total response. This simple procedure cannot be used for damped systems unless the modal vectors are orthogonal with respect to \mathbf{C} as well.

In modal vibration, all DoF move in the same displacement proportion, as given by the modal vector. This type of synchronous motion may not be possible in damped systems. Another way to state this is that most damped systems do not possess real modes. If we try to excite such a damped system at one of its natural frequencies, we will notice that the constant proportion, given by the modal vector (for the undamped system), is violated during motion. Furthermore, if the undamped system has a (fixed) node point in the particular mode, that point would not remain fixed but would move in a cyclic manner when set to vibrate at the natural frequency of the mode.

Note that viscous damping is just a model for energy dissipation. If we become rather restrictive in choosing the parameters of viscous damping, we will be able to develop an equivalent damping matrix, with respect to which, the modal vectors of the undamped system would be orthogonal. In other words, we require that the transformed damping matrix $\bar{\mathbf{C}}$ be a diagonal matrix; thus

$$\Psi^T \mathbf{C} \Psi = \text{diag}[C_1, C_2, \dots, C_n] = \bar{\mathbf{C}} \quad (3.60)$$

In this case, the corresponding viscous damping model is termed *proportional damping* or *Rayleigh damping* (after the person who first identified this simplification).

Modal decomposition of Equation 3.59, assuming proportional damping using the transformation 3.43, results in the canonical form (uncoupled modal equation)

$$\bar{\mathbf{M}}\ddot{\mathbf{q}} + \bar{\mathbf{C}}\dot{\mathbf{q}} + \bar{\mathbf{K}}\mathbf{q} = \bar{\mathbf{f}}(t) \quad (3.61)$$

or

$$M_i \ddot{q}_i + C_i \dot{q}_i + K_i q_i = \bar{f}_i(t) \quad \text{for } i = 1, 2, \dots, n$$

Equation 3.61 can be written in the standard form for a damped simple oscillator:

$$\ddot{q}_i + 2\zeta_i \omega_i \dot{q}_i + \omega_i^2 q_i = \bar{f}_i(t) \quad \text{for } i = 1, 2, \dots, n \quad (3.62)$$

in which, the modal matrix is assumed \mathbf{M} -normal (i.e., $M_i = 1$). It can be concluded that a proportionally damped system possesses real modal vectors that are identical to the modal vectors of its undamped counterpart. The damped natural frequency, however, is smaller than the undamped natural frequency and is given by

$$\omega_{di} = \sqrt{1 - \zeta_i^2} \omega_i \quad (3.63)$$

One way to guarantee proportional damping is to pick a damping matrix that satisfies

$$\mathbf{C} = c_m \mathbf{M} + c_k \mathbf{K} \quad (3.64)$$

From modal transformation (see Equation 3.61), it follows that Equation 3.64 corresponds to

$$\text{Modal damping constant } C_i = c_m M_i + c_k K_i$$

or

$$2\zeta_i \omega_i = c_m + c_k \omega_i^2$$

or

$$\text{Modal damping ratio } \zeta_i = \frac{1}{2} \left(\frac{c_m}{\omega_i} + c_k \omega_i \right) \quad (3.64a)$$

Equation 3.64, however, is not the only way to achieve real modes in a damped system (Equation 3.60). The first term on the right-hand side (RHS) of Equation 3.64 is termed the *inertial damping matrix*. The corresponding damping force on each lumped mass in the model will be proportional to the momentum. This term may represent the energy loss associated with a momentum and is termed *momentum damping*. Physically, this is incorporated by assigning a viscous damper between each DoF and its fixed reference, with the damping constant proportional to the mass concentrated at that location.

The second term in Equation 3.64 is termed the *stiffness damping matrix*. The corresponding damping force is proportional to the rate of change of the local deformation forces (stresses) in flexible structural members and joints. It may be interpreted as a simplified model for *structural damping*. Physically, this model is realized by assigning a viscous damper across every spring element in the model, with the damping constant proportional to the stiffness. It is known that rate of change of stresses or rate of change of strains will give rise to *viscoelastic damping*, which is associated with plasticity and viscoelasticity. This type of damping is known as *strain-rate damping*.

Usually, structural damping is most appropriately modeled as being present across (lumped) stiffness elements. Coulomb damping is modeled as acting between an inertia element and its fixed reference point. These intuitive observations also support the damping model given by Equation 3.64. Some terminology and properties of damped systems are summarized in Box 3.5.

Example 3.8

Let us examine the lumped-parameter damped model shown in Figure 3.12 to determine whether it has real modes.

Note that if we modify the model as in Figure 3.13, the damping matrix will become proportional to the stiffness matrix. This will be a case of proportional damping and the modified (damping) system will possess real modes with modal vectors that are identical to those for the corresponding undamped system. It should be verified that the equations of motion for this modified system (Figure 3.13) are

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} 2c & -c \\ -c & 2c \end{bmatrix} \dot{\mathbf{y}} + \begin{bmatrix} 2k & -k \\ -k & 2k \end{bmatrix} \mathbf{y} = \begin{bmatrix} 0 \\ f(t) \end{bmatrix}$$

Notice the similarity between the stiffness matrix and the damping matrix.

Another damped system that possesses classical modes is shown in Figure 3.14. In this model, the damping matrix is proportional to the mass (inertia) matrix. It may be easily verified that the system equations are

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} c & 0 \\ 0 & c \end{bmatrix} \dot{\mathbf{y}} + \begin{bmatrix} 2k & -k \\ -k & 2k \end{bmatrix} \mathbf{y} = \begin{bmatrix} 0 \\ f(t) \end{bmatrix}$$

Here, notice the similarity between the inertia matrix and the damping matrix.

Returning to the original system shown in Figure 3.12, the equations of motion can be written as

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \dot{\mathbf{y}} + \begin{bmatrix} 2k & -k \\ -k & 2k \end{bmatrix} \mathbf{y} = \begin{bmatrix} 0 \\ f(t) \end{bmatrix}$$

From these equations, it is not obvious whether this system possesses real modes. The undamped natural frequencies are given by the roots of the characteristic equation

$$\det \begin{bmatrix} \omega^2 m - 2k & k \\ k & \omega^2 m - 2k \end{bmatrix} = 0$$

Box 3.5

TERMINOLOGY AND PROPERTIES OF DAMPED SYSTEMS

Characteristic equation:

$$\det[\mathbf{M}s^2 + \mathbf{C}s + \mathbf{K}] = 0$$

Roots s are the eigenvalues λ_i

$\text{Im}(\lambda_i) = \omega_{di} =$ damped natural frequencies

$|\lambda_i| = \omega_i =$ undamped natural frequencies

$-\text{Re}(\lambda_i)/\omega_i = \zeta_i =$ modal damping ratios

$\sqrt{1 - 2\zeta_i^2}\omega_i = \omega_{ri} =$ resonant frequencies

$$\sqrt{1 - \zeta_i^2}\omega_i = \omega_{di}$$

Existence of real modes:

- Condition for existence of modes that are identical to undamped modes

$$\mathbf{\Psi}^T \mathbf{C} \mathbf{\Psi} = \text{diagonal matrix}$$

where

$\mathbf{\Psi} =$ modal matrix of undamped modes

- Another (equivalent) condition

$$\mathbf{M}^{-1} \mathbf{C} \mathbf{M}^{-1} \mathbf{K} = \mathbf{M}^{-1} \mathbf{K} \mathbf{M}^{-1} \mathbf{C} \quad (\text{Prove})$$

i.e., $\mathbf{M}^{-1} \mathbf{C}$ and $\mathbf{M}^{-1} \mathbf{K}$ must commute

- Special case:

Proportional damping $\mathbf{C} = c_m \mathbf{M} + c_k \mathbf{K}$

\Rightarrow Modal damping constant $C_i = c_m M_i + c_k K_i$

Modal damping ratio $\zeta_i = \frac{1}{2} \left(\frac{c_m}{\omega_i} + c_k \omega_i \right)$

The natural frequencies are $\omega_1 = \sqrt{k/m}$ and $\omega_2 = \sqrt{3k/m}$. The corresponding mode shapes are given by the nontrivial solution of

$$\begin{bmatrix} \omega_i^2 m - 2k & k \\ k & \omega_i^2 m - 2k \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_i = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad \text{for } i = 1, 2$$

Also, let us normalize the modal vectors by choosing the first element of each vector to be unity. Then, by following the usual procedure of modal analysis, we will obtain the normalized modal vectors

$$\mathbf{\psi}_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \quad \text{and} \quad \mathbf{\psi}_2 = \begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

The modal matrix is

$$\Psi = [\psi_1, \psi_2] = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

Consequently, we obtain

$$\Psi^T \mathbf{M} \Psi = \bar{\mathbf{M}} = \begin{bmatrix} 2m & 0 \\ 0 & 2m \end{bmatrix}$$

$$\Psi^T \mathbf{K} \Psi = \bar{\mathbf{K}} = \begin{bmatrix} 2k & 0 \\ 0 & 6k \end{bmatrix}$$

$$\Psi^T \mathbf{C} \Psi = \bar{\mathbf{C}} = \begin{bmatrix} c_1 & c_1 \\ c_1 & c_1 + 4c_2 \end{bmatrix}$$

and

$$\Psi^T \mathbf{f}(t) = \bar{\mathbf{f}}(t) = \begin{bmatrix} f(t) \\ -f(t) \end{bmatrix}$$

Notice that the transformed damping matrix $\bar{\mathbf{C}}$ is not diagonal in general and, consequently, real modes will not exist. This is to be expected without the condition of proportional damping. Proportional damping is realized in this model if $c_1 = 0$. Then, $\bar{\mathbf{C}}$ will be diagonal and the transformed systems equations will be uncoupled. The uncoupled model equations are

$$2m\ddot{q}_1 + 2kq_1 = f(t)$$

$$2m\ddot{q}_2 + 4c_2\dot{q}_2 + 6kq_2 = -f(t)$$

The first mode is always undamped for this choice of damping model. This confirms that, in the case of proportional damping, it is not generally possible to pick an arbitrary structure for the damping matrix. For this reason, proportional damping is sometimes an analytical convenience rather than a strict physical reality.

Modal analysis and response analysis of a system with general viscous damping can also be accomplished using the *state-space* concepts. In this case, modal analysis is carried out in terms of the eigenvalues and eigenvectors of the *system matrix* of a suitable *state-variable* model. These “eigen results,” if complex, will occur in complex conjugate pairs and then the modes are said to be *complex*. This approach is outlined next.

3.10 State-Space Approach

The state-space approach to modal analysis may be used for any linear dynamic system. The starting point is to formulate a state-space model of the system, which is a set of coupled first-order differential equations:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (3.65)$$

where \mathbf{x} = state vector; \mathbf{u} = input vector; \mathbf{A} = system matrix; and \mathbf{B} = input gain matrix.

FIGURE 3.12 A system with linear viscous damping.

FIGURE 3.13 A system with proportional damping in proportion to stiffness.

FIGURE 3.14 A system with proportional damping in proportion to inertia.

There are many approaches to formulating a vibration problem as a state-space model 3.65. One simple method is to first obtain the conventional, coupled, second-order differential equations:

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t)$$

Next, the state vector and the input vector are defined as

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{bmatrix} \quad \text{and} \quad \mathbf{u} = \mathbf{f}(t) \quad (3.66)$$

Note that Equation 3.59 may be written as

$$\ddot{\mathbf{y}} = -\mathbf{M}^{-1}\mathbf{K}\mathbf{y} - \mathbf{M}^{-1}\mathbf{C}\dot{\mathbf{y}} + \mathbf{M}^{-1}\mathbf{f}(t) \quad (3.67)$$

which is identical to

$$\ddot{\mathbf{y}} = [-\mathbf{M}^{-1}\mathbf{K} - \mathbf{M}^{-1}\mathbf{C}] \begin{bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{bmatrix} + \mathbf{f}(t) \quad (3.67a)$$

This, together with the identity $\dot{\mathbf{y}} = \dot{\mathbf{y}}$, can be expressed in the form

$$\begin{bmatrix} \dot{\mathbf{y}} \\ \ddot{\mathbf{y}} \end{bmatrix} = \begin{bmatrix} 0 & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \begin{bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{bmatrix} + \begin{bmatrix} 0 \\ \mathbf{M}^{-1} \end{bmatrix} \mathbf{f}(t) \quad (3.68)$$

which is in the state-space form 3.65 where

$$\mathbf{A} = \begin{bmatrix} 0 & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \quad \text{and} \quad \mathbf{B} = \begin{bmatrix} 0 \\ \mathbf{M}^{-1} \end{bmatrix} \quad (3.69)$$

Note that, in Equation 3.68 and Equation 3.69, \mathbf{I} denotes an identity matrix of an appropriate size.

3.10.1 Modal Analysis

Consider the free motion ($\mathbf{u} = 0$) of the n th order system given by Equation 3.65. Its solution is given by

$$\mathbf{x} = \Phi(t)\mathbf{x}(0) \quad (3.70)$$

It is known that the state transition matrix $\Phi(t)$ is given by the matrix-exponential expansion equation.

$$\Phi(t) = \exp(\mathbf{A}t) = \mathbf{I} + \mathbf{A}t + \frac{1}{2!}\mathbf{A}^2t^2 + \dots \quad (3.71)$$

To discuss the rationale for this exponential response further, we begin by assuming a homogeneous solution of the form

$$\mathbf{x} = \mathbf{X} \exp(\lambda t) \quad (3.72)$$

By substituting Equation 3.72 in the homogeneous equation of motion (that is, Equation 3.65 with $\mathbf{u} = 0$), the following matrix-eigenvalue problem results:

$$(\mathbf{A} - s\mathbf{I})\mathbf{X} = 0 \quad (3.73)$$

We shall assume that the n eigenvalues ($\lambda_1, \lambda_2, \dots, \lambda_n$) of \mathbf{A} are distinct. Then, the corresponding eigenvectors $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n$ are linearly independent vectors; that is, any one eigenvector cannot be expressed as a linear combination of the rest of the eigenvectors in the set. Thus, the general solution for free dynamics is

$$\mathbf{x}(t) = \mathbf{X}_1 \exp(\lambda_1 t) + \mathbf{X}_2 \exp(\lambda_2 t) + \dots + \mathbf{X}_n \exp(\lambda_n t) \quad (3.74)$$

Each of the n eigenvectors has an unknown parameter. The total of n unknowns is determined using n initial conditions:

$$\mathbf{x}(0) = \mathbf{x}_0 \quad (3.75)$$

3.10.2 Mode Shapes of Nonoscillatory Systems

Since the eigenvectors are independent, if the initial state is set at $\mathbf{x}_0 = \mathbf{X}_i$, then the subsequent motion should not have any \mathbf{X}_j terms with $j \neq i$ in Equation 3.74. Otherwise, when we set $t = 0$, \mathbf{X}_i becomes a linear combination of the remaining eigenvectors, which contradicts the linear independence. Hence, the motion due to this eigenvector initial condition is given by $\mathbf{x}(t) = \mathbf{X}_i \exp(\lambda_i t)$, which vector is parallel to \mathbf{X}_i throughout the motion. Thus, \mathbf{X}_i gives the mode shape of the system corresponding to the eigenvalue λ_i .

3.10.3 Mode Shapes of Oscillatory Systems

The analysis in the preceding section is valid for real eigenvalues and eigenvectors. In vibratory systems, λ_i and \mathbf{X}_i generally are complex. Let

$$\lambda_i = \sigma_i + j\omega_i \quad (3.76)$$

$$\mathbf{X}_i = \mathbf{R}_i + j\mathbf{I}_i \quad (3.77)$$

For real systems, corresponding complex conjugates exist:

$$\bar{\lambda}_i = \sigma_i - j\omega_i \quad (3.78)$$

$$\bar{\mathbf{X}}_i = \mathbf{R}_i - j\mathbf{I}_i \quad (3.79)$$

Equation 3.76 to Equation 3.79 represent the i th mode of the system. The corresponding damped natural frequency is ω_i and the damping parameter is σ_i . The net contribution of the i th mode to the solution (Equation 3.74) is

$$(\mathbf{R}_i \cos \omega_i t - \mathbf{I}_i \sin \omega_i t) 2 \exp(\sigma_i t)$$

It should be clear, for instance from Equation 3.66, that only some of the state variables in $\mathbf{x}(t)$ correspond to displacements of the masses (or spring forces). These can be extracted through an output relationship of the form

$$\mathbf{y} = \mathbf{C}\mathbf{x} \quad (3.80)$$

The contribution of the i th mode to displacement variables is

$$\mathbf{Y}_i = \mathbf{C}[\mathbf{R}_i \cos \omega_i t - \mathbf{I}_i \sin \omega_i t] 2 \exp(\sigma_i t) \quad (3.81)$$

If Equation 3.81 can be expressed in the form

$$\mathbf{Y}_i = \mathbf{S}_i \sin(\omega_i t + \phi_i) \exp(\sigma_i t) \quad (3.82)$$

in which \mathbf{S}_i is a constant vector that is defined up to one unknown, then it is possible to excite the system so that every independent mass element undergoes oscillations in phase (hence, passing through the equilibrium state simultaneously) at a specific frequency ω_i . We have noted that this type of motion is known as normal mode motion. The vector \mathbf{S}_i gives the mode shape corresponding to the (damped) natural frequency ω_i . A normal mode motion is possible for undamped systems and for certain classes of damped systems. The initial state that is required to excite the i th mode is $\mathbf{x}_0 = \mathbf{R}_i$. The corresponding displacement and velocity initial conditions are obtained from Equation 3.81; thus

$$\mathbf{Y}_i(0) = \mathbf{C}\mathbf{R}_i \quad (3.83)$$

$$\dot{\mathbf{Y}}_i(0) = \mathbf{C}(\mathbf{R}_i \sigma_i - \mathbf{I}_i \omega_i) \quad (3.84)$$

Note that the constant factor 2 has been ignored, because \mathbf{X}_i is known up to one unknown complex parameter.

Example 3.9

A torsional dynamic model of a pipeline segment is shown in Figure 3.15(a). Free-body diagrams in Figure 3.15(b) show internal torques acting at sectioned inertia junctions for free motion. A state model is obtained using the generalized velocities (angular velocities Ω_i) of the inertia elements and the generalized forces (torques T_i) as state variables. A minimum set that is required for complete representation determines the system order. There are two inertia elements and three spring elements — a total of five energy-storage elements. The three springs are not independent, however. The motion of two springs completely determines the motion of the third. This indicates that the system is a fourth-order system. We obtain the model as follows.

Newton's Second Law gives

$$I_1 \dot{\Omega}_1 = -T_1 + T_2 \quad (\text{i})$$

$$I_2 \dot{\Omega}_2 = -T_2 - T_3 \quad (\text{ii})$$

and Hooke's Law gives

$$\dot{T}_1 = k_1 \Omega_1 \quad (\text{iii})$$

$$\dot{T}_2 = k_2 (\Omega_2 - \Omega_1) \quad (\text{iv})$$

Torque T_3 is determined in terms of T_1 and T_2 , using the displacement relation for the inertia I_2 :

$$\frac{T_1}{k_1} + \frac{T_2}{k_2} = \frac{T_3}{k_3} \quad (\text{v})$$

The state vector is chosen as

$$\mathbf{x} = [\Omega_1, \Omega_2, T_1, T_2]^T \quad (\text{vi})$$

The corresponding system matrix is

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & -\frac{1}{I_1} & \frac{1}{I_1} \\ 0 & 0 & -\frac{1}{I_2} \left(\frac{k_3}{k_1} \right) & -\frac{1}{I_2} \left(1 + \frac{k_3}{k_2} \right) \\ k_1 & 0 & 0 & 0 \\ -k_2 & k_1 & 0 & 0 \end{bmatrix} \quad (\text{vii})$$

The output-displacement vector is

$$\mathbf{y} = \left[\frac{T_1}{k_1}, \frac{T_1}{k_1} + \frac{T_2}{k_2} \right] \quad (\text{viii})$$

FIGURE 3.15 (a) Dynamic model of a pipeline segment; (b) free-body diagrams.

which corresponds to the output-gain matrix

$$\mathbf{C} = \begin{bmatrix} 0 & 0 & \frac{1}{k_1} & 0 \\ 0 & 0 & \frac{1}{k_1} & \frac{1}{k_2} \end{bmatrix} \quad (\text{ix})$$

For the special case given by $I_1 = I_2 = I$ and $k_1 = k_3 = k$, the system eigenvalues are

$$\lambda_1, \bar{\lambda}_1 = \pm j\omega_1 = \pm j\sqrt{\frac{k}{I}} \quad (\text{x})$$

$$\lambda_2, \bar{\lambda}_2 = \pm j\omega_2 = \pm j\sqrt{\frac{k+2k_2}{I}} \quad (\text{xi})$$

FIGURE 3.16 Mode shapes of the pipeline segment.

and the corresponding eigenvectors are

$$\mathbf{X}_1, \bar{\mathbf{X}}_1 = \mathbf{R}_1 \pm j\mathbf{I}_1 = \frac{\alpha_1}{2} [\omega_1, \omega_1, \mp jk_1, 0]^T \quad (\text{xii})$$

$$\mathbf{X}_2, \bar{\mathbf{X}}_2 = \mathbf{R}_2 \pm j\mathbf{I}_2 = \frac{\alpha_2}{2} [\omega_2, -\omega_2, \mp jk_1, \pm 2jk_2]^T \quad (\text{xiii})$$

In view of Equation 3.81, the modal contributions to the displacement vector are

$$\mathbf{Y}_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \alpha_1 \sin \omega_1 t \quad \text{and} \quad \mathbf{Y}_2 = \begin{bmatrix} 1 \\ -1 \end{bmatrix} \alpha_2 \sin \omega_2 t \quad (\text{xiv})$$

This Equation xiv is of the form given by Equation 3.82. The mode shapes are given by the vectors $\mathbf{S}_1 = [1, 1]^T$ and $\mathbf{S}_2 = [1, -1]^T$, which are illustrated in Figure 3.16. In general, each modal contribution introduces two unknown parameters, a_i and ϕ_i , into the free response (homogeneous solution) where ϕ_i are the phase angles associated with the sinusoidal terms. For an n -DoF (order- $2n$) system, this results in $2n$ unknowns, which require the $2n$ initial conditions $\mathbf{x}(0)$.

Appendix 3A

Linear Algebra

3A.1 Introduction

Linear algebra, the algebra of *sets*, *vectors*, and *matrices*, is useful in the study of mechanical vibrating systems in general, and modal analysis in particular. In practical mechanical systems, interactions among various components are inevitable. There are many response variables associated with many excitations. It is convenient to consider all excitations (inputs) simultaneously as a single variable, and also all responses (outputs) as a single variable. Use of linear algebra makes the analysis of such a system convenient. Modal analysis using such a vector–matrix representation will provide natural frequencies and mode shapes, as discussed in Chapter 3 and other places in the handbook. The subject of linear algebra is complex and is based on a rigorous mathematical foundation. In this appendix, we will review the basics of vectors and matrices.

3A.2 Vectors and Matrices

In the analysis of mechatronic systems, vectors and matrices will be useful in both time and frequency domains. First, consider the time-domain formulation of a mechanical system. For a single-DoF system with a single forcing excitation, $f(t)$, and a corresponding single displacement response, y , the dynamic equation would be

$$m\ddot{y} + c\dot{y} + ky = f(t) \quad (3A.1)$$

Note that, in this single-DoF case, the quantities f , y , m , c , and k are *scalars*. If the system has n DoF, with excitation forces $(\mathbf{x}, \mathbf{y} + \mathbf{z}) = (\mathbf{x}, \mathbf{y}) + (\mathbf{x}, \mathbf{z})$ and associated displacement responses, y_1, y_2, \dots, y_n , the equations of motion may be expressed as

$$\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\| \quad (3A.2)$$

in which

$$\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix} = \text{displacement vector (} n\text{th-order column vector)}$$

$$\mathbf{f} = \begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{bmatrix} = \text{forcing excitation vector (} n\text{th-order column vector)}$$

$$\mathbf{M} = \begin{bmatrix} m_{11} & m_{12} & \cdots & m_{1n} \\ m_{21} & m_{22} & \cdots & m_{2n} \\ \vdots & & & \\ m_{n1} & m_{n2} & \cdots & m_{nn} \end{bmatrix} = \text{mass matrix } (n \times n \text{ square matrix})$$

$$\mathbf{C} = \begin{bmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & c_{22} & \cdots & c_{2n} \\ \vdots & & & \\ c_{n1} & c_{n2} & \cdots & c_{nn} \end{bmatrix} = \text{damping matrix } (n \times n \text{ square matrix})$$

$$\mathbf{K} = \begin{bmatrix} k_{11} & k_{12} & \cdots & k_{1n} \\ k_{21} & k_{22} & \cdots & k_{2n} \\ \vdots & & & \\ k_{n1} & k_{n2} & \cdots & k_{nn} \end{bmatrix} = \text{stiffness matrix } (n \times n \text{ square matrix})$$

In this manner, vectors and matrices are introduced into the formulation of a multi-DoF mechanical system. Further vector–matrix concepts will enter into the picture in subsequent analysis of the system (e.g., in modal analysis).

Next consider the frequency-domain formulation. In the single-input single-output (SISO) case, the system equation may be given as

$$y = Gu \quad (3A.3)$$

in which

- u = frequency spectrum (Fourier spectrum) of the forcing excitation (input)
- y = frequency spectrum (Fourier spectrum) of the response (output)
- G = frequency transfer function (frequency-response function) of the system

The quantities u , y , and G are *scalars* because each one is a single quantity and not a collection of several quantities.

Next, consider a multi-input multi-output (MIMO) system having two excitations, u_1 and u_2 , and two responses, y_1 and y_2 ; each y_i now depends on both u_1 and u_2 . It follows that we need four transfer functions to represent all the excitation–response relationships that exist in this system. We use the four transfer functions (G_{11} , G_{12} , and G_{22}). For example, the transfer function G_{12} relates the excitation u_2 to the response y_1 . The associated two equations that govern the system are

$$\begin{aligned} y_1 &= G_{11}u_1 + G_{12}u_2 \\ y_2 &= G_{21}u_1 + G_{22}u_2 \end{aligned} \quad (3A.4)$$

Instead of considering the two excitations (two inputs) as two separate quantities, we can consider them as a single “vector” \mathbf{u} having the two components u_1 and u_2 . As before, we can write this as a column consisting of the two elements:

$$\mathbf{u} = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

In this case we have a “column vector.” Alternately, we can write a “row vector” as

$$\mathbf{u} = [u_1, u_2]$$

The column-vector representation is more common.

Similarly, we can express the two outputs, y_1 and y_2 , as a vector \mathbf{y} . Consequently, we have the column vector

$$\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$$

or the row vector

$$\mathbf{y} = [y_1, y_2]$$

It should be kept in mind that the order in which the components (or elements) are given is important since the vector $[u_1, u_2]$ is not equal to the vector $[u_2, u_1]$. In other words, a vector is an “ordered” collection of quantities.

Summarizing, we can express a collection of quantities, in an orderly manner, as a single vector. Each quantity in the vector is known as a *component* or an *element* of the vector. What each component means will depend on the particular situation. For example, in a dynamic system it may represent a quantity such as voltage, current, force, velocity, pressure, flow rate, temperature, or heat transfer rate. The number of components (elements) in a vector is called the *order*, or *dimension* of the vector.

Next let us introduce the concept of a matrix using the frequency-domain example given above. Note that we needed four transfer functions to relate the two excitations to the two responses. Instead of considering these four quantities separately we can express them as a single matrix \mathbf{G} having four elements. Specifically, the *transfer function matrix* for the present example is

$$\mathbf{G} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix}$$

Note that our matrix has two rows and two columns. Hence the size or order of the matrix is 2×2 . Since the number of rows is equal to the number of columns in this example, we have a *square matrix*. If the number of rows is not equal to the number of columns, we have a *rectangular matrix*. Actually, we can interpret a matrix as a collection of vectors. Hence, in the previous example, the matrix \mathbf{G} is an assembly of the two column vectors

$$\begin{bmatrix} G_{11} \\ G_{21} \end{bmatrix} \text{ and } \begin{bmatrix} G_{12} \\ G_{22} \end{bmatrix}$$

or alternatively, an assembly of the two row vectors

$$[G_{11}, G_{12}]$$

and

$$[G_{21}, G_{22}]$$

3A.3 Vector–Matrix Algebra

The advantage of representing the excitations and the responses of a mechatronic system as the vectors \mathbf{u} and \mathbf{y} , and the transfer functions as the matrix \mathbf{G} is clear from the fact that the excitation–response (input–output) equations can be expressed as the single equation

$$\mathbf{y} = \mathbf{G}\mathbf{u} \quad (3A.5)$$

instead of the collection of scalar equations (Equation 3A.4).

Hence, the response vector \mathbf{y} is obtained by premultiplying the excitation vector \mathbf{u} by the transfer function matrix \mathbf{G} . Of course, certain rules of vector–matrix multiplication have to be agreed upon in order that this single equation is consistent with the two scalar equations given by Equation 3A.4. Also, we have to agree upon rules for the addition of vectors or matrices.

A vector is a special case of a matrix. Specifically, a third-order column vector is a matrix having three rows and one column. Hence, it is a 3×1 matrix. Similarly, a third-order row vector is a matrix having one row and three columns. Accordingly, it is a 1×3 matrix. It follows that we only need to know matrix algebra; the vector algebra will follow from the results for matrices.

3A.3.1 Matrix Addition and Subtraction

Only matrices of the same size can be added. The result (sum) will also be a matrix of the same size. In matrix addition, we add the corresponding elements (i.e., the elements at the same position) in the two matrices, and write the results at the corresponding places in the resulting matrix.

As an example, consider the 2×3 matrix

$$\mathbf{A} = \begin{bmatrix} -1 & 0 & 3 \\ 2 & 6 & -2 \end{bmatrix}$$

and a second matrix

$$\mathbf{B} = \begin{bmatrix} 2 & 1 & -5 \\ 0 & -3 & 2 \end{bmatrix}$$

The sum of these two matrices is given by

$$\mathbf{A} + \mathbf{B} = \begin{bmatrix} 1 & 1 & -2 \\ 2 & 3 & 0 \end{bmatrix}$$

The order in which the addition is done is immaterial. Hence

$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A} \quad (3A.6)$$

In other words, matrix addition is *commutative*.

Matrix subtraction is defined just like matrix addition, except the corresponding elements are subtracted. An example is given below:

$$\begin{bmatrix} -1 & 2 \\ 3 & 0 \\ -4 & 1 \end{bmatrix} - \begin{bmatrix} 4 & 2 \\ 2 & -1 \\ -3 & 0 \end{bmatrix} = \begin{bmatrix} -5 & 0 \\ 1 & 1 \\ -1 & 1 \end{bmatrix}$$

3A.3.2 Null Matrix

The null matrix is a matrix whose elements are all zeros. Hence, when we add a null matrix to an arbitrary matrix, the result is equal to the original matrix. We can define a *null vector* in a similar manner. We can write

$$\mathbf{A} + \mathbf{0} = \mathbf{A} \quad (3A.7)$$

As an example, the 2×2 null matrix is

$$\begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

3A.3.3 Matrix Multiplication

Consider the product \mathbf{AB} of the two matrices \mathbf{A} and \mathbf{B} . Let us write this as

$$\mathbf{C} = \mathbf{AB} \quad (3A.8)$$

We say that **B** is premultiplied by **A** or, equivalently, **A** is postmultiplied by **B**. For this multiplication to be possible, the number of columns in **A** has to be equal to the number of rows in **B**. Then, the number of rows of the product matrix **C** is equal to the number of rows in **A**, and the number of columns in **C** is equal to the number of columns in **B**.

The actual multiplication is done by multiplying the elements in a given row (say, the *i*th row) of **A** by the corresponding elements in a given column (say, the *j*th column) of **B** and summing these products. The result is the element c_{ij} of the product matrix **C**. Note that c_{ij} denotes the element that is common to the *i*th row and the *j*th column of matrix **C**. So, we have

$$c_{ij} = \sum_k a_{ik} b_{kj} \quad (3A.9)$$

As an example, suppose

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & -1 \\ 3 & -3 & 4 \end{bmatrix}$$

$$\mathbf{B} = \begin{bmatrix} 1 & -1 & 2 & 4 \\ 2 & 3 & -4 & 2 \\ 5 & -3 & 1 & 0 \end{bmatrix}$$

Note that the number of columns in **A** is equal to three and the number of rows in **B** is also equal to three. Hence, we can perform the premultiplication of **B** by **A**. For example

$$\begin{aligned} c_{11} &= 1 \times 1 + 2 \times 2 + (-1) \times 5 = 0 \\ c_{12} &= 1 \times (-1) + 2 \times 3 + (-1) \times (-3) = 8 \\ c_{13} &= 1 \times 2 + 2 \times (-4) + (-1) \times 1 = -7 \\ c_{14} &= 1 \times 4 + 2 \times 2 + (-1) \times 0 = 8 \\ c_{21} &= 3 \times 1 + (-3) \times 2 + 4 \times 5 = 17 \\ c_{22} &= 3 \times (-1) + (-3) \times 3 + 4 \times (-3) = -24 \end{aligned}$$

and so on. The product matrix is

$$\mathbf{C} = \begin{bmatrix} 0 & 8 & -7 & 8 \\ 17 & -24 & 22 & 6 \end{bmatrix}$$

It should be noted that both products **AB** and **BA** are not always defined and, even when they are defined, the two results are not equal in general. Unless both **A** and **B** are square matrices of the same order, the two product matrices will not be of the same order.

Summarizing, matrix multiplication is not commutative:

$$\mathbf{AB} \neq \mathbf{BA} \quad (3A.10)$$

3A.3.4 Identity Matrix

An identity matrix (or unity matrix) is a square matrix whose diagonal elements are all equal to 1 and all the remaining elements are zeros. This matrix is denoted by **I**.

For example, the third-order identity matrix is

$$\mathbf{I} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

It is easy to see that when any matrix is multiplied by an identity matrix (provided, of course, that the multiplication is possible) the product is equal to the original matrix; thus

$$\mathbf{AI} = \mathbf{IA} = \mathbf{A} \quad (3A.11)$$

3A.4 Matrix Inverse

An operation similar to scalar division can be defined in terms of the inverse of a matrix. A proper inverse is defined only for a square matrix and, even for a square matrix, an inverse may not exist. The inverse of a matrix is defined as follows.

Suppose that a square matrix \mathbf{A} has the inverse \mathbf{B} . Then, these must satisfy the equation

$$\mathbf{AB} = \mathbf{I} \quad (3A.12)$$

or equivalently

$$\mathbf{BA} = \mathbf{I} \quad (3A.13)$$

where \mathbf{I} is the identity matrix, as defined before.

The inverse of \mathbf{A} is denoted by \mathbf{A}^{-1} . The inverse exists for a matrix if and only if the *determinant* of the matrix is nonzero. Such matrices are termed *nonsingular*. We shall discuss the determinant in Section 3A.6. Before explaining a method for determining the inverse of a matrix, let us verify that

$$\begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix}$$

is the inverse of

$$\begin{bmatrix} 1 & -1 \\ -1 & 2 \end{bmatrix}$$

To show this, we simply multiply the two matrices and show that the product is the second-order unity matrix. Specifically,

$$\begin{bmatrix} 1 & -1 \\ -1 & 2 \end{bmatrix} \begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

or

$$\begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix} \begin{bmatrix} 1 & -1 \\ -1 & 2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

3A.4.1 Matrix Transpose

The transpose of a matrix is obtained by simply interchanging the rows and the columns of the matrix. The transpose of \mathbf{A} is denoted by \mathbf{A}^T .

For example, the transpose of the 2×3 matrix

$$\mathbf{A} = \begin{bmatrix} 1 & -2 & 3 \\ -2 & 2 & 0 \end{bmatrix}$$

is the 3×2 matrix

$$\mathbf{A}^T = \begin{bmatrix} 1 & -2 \\ -2 & 2 \\ 3 & 0 \end{bmatrix}$$

Note that the first row of the original matrix has become the first column of the transposed matrix, and the second row of the original matrix has become the second column of the transposed matrix.

If $\mathbf{A}^T = \mathbf{A}$, then we say that the matrix \mathbf{A} is *symmetric*. Another useful result on the matrix transpose is expressed by

$$(\mathbf{AB})^T = \mathbf{B}^T \mathbf{A}^T \quad (3A.14)$$

It follows that the transpose of a matrix product is equal to the product of the transposed matrices, taken in the reverse order.

3A.4.2 Trace of a Matrix

The trace of a square matrix is given by the sum of the diagonal elements. The trace of matrix \mathbf{A} is denoted by $\text{tr}(\mathbf{A})$.

$$\text{tr}(\mathbf{A}) = \sum_i a_{ii} \quad (3A.15)$$

For example, the trace of the matrix

$$\mathbf{A} = \begin{bmatrix} -2 & 3 & 0 \\ 4 & -4 & 1 \\ -1 & 0 & 3 \end{bmatrix}$$

is given by

$$\text{tr}(\mathbf{A}) = (-2) + (-4) + 3 = -3$$

3A.4.3 Determinant of a Matrix

The determinant is defined only for a square matrix. It is a scalar value computed from the elements of the matrix. The determinant of a matrix \mathbf{A} is denoted by $\det(\mathbf{A})$ or $|\mathbf{A}|$.

Instead of giving a complex mathematical formula for the determinant of a general matrix in terms of the elements of the matrix, we now explain a way to compute the determinant.

First, consider the 2×2 matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

Its determinant is given by

$$\det(\mathbf{A}) = a_{11}a_{22} - a_{12}a_{21}$$

Next, consider the 3×3 matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}$$

Its determinant can be expressed as

$$\det(\mathbf{A}) = a_{11}M_{11} - a_{12}M_{12} + a_{13}M_{13}$$

where the *minors* of the associated matrix elements are defined as

$$M_{11} = \det \begin{bmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{bmatrix}, \quad M_{12} = \det \begin{bmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{bmatrix}, \quad M_{13} = \det \begin{bmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{bmatrix}$$

Note that M_{ij} , the determinant of the matrix, is obtained by deleting the i th row and the j th column of the original matrix. The quantity M_{ij} is known as the *minor* of the element a_{ij} of the matrix \mathbf{A} . If we attach a proper sign to the minor depending on the position of the corresponding matrix element, we have a quantity known as the *cofactor*. Specifically, the cofactor, C_{ij} , corresponding to the minor, M_{ij} , is given by

$$C_{ij} = (-1)^{i+j} M_{ij} \quad (3A.16)$$

Hence, the determinant of the 3×3 matrix may be given by

$$\det(\mathbf{A}) = a_{11}C_{11} + a_{12}C_{12} + a_{13}C_{13}$$

Note that in the two formulas given above for computing the determinant of a 3×3 matrix, we have expanded along the first row of the matrix. We get the same answer, however, if we expand along any row or any column. Specifically, when expanded along the i th row, we have

$$\det(\mathbf{A}) = a_{i1}C_{i1} + a_{i2}C_{i2} + a_{i3}C_{i3}$$

Similarly, if we expand along the j th column, we have

$$\det(\mathbf{A}) = a_{1j}C_{1j} + a_{2j}C_{2j} + a_{3j}C_{3j}$$

These ideas of computing a determinant can be easily extended to 4×4 and higher-order matrices in a straightforward manner. Hence, we can write

$$\det(\mathbf{A}) = \sum_j a_{ij}C_{ij} = \sum_i a_{ij}C_{ij} \quad (3A.17)$$

3A.4.4 Adjoint of a Matrix

The adjoint of a matrix is the transpose of the matrix whose elements are the cofactors of the corresponding elements of the original matrix. The adjoint of matrix \mathbf{A} is denoted by $\text{adj}(\mathbf{A})$.

As an example, in the 3×3 case, we have

$$\text{adj}(\mathbf{A}) = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & C_{22} & C_{23} \\ C_{31} & C_{32} & C_{33} \end{bmatrix}^T = \begin{bmatrix} C_{11} & C_{21} & C_{31} \\ C_{12} & C_{22} & C_{32} \\ C_{13} & C_{23} & C_{33} \end{bmatrix}$$

In particular, it is easily seen that the adjoint of the matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & -1 \\ 0 & 3 & 2 \\ 1 & 1 & 1 \end{bmatrix}$$

is given by

$$\text{adj}(\mathbf{A}) = \begin{bmatrix} 1 & 2 & -3 \\ -3 & 2 & 1 \\ 7 & -2 & 3 \end{bmatrix}^T$$

Accordingly, we have

$$\text{adj}(\mathbf{A}) = \begin{bmatrix} 1 & -3 & 7 \\ 2 & 2 & -2 \\ -3 & 1 & 3 \end{bmatrix}$$

Hence, in general

$$\text{adj}(\mathbf{A}) = [C_{ij}]^T \quad (3A.18)$$

3A.4.5 Inverse of a Matrix

At this juncture, it is appropriate to give a formula for the inverse of a square matrix. Specifically,

$$\mathbf{A}^{-1} = \frac{\text{adj}(\mathbf{A})}{\det(\mathbf{A})} \quad (3A.19)$$

Hence, in the 3×3 matrix example given before, since we have already determined the adjoint, it remains only to compute the determinant in order to obtain the inverse. Now, expanding along the first row of the matrix, the determinant is given by

$$\det(\mathbf{A}) = 1 \times 1 + 2 \times 2 + (-1) \times (-3) = 8$$

Accordingly, the inverse is given by

$$\mathbf{A}^{-1} = \frac{1}{8} \begin{bmatrix} 1 & -3 & 7 \\ 2 & 2 & -2 \\ -3 & 1 & 3 \end{bmatrix}$$

For two square matrices \mathbf{A} and \mathbf{B} we have

$$(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1} \quad (3A.20)$$

As a final note, if the determinant of a matrix is zero, the matrix does not have an inverse. Then we say that the matrix is *singular*. Some important matrix properties are summarized in Box 3A.1.

Box 3A.1

SUMMARY OF MATRIX PROPERTIES

Addition: $\mathbf{A}_{m \times n} + \mathbf{B}_{m \times n} = \mathbf{C}_{m \times n}$

Multiplication: $\mathbf{A}_{m \times n} \mathbf{B}_{n \times r} = \mathbf{C}_{m \times r}$

Identity: $\mathbf{AI} = \mathbf{IA} = \mathbf{A} \Rightarrow \mathbf{I}$ is the identity matrix

Note: $\mathbf{AB} = 0 \not\Rightarrow \mathbf{A} = 0$ or $\mathbf{B} = 0$ in general

Transposition: $\mathbf{C}^T = (\mathbf{AB})^T = \mathbf{B}^T \mathbf{A}^T$

Inverse: $\mathbf{AP} = \mathbf{I} = \mathbf{PA} \Rightarrow \mathbf{A} = \mathbf{P}^{-1}$ and $\mathbf{P} = \mathbf{A}^{-1}$

$$(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$$

Commutativity: $\mathbf{AB} \neq \mathbf{BA}$ in general

Associativity: $(\mathbf{AB})\mathbf{C} = \mathbf{A}(\mathbf{BC})$

Distributivity: $\mathbf{C}(\mathbf{A} + \mathbf{B}) = \mathbf{CA} + \mathbf{CB}$

Distributivity: $(\mathbf{A} + \mathbf{B})\mathbf{D} = \mathbf{AD} + \mathbf{BD}$

3A.5 Vector Spaces

3A.5.1 Field (F)

Consider a set of scalars.

For any α and β from the set, if $\alpha + \beta$ and $\alpha\beta$ are also elements in the set; if

1. $\alpha + \beta = \beta + \alpha$ and $\alpha\beta = \beta\alpha$ (commutativity)
2. $(\alpha + \beta) + \gamma = \alpha + (\beta + \gamma)$ and $(\alpha\beta)\gamma = \alpha(\beta\gamma)$ (associativity)
3. $\alpha(\beta + \gamma) = \alpha\beta + \alpha\gamma$ (distributivity)

are satisfied; and if

1. Identity elements 0 and 1 exist in the set such that $\alpha + 0 = \alpha$ and $1\alpha = \alpha$
2. Inverse elements exist in the set such that $\alpha + (-\alpha) = 0$ and $\alpha \cdot \alpha^{-1} = 1$

then the set is a field.

For example, the set of real numbers is a field.

3A.5.2 Vector Space (L)

Properties:

1. Vector addition ($\mathbf{x} + \mathbf{y}$) and scalar multiplication ($\alpha\mathbf{x}$) are defined.
2. Commutativity: $\mathbf{x} + \mathbf{y} = \mathbf{y} + \mathbf{x}$ and associativity: $(\mathbf{x} + \mathbf{y}) + \mathbf{z} = \mathbf{x} + (\mathbf{y} + \mathbf{z})$ are satisfied.
3. Unique null vector 0 and negation ($-\mathbf{x}$) exist such that $\mathbf{x} + 0 = \mathbf{x}$, $\mathbf{x} + (-\mathbf{x}) = 0$.
4. Scalar multiplication satisfies

$$\alpha(\beta\mathbf{x}) = (\alpha\beta)\mathbf{x} \quad (\text{associativity})$$

$$\left. \begin{aligned} \alpha(\mathbf{x} + \mathbf{y}) &= \alpha\mathbf{x} + \alpha\mathbf{y} \\ (\alpha + \beta)\mathbf{x} &= \alpha\mathbf{x} + \beta\mathbf{x} \end{aligned} \right\} \quad (\text{distributivity})$$

$$1\mathbf{x} = \mathbf{x}, \quad 0\mathbf{x} = 0$$

Special case: Vector space L^n has vectors with n elements from the field F .

Consider

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad \mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix}$$

Then

$$\mathbf{x} + \mathbf{y} = \begin{bmatrix} x_1 + y_1 \\ \vdots \\ x_n + y_n \end{bmatrix} = \mathbf{y} + \mathbf{x}$$

and

$$\alpha \mathbf{x} = \begin{bmatrix} \alpha x_1 \\ \vdots \\ \alpha x_n \end{bmatrix}$$

3A.5.3 Subspace S of L

1. If \mathbf{x} and \mathbf{y} are in S then $\mathbf{x} + \mathbf{y}$ is also in S .
2. If \mathbf{x} is in S and α is in F then $\alpha \mathbf{x}$ is also in S .

3A.5.4 Linear Dependence

Consider the set of vectors: $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$. They are linearly independent if any one of these vectors cannot be expressed as a linear combination of one or more remaining vectors.

Necessary and sufficient condition for linear independence:

$$\alpha_1 \mathbf{x}_1 + \alpha_2 \mathbf{x}_2 + \dots + \alpha_n \mathbf{x}_n = 0 \quad (3A.21)$$

gives $\alpha = 0$ (trivial solution) as the only solution.

For example,

$$\mathbf{x}_1 = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}, \quad \mathbf{x}_2 = \begin{bmatrix} 2 \\ -1 \\ 1 \end{bmatrix}, \quad \mathbf{x}_3 = \begin{bmatrix} 5 \\ 0 \\ 5 \end{bmatrix}$$

These vectors are not linearly independent because $\mathbf{x}_1 + 2\mathbf{x}_2 = \mathbf{x}_3$.

3A.5.5 Bases and Dimension of a Vector Space

1. If a set of vectors can be combined to form any vector in L then that set of vectors is said to *span* the vector space L (i.e., a generating system of vectors).
2. If the spanning vectors are all linearly independent, then this set of vectors is a *basis* for that vector space.
3. The number of vectors in the basis = the dimension of the vector space.

Note: The dimension of a vector space is not necessarily the order of the vectors.

For example, consider two intersecting third-order vectors. They will form a basis for the plane (two-dimensional) that contains the two vectors. Hence, the dimension of the vector space = 2, but the order of each vector in the basis = 3.

Note: L^n is spanned by n linearly independent vectors

$$\Rightarrow \dim(L^n) = n$$

For example,

$$\begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \dots, \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

3A.5.6 Inner Product

$$(\mathbf{x}, \mathbf{y}) = \mathbf{y}^H \mathbf{x} \quad (3A.22)$$

where H denotes the *Hermitian transpose* (i.e., complex conjugate and transpose). Hence, $\mathbf{y}^H = (\mathbf{y}^*)^T$ where $(\)^*$ denotes complex conjugation.

Note:

1. $(\mathbf{x}, \mathbf{x}) \geq 0$ and $(\mathbf{x}, \mathbf{x}) = 0$ if and only if (iff) $\mathbf{x} = 0$
2. $(\mathbf{x}, \mathbf{y}) = (\mathbf{y}, \mathbf{x})^*$
3. $(\lambda \mathbf{x}, \mathbf{y}) = \lambda(\mathbf{x}, \mathbf{y})$ and $(\mathbf{x}, \lambda \mathbf{y}) = \lambda^*(\mathbf{x}, \mathbf{y})$
4. $(\mathbf{x}, \mathbf{y} + \mathbf{z}) = (\mathbf{x}, \mathbf{y}) + (\mathbf{x}, \mathbf{z})$

3A.5.7 Norm

Properties

$$\|\mathbf{x}\| \geq 0 \text{ and } \|\mathbf{x}\| = 0 \text{ iff } \mathbf{x} = 0$$

$$\|\lambda \mathbf{x}\| = |\lambda| \|\mathbf{x}\| \text{ for any scalar } \lambda$$

$$\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$$

For example, the Euclidean norm:

$$\|\mathbf{x}\| = \mathbf{x}^H \mathbf{x} = \left(\sum_{i=1}^n x_i^2 \right)^{1/2} \quad (3A.23)$$

Unit vector

$$\|\mathbf{x}\| = 1$$

Normalization

$$\frac{\mathbf{x}}{\|\mathbf{x}\|} = \hat{\mathbf{x}}$$

Angle between vectors

We have

$$\cos \theta = \frac{(\mathbf{x}, \mathbf{y})}{\|\mathbf{x}\| \|\mathbf{y}\|} = (\hat{\mathbf{x}}, \hat{\mathbf{y}}) \quad (3A.24)$$

where θ is the angle between \mathbf{x} and \mathbf{y} .

Orthogonal vectors

$$\text{iff } (\mathbf{x}, \mathbf{y}) = 0 \quad (3A.25)$$

Note: n orthogonal vectors in L^n are linearly independent and span L^n , and form a basis for L^n .

3A.5.8 Gram–Schmidt Orthogonalization

Given a set of vectors, $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$, that are linearly independent in L^n , we construct a set of orthonormal (orthogonal and normalized) vectors, $\hat{\mathbf{y}}_1, \hat{\mathbf{y}}_2, \dots, \hat{\mathbf{y}}_n$, which are linear combinations of $\hat{\mathbf{x}}_i$.

Start

$$\hat{\mathbf{y}}_1 = \hat{\mathbf{x}}_1 = \frac{\mathbf{x}_1}{\|\mathbf{x}_1\|}$$

Then

$$\mathbf{y}_i = \mathbf{x}_i - \sum_{j=1}^{i-1} (\mathbf{x}_i, \hat{\mathbf{y}}_j) \hat{\mathbf{y}}_j \quad \text{for } i = 1, 2, \dots, n$$

Normalize \mathbf{y}_i to produce $\hat{\mathbf{y}}_i$.

3A.5.9 Modified Gram–Schmidt Procedure

In each step, compute new vectors that are orthogonal to the just-computed vector.

Initialization:

$$\hat{\mathbf{y}}_1 = \frac{\mathbf{x}_1}{\|\mathbf{x}_1\|}$$

as before.

Then

$$\mathbf{x}_i^{(1)} = \mathbf{x}_i - (\hat{\mathbf{y}}_1, \mathbf{x}_i) \hat{\mathbf{y}}_1 \quad \text{for } i = 2, 3, \dots, n$$

$$\hat{\mathbf{y}}_i = \frac{\mathbf{x}_i^{(1)}}{\|\mathbf{x}_i^{(1)}\|} \quad \text{for } i = 2, 3, \dots, n$$

and

$$\mathbf{x}_i^{(2)} = \mathbf{x}_i^{(1)} - (\hat{\mathbf{y}}_2, \mathbf{x}_i^{(1)}) \hat{\mathbf{y}}_2, \quad i = 3, 4, \dots, n$$

and so on.

3A.6 Determinants

Now, let us address several analytical issues of the determinant of a square matrix. Consider the matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \\ a_{n1} & \cdots & a_{nn} \end{bmatrix}$$

The minor of $a_{ij} = M_{ij}$ = the determinant of matrix formed by deleting the i th row and the j th column of the original matrix.

The cofactor of $a_{ij} = C_{ij} = (-1)^{i+j} M_{ij}$

$\text{cof}(\mathbf{A})$ = cofactor matrix of \mathbf{A}

$\text{adj}(\mathbf{A})$ = adjoint $\mathbf{A} = (\text{cof } \mathbf{A})^T$

3A.6.1 Properties of Determinant of a Matrix

1. Interchange two rows (columns) \Rightarrow determinant's sign changes.
2. Multiply one row (column) by $\alpha \Rightarrow \alpha \det(\mathbf{A})$.
3. Add a $[\alpha \times \text{row}(\text{column})]$ to a second row(column) \Rightarrow determinant unchanged.
4. Identical rows(columns) \Rightarrow zero determinant.
5. For two square matrices \mathbf{A} and \mathbf{B} , $\det(\mathbf{AB}) = \det(\mathbf{A})\det(\mathbf{B})$.

3A.6.2 Rank of a Matrix

Rank \mathbf{A} = number of linearly independent columns = number of linearly independent rows = $\dim(\text{column space}) = \dim(\text{row space})$

Here “dim” denotes the “dimension of.”

3A.7 System of Linear Equations

Consider the following set of linear algebraic equations:

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= c_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= c_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= c_m \end{aligned}$$

We need to solve for x_1, x_2, \dots, x_n .

This problem can be expressed in the vector-matrix form:

$$\mathbf{A}_{m \times n} \mathbf{x}_n = \mathbf{c}_m \quad \mathbf{B} = [\mathbf{A}, \mathbf{c}]$$

A solution exists iff $\text{rank}[\mathbf{A}, \mathbf{c}] = \text{rank}[\mathbf{A}]$

Two cases can be considered:

Case 1:

If $m \geq n$ and $\text{rank}[\mathbf{A}] = n \Rightarrow$ unique solution for \mathbf{x} .

Case 2:

If $m \leq n$ and $\text{rank}[\mathbf{A}] = m \Rightarrow$ infinite number of solutions for \mathbf{x}

$$\mathbf{x} = \mathbf{A}^H (\mathbf{A} \mathbf{A}^H)^{-1} \mathbf{C} \Leftarrow \text{minimum norm form}$$

Specifically, out of the infinite possibilities, this is the solution that minimizes the norm, $\mathbf{x}^H \mathbf{x}$.

Note that the superscript H denotes the Hermitian transpose, which is the transpose of the complex conjugate of the matrix.

For example,

$$\mathbf{A} = \begin{bmatrix} 1+j & 2+3j & 6 \\ 3-j & 5 & -1-2j \end{bmatrix}$$

Then

$$\mathbf{A}^H = \begin{bmatrix} 1-j & 3+j \\ 2-3j & 5 \\ 6 & -1+2j \end{bmatrix}$$

If the matrix is real, its Hermitian transpose is simply the ordinary transpose.

In general, if $\text{rank}[\mathbf{A}] \leq n \Rightarrow$ infinite number of solutions.

The space formed by solutions $\mathbf{A}\mathbf{x} = 0 \Rightarrow$ is called the *null space*

$$\dim(\text{null space}) = n - k \text{ where } \text{rank}[\mathbf{A}] = k$$

3A.8 Quadratic Forms

Consider a vector, \mathbf{x} , and a square matrix, \mathbf{A} . Then the function $Q(\mathbf{x}) = (\mathbf{x}, \mathbf{A}\mathbf{x})$ is called a quadratic form.

For a real vector \mathbf{x} and a real and symmetric matrix \mathbf{A} ,

$$Q(\mathbf{x}) = \mathbf{x}^T \mathbf{A} \mathbf{x}$$

Positive definite matrix: If $(\mathbf{x}, \mathbf{A}\mathbf{x}) > 0$ for all $\mathbf{x} \neq 0$, then \mathbf{A} is said to be a positive definite matrix. Also, the corresponding quadratic form is also said to be positive definite.

Positive semidefinite matrix: If $(\mathbf{x}, \mathbf{Ax}) \geq 0$ for all $\mathbf{x} \neq 0$, then \mathbf{A} is said to be a positive semidefinite matrix. Note that in this case the quadratic form can assume a zero value for a nonzero \mathbf{x} . The corresponding quadratic form is also said to be positive semidefinite.

Negative definite matrix: If $(\mathbf{x}, \mathbf{Ax}) < 0$ for all $\mathbf{x} \neq 0$, then \mathbf{A} is said to be a negative definite matrix. The corresponding quadratic form is also said to be negative definite.

Negative semidefinite matrix: If $(\mathbf{x}, \mathbf{Ax}) \leq 0$ for all $\mathbf{x} \neq 0$, then \mathbf{A} is said to be a negative semidefinite matrix. Note that, in this case, the quadratic form can assume a zero value for a nonzero \mathbf{x} . The corresponding quadratic form is also said to be negative semidefinite.

Note: If \mathbf{A} is positive definite, then $-\mathbf{A}$ is negative definite. If \mathbf{A} is positive semidefinite, then $-\mathbf{A}$ is negative semidefinite.

Principal minors: Consider the matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & & & \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix}$$

Its principal minors are the determinants of the various matrices along the principal diagonal, as given by

$$\Delta_1 = a_{11}, \quad \Delta_2 = \det \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}, \quad \Delta_3 = \det \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}, \text{ and so on}$$

Sylvester's theorem: A matrix is positive if definite if all its principal minors are positive.

3A.9 Matrix Eigenvalue Problem

3A.9.1 Characteristic Polynomial

Consider a square matrix \mathbf{A} . The polynomial

$$\Delta(s) = \det[s\mathbf{I} - \mathbf{A}]$$

is called the characteristic polynomial of \mathbf{A} .

3A.9.2 Characteristic Equation

The polynomial equation

$$\Delta(s) = \det[s\mathbf{I} - \mathbf{A}] = 0$$

is called the characteristic equation of the square matrix \mathbf{A} .

3A.9.3 Eigenvalues

The roots of the characteristic equation of a square matrix \mathbf{A} are the eigenvalues of \mathbf{A} . For an $n \times n$ matrix, there will be n eigenvalues.

3A.9.4 Eigenvectors

The eigenvalue problem of a square matrix \mathbf{A} is given by

$$\mathbf{Av} = \lambda \mathbf{v}$$

where the objective is to solve for λ and the corresponding nontrivial (i.e., nonzero) solutions for \mathbf{v} . The problem can be expressed as

$$(\lambda \mathbf{I} - \mathbf{A})\mathbf{v} = 0$$

Note: If \mathbf{v} is a solution of this equation, then any multiple of it, $a\mathbf{v}$, is also a solution. Hence, an eigenvector is arbitrary up to a multiplication factor.

For a nontrivial (i.e., nonzero) solution to be possible for \mathbf{v} , one must have

$$\det[\lambda \mathbf{I} - \mathbf{A}] = 0$$

Since this is the characteristic equation of \mathbf{A} , as defined above, it is clear that the roots of λ are the eigenvalues of \mathbf{A} . The corresponding solutions for \mathbf{v} are the eigenvectors of \mathbf{A} . For an $n \times n$ matrix, there will be n eigenvalues and n corresponding eigenvectors.

3A.10 Matrix Transformations

3A.10.1 Similarity Transformation

Consider a square matrix, \mathbf{A} , and a nonsingular square matrix, \mathbf{T} . Then, the matrix obtained according to

$$\mathbf{B} = \mathbf{T}^{-1}\mathbf{A}\mathbf{T}$$

is the similarity transformation of \mathbf{A} by \mathbf{T} . The transformed matrix \mathbf{B} has the same eigenvalues as the original matrix \mathbf{A} . Also, \mathbf{A} and \mathbf{B} are said to be similar.

3A.10.2 Orthogonal Transformation

Consider a square matrix \mathbf{A} and another square matrix \mathbf{T} . Then, the matrix obtained according to

$$\mathbf{B} = \mathbf{T}^T\mathbf{A}\mathbf{T}$$

is the orthogonal transformation of \mathbf{A} by \mathbf{T} .

If $\mathbf{T}^{-1} = \mathbf{T}^T$ then the matrix \mathbf{T} is said to be an orthogonal matrix. In this case, the similarity transformation and the orthogonal transformation become identical.

3A.11 Matrix Exponential

The matrix exponential is given by the infinite series

$$\exp(\mathbf{A}t) = \mathbf{I} + \mathbf{A}t + \frac{1}{2!}\mathbf{A}^2t^2 + \cdots \quad (3A.26)$$

exactly like the scalar exponential

$$\exp(\lambda t) = 1 + \lambda t + \frac{1}{2!}\lambda^2t^2 + \cdots \quad (3A.27)$$

The matrix exponential may be determined by reducing the infinite series given in Equation 3A.26 into a finite matrix polynomial of order $n - 1$ (where, \mathbf{A} is $n \times n$) by using the Cayley–Hamilton theorem.

3A.11.1 Cayley–Hamilton Theorem

This theorem states that a matrix satisfies its own characteristic equation. The characteristic polynomial of \mathbf{A} can be expressed as

$$\Delta(\lambda) = \det(\mathbf{A} - \lambda \mathbf{I}) = a_n\lambda^n + a_{n-1}\lambda^{n-1} + \cdots + a_0 \quad (3A.28)$$

in which $\det(\cdot)$ denotes determinant. The notation

$$\Delta(\mathbf{A}) = a_n \mathbf{A}^n + a_{n-1} \mathbf{A}^{n-1} + \cdots + a_0 \mathbf{I} \quad (3A.29)$$

is used. Then, by the Cayley–Hamilton theorem, we have

$$0 = a_n \mathbf{A}^n + a_{n-1} \mathbf{A}^{n-1} + \cdots + a_0 \mathbf{I} \quad (3A.30)$$

3A.11.2 Computation of Matrix Exponential

Using the Cayley–Hamilton theorem, we can obtain a finite polynomial expansion for $\exp(\mathbf{A}t)$. First, we express Equation 3A.26 and Equation 3A.27 as

$$\exp(\mathbf{A}t) = S(\mathbf{A}) \cdot \Delta(\mathbf{A}) + \alpha_{n-1} \mathbf{A}^{n-1} + \alpha_{n-2} \mathbf{A}^{n-2} + \cdots + \alpha_0 \mathbf{I} \quad (3A.31)$$

$$\exp(\lambda t) = S(\lambda) \cdot \Delta(\lambda) + \alpha_{n-1} \lambda^{n-1} + \alpha_{n-2} \lambda^{n-2} + \cdots + \alpha_0 \quad (3A.32)$$

in which $S(\cdot)$ is an appropriate infinite series, which is the result of dividing the exponential (infinite) series by the characteristic polynomial $\Delta(\cdot)$.

Next, since $\Delta(\mathbf{A}) = 0$ by the Cayley–Hamilton theorem, Equation 3A.31 becomes

$$\exp(\mathbf{A}t) = \alpha_{n-1} \mathbf{A}^{n-1} + \alpha_{n-2} \mathbf{A}^{n-2} + \cdots + \alpha_0 \mathbf{I} \quad (3A.33)$$

Now it is just a matter of determining the coefficients, $\alpha_0, \alpha_1, \dots, \alpha_{n-1}$, which are functions of time. This is done as follows. If $\lambda_1, \lambda_2, \dots, \lambda_n$ are the eigenvalues of \mathbf{A} , however, then, by definition

$$\Delta(\lambda_i) = \det(\mathbf{A} - \lambda_i \mathbf{I}) = 0 \quad \text{for } i = 1, 2, \dots, n \quad (3A.34)$$

Thus, from Equation 3A.32, we obtain

$$\exp(\lambda_i t) = \alpha_{n-1} \lambda_i^{n-1} + \alpha_{n-2} \lambda_i^{n-2} + \cdots + \alpha_0 \quad \text{for } i = 1, 2, \dots, n \quad (3A.35)$$

If the eigenvalues are all distinct, Equation 3A.35 represents a set of n independent algebraic equations from which the n unknowns $\alpha_0, \alpha_1, \dots, \alpha_{n-1}$ could be determined. If some eigenvalues are repeated, the derivatives of the corresponding equations (Equation 3A.35) have to be used as well.

Summary

This chapter presents the analysis of continuous (or distributed-parameter) mechanical vibrating systems. In these systems, inertial, elastic, and dissipative effects are found continuously distributed in one, two, or three dimensions. Examples such as strings, rods, shafts, beams, membranes, and plates are studied. Modal analysis is carried out using the separation of time and space. The orthogonality property of mode shapes is established. Boundary conditions are derived. Free vibration and forced vibration are analyzed.

4.1 Introduction

Often in vibration analysis, it is assumed that inertial (mass), flexibility (spring), and dissipative (damping) characteristics can be “lumped” as a finite number of “discrete” elements. Such models are termed *lumped-parameter* or *discrete-parameter* systems. Generally, in practical vibrating systems, inertial, elastic, and dissipative effects are found continuously distributed in one, two, or three dimensions. Correspondingly,

we have line structures, surface/planar structures, or spatial structures. They will possess an infinite number of mass elements, continuously distributed in the structure, and integrated with some connecting flexibility (elasticity) and energy dissipation. In view of the connecting flexibility, each small element of mass will be able to move out of phase (or somewhat independently) with the remaining mass elements. It follows that a *continuous system* (or a distributed-parameter system) will have an infinite number of degrees of freedom (DoFs) and will require an infinite number of coordinates to represent its motion. In other words, extending the concept of a finite-degree-of-freedom system as analyzed previously, an infinite-dimensional vector is needed to represent the general motion of a continuous system. Equivalently, a one-dimensional continuous system (a line structure) will need one independent spatial variable, in addition to time, to represent its response. In view of the need for two independent variables in this case, one for time and the other for space, the representation of system dynamics will require partial differential equations (PDEs) rather than ordinary differential equations (ODEs). Furthermore, the system will depend on the boundary conditions as well as the initial conditions.

Strings, cables, rods, shafts, beams, membranes, plates, and shells are example of continuous members. In special cases, closed-form analytical solutions can be obtained for the vibration of these members. A general structure may consist of more than one such member, and furthermore, boundary conditions (BCs) could be various, individual members may be *nonuniform*, and the material characteristics may be *inhomogeneous* and *anisotropic*. Closed-form analytical solutions would not be generally possible in such cases. Nevertheless, the insight gained by analyzing the vibration of standard members will be quite beneficial in studying the vibration behavior of more complex structures.

The concepts of modal analysis may be extended from lumped-parameter systems to continuous systems. In particular, since the number of principal modes is equal to the number of DoFs of the system, a distributed-parameter system will have an infinite number of natural modes of vibration. A particular mode may be excited by deflecting the member so that its *elastic curve* assumes the shape of the particular mode, and then releasing from this initial condition. When damping is significant and nonproportional, however, there is no guarantee that such an initial condition could accurately excite the required mode. A general excitation consisting of a force or an initial condition will excite more than one mode of motion. However, as in the case of discrete-parameter systems, the general motion may be analyzed and expressed in terms of modal motions, through modal analysis. In a modal motion, the mass elements will move at a specific frequency (the natural frequency), and bearing a constant proportion in displacement (i.e., maintaining the mode shape), and passing the static equilibrium of the system simultaneously. In view of this behavior, it is possible to separate the time response and spatial response of a vibrating system in a modal motion. This *separability* is fundamental to modal analysis of a continuous system. Furthermore, in practice an infinite number of natural frequencies and mode shapes are not significant and typically the very high modes may be neglected. Such a modal-truncation procedure, even though carried out by continuous-system analysis, is equivalent to approximating the original infinite-degree-of-freedom system by a finite-degree-of-freedom one. Vibration analysis of continuous systems may be applied in the modeling, analysis, design, and evaluation of such practical systems as cables; musical instruments; transmission belts and chains; containers of fluid; animals; structures including buildings, bridges, guideways, and space stations; and transit vehicles, including automobiles, ships, aircraft, and spacecraft.

4.2 Transverse Vibration of Cables

The first continuous member which we will study is a string or cable in tension. This is a line structure whose geometric configuration can be completely defined by the position of its axial line with reference to a fixed coordinate line. We will study the transverse (lateral) vibration problem; that is, the vibration in a direction perpendicular to its axis and in a single plane. Applications will include stringed musical instruments, overhead transmission lines (of electric power or telephone signals), drive systems (belt drives, chain drives, pulley ropes, etc.), suspension bridges, and structural cables carrying cars (e.g., ski lifts, elevators, overhead sightseeing systems, and cable cars).

As usual, we will make some simplifying assumptions for analytical convenience. However, the results and insight obtained in this manner will be useful in understanding the behavior of more complex systems containing cable-like structures. The main assumptions are:

1. The system is a line structure. The lateral dimensions are much smaller compared with the longitudinal dimension (normally in the x direction).
2. The structure stays in a single plane and the motion of every element of the structure will be in a fixed transverse direction (y).
3. The cable tension (T) remains constant during motion. In other words, the initial tension is sufficiently large that the variations during motion are negligible.
4. Variations in slope (θ) along the structure are small. Hence, for example, $\theta \cong \sin \theta \cong \tan \theta = \frac{\partial v}{\partial x}$.

A general configuration of a cable (or string) is shown in Figure 4.1(a). Consider a small element of length dx of the cable at location x , as shown in Figure 4.1(b). The equation (Newton's Second Law) of motion (transverse) of this element is given by

$$f(x,t)dx - T \sin \theta + T \sin(\theta + d\theta) = m(x)dx \frac{\partial^2 v(x,t)}{\partial t^2} \quad (4.1)$$

in which

$v(x,t)$ = transverse displacement of the cable

$f(x,t)$ = lateral force per unit length of cable

$m(x)$ = mass per unit length of cable

T = cable tension

θ = cable slope at location x .

Note that the dynamic loading $f(x,t)$ may arise due to such causes as aerodynamic forces, fluid drag, and electromagnetic forces, depending on the specific application.

FIGURE 4.1 (a) Transverse vibration of a cable in tension; (b) motion of a general element.

Using the small slope assumption we have $\sin \theta \cong \theta$ and $\sin(\theta + d\theta) \cong \theta + d\theta$ with $\theta = \partial v / \partial x$ and $d\theta = (\partial^2 v / \partial x^2) dx$ as $dx \rightarrow 0$. On substitution of these approximations into Equation 4.1 and canceling out dx , we obtain

$$m(x) \frac{\partial^2 v(x, t)}{\partial t^2} = T \frac{\partial^2 v(x, t)}{\partial x^2} + f(x, t) \quad (4.2)$$

Now consider the case of free vibration where $f(x, t) = 0$. We have

$$\frac{\partial^2 v(x, t)}{\partial t^2} = c^2 \frac{\partial^2 v(x, t)}{\partial x^2} \quad (4.3)$$

with

$$c = \sqrt{T/m} \quad (4.4)$$

Also, assume that the cable is uniform so that m is constant.

4.2.1 Wave Equation

The solution to any equation of the form (Equation 4.3) will appear as a wave, traveling either in the forward (positive x) or in the backward (negative x) direction at speed c . Hence, Equation 4.3 is called the wave equation and c is the *wave speed*. To prove this fact, first, we show that a solution to Equation 4.3 can take the form

$$v(x, t) = v_1(x - ct) \quad (4.5)$$

First, let $x - ct = z$. Hence, $v_1(x - ct) = v_1(z)$. Then,

$$\frac{\partial v_1}{\partial x} = \frac{dv_1}{dz} \frac{\partial z}{\partial x} \quad \text{and} \quad \frac{\partial v_1}{\partial t} = \frac{dv_1}{dz} \frac{\partial z}{\partial t}$$

with

$$\frac{\partial z}{\partial x} = 1 \quad \text{and} \quad \frac{\partial z}{\partial t} = -c$$

It follows that

$$\frac{\partial^2 v_1}{\partial x^2} = v_1'' \quad \text{and} \quad \frac{\partial^2 v_1}{\partial t^2} = c^2 v_1''$$

where

$$v_1'' = \frac{d^2 v_1}{dz^2}$$

Clearly, then, v_1 satisfies Equation 4.3.

Now, let us examine the nature of the solution $v_1(x - ct)$. It is clear that v_1 will be constant when $x - ct = \text{constant}$. However, the equation $x - ct = \text{constant}$ corresponds to a point moving along the x axis in the positive direction at speed c . What this means is that the shape of the cable at $t = 0$ will “appear” to travel along the cable at speed c . This is analogous to the waves we observe in a pond when excited by dropping a stone. Note that the particles of the cable do not travel along x : it is the deformation “shape” (the wave) that travels.

Similarly, it can be shown that

$$v(x, t) = v_2(x + ct) \quad (4.6)$$

is also a solution to Equation 4.3 and this corresponds to a wave that travels backward (negative x direction) at speed c . The general solution, of course, will be of the form

$$v(x, t) = v_1(x - ct) + v_2(x + ct) \quad (4.7)$$

which represents two waves, one traveling forward and the other backward.

4.2.2 General (Modal) Solution

As usual, we look for a separable solution of the form

$$v(x, t) = Y(x)q(t) \quad (4.8)$$

for the cable/string vibration problem given by the wave equation 4.3. If a solution in the form of Equation 4.8 is obtained, it will be essentially a modal solution. This should be clear from the *separability* itself of the solution. Specifically, at any given time t , the time function $q(t)$ will be fixed and the structure will have a shape given by $Y(x)$. Hence, at all times the structure will maintain a particular shape $Y(x)$ and this will be a *mode shape*. Also, at a given point x of the structure, the space function $Y(x)$ will be fixed and the structure will vibrate according to the time response $q(t)$. It will be shown that $q(t)$ will obey the simple harmonic motion of a specific frequency. This is the *natural frequency* of vibration corresponding to that particular mode. Note that, for a continuous system, there will be an infinite number of solutions of the form of Equation 4.8 with different natural frequencies. The corresponding functions $Y(x)$ will be “orthogonal” in some sense. Hence, they are called *normal modes* (normal meaning *perpendicular*). The systems will be able to move independently in each mode and this collection of solutions in the form of Equation 4.8 will be a complete set. With this qualitative understanding, let us now seek a solution of the form of Equation 4.8 for the system Equation 4.3.

Substitute Equation 4.8 in Equation 4.3. We obtain

$$Y(x) \frac{d^2 q(t)}{dt^2} = c^2 \frac{d^2 Y(x)}{dx^2} q(t)$$

or

$$\frac{1}{Y(x)} \frac{d^2 Y(x)}{dx^2} = \frac{1}{c^2 q(t)} \frac{d^2 q(t)}{dt^2} = -\lambda^2 \quad (4.9)$$

In Equation 4.9, since the left-hand terms are a function of x only and the right-hand terms are a function of t only, for the two sides to be equal in general, each function should be a constant (that is independent of both x and t). This constant is denoted by $-\lambda^2$, which is called the separation constant and is designated to be negative. There are two reasons for this. If this common constant were positive, the function $q(t)$ would be nonoscillatory and transient, which is contrary to the nature of undamped vibration. Furthermore, it can be shown that a nontrivial solution for $Y(x)$ would not be possible if the common constant were positive.

The unknown constant λ is determined by solving the space equation (mode shape equation) of Equation 4.9; specifically

$$\frac{d^2 Y(x)}{dx^2} + \lambda^2 Y(x) = 0 \quad (4.10)$$

and then applying the BCs of the problem. There will be an infinite number of solutions for λ , with corresponding natural frequencies ω and mode shapes $Y(x)$.

The characteristic equation of 4.10 is

$$p^2 + \lambda^2 = 0 \quad (4.11)$$

which has the *characteristic roots* (or *eigenvalues*)

$$p = \pm j\lambda \quad (4.12)$$

The general solution is

$$Y(x) = A_1 e^{j\lambda x} + A_2 e^{-j\lambda x} = C_1 \cos \lambda x + C_2 \sin \lambda x \quad (4.13)$$

Note that, since $Y(x)$ is a real function representing a geometric shape, the constants A_1 and A_2 have to be complex conjugates and C_1 and C_2 have to be real. Specifically, in view of the fact that $\cos \lambda x = (e^{j\lambda x} + e^{-j\lambda x})/2$ and $\sin \lambda x = (e^{j\lambda x} - e^{-j\lambda x})/2j$, we can show that

$$A_1 = \frac{1}{2}(C_1 - jC_2) \quad \text{and} \quad A_2 = \frac{1}{2}(C_1 + jC_2)$$

For analytical convenience, we will use the real-parameter form of Equation 4.13.

Note that we cannot determine both constants C_1 and C_2 using BCs. Only their ratio is determined and the constant multiplier is absorbed into $q(t)$ in Equation 4.8 and then determined using the appropriate initial conditions (at $t = 0$). It follows that the ratio of C_1 and C_2 and the value of λ are determined using the BCs. Two BCs will be needed. Some useful situations and appropriate relations are given in Table 4.1.

4.2.3 Cable with Fixed Ends

Let us obtain the complete solution for the free vibration of a taut cable that is fixed at both ends. The applicable BCs are

$$Y(0) = Y(l) = 0 \quad (4.14)$$

where l is the length of the cable. Substitution into Equation 4.13 gives

$$\begin{aligned} C_1 \times 1 + C_2 \times 0 &= 0 \\ C_1 \cos \lambda l + C_2 \sin \lambda l &= 0 \end{aligned}$$

Hence, we have

$$C_1 = 0 \quad \text{and} \quad C_2 \sin \lambda l = 0 \quad (4.15)$$

A possible solution for Equation 4.15 is $C_2 = 0$. However, this is the *trivial solution*, which corresponds to $Y(x) = 0$ (i.e., a stationary cable with no vibration). It follows that the applicable, nontrivial solution is

$$\sin \lambda l = 0$$

which produces an *infinite* number of solutions for λ given by

$$\lambda_i = \frac{i\pi}{l} \quad \text{with } i = 1, 2, \dots, \infty \quad (4.16)$$

As mentioned earlier, the corresponding infinite number of mode shapes is given by

$$Y_i(x) = C_i \sin \frac{i\pi x}{l} \quad (4.17)$$

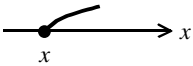

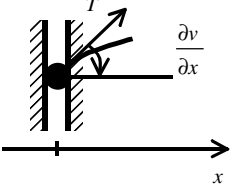

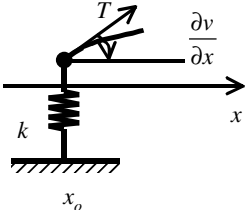

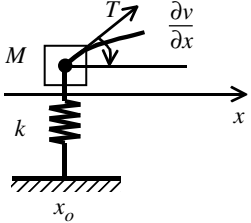

Note: If we had used a positive constant λ^2 instead of $-\lambda^2$ in Equation 4.9, only a trivial solution (with $C_1 = 0$ and $C_2 = 0$) would be possible for $Y(x)$. This further justifies our decision to use $-\lambda^2$. Substitute Equation 4.16 into Equation 4.9 to determine the corresponding time response (generalized coordinates) $q_i(t)$; thus

$$\frac{d^2 q_i(t)}{dt^2} + \omega_i^2 q_i(t) = 0 \quad (4.18)$$

in which

$$\omega_i = \lambda_i c = \frac{i\pi}{l} \sqrt{\frac{T}{m}} \quad \text{for } i = 1, 2, \dots, \infty \quad (4.19)$$

TABLE 4.1 Some Useful Boundary Conditions for the Cable Vibration Problem

Type of End Condition	Nature of End $x = x_0$	Boundary Condition	Modal Boundary Condition
Fixed		$v(x_0, t) = 0$	$Y_i(x_0) = 0$
Free		$T \frac{\partial v(x_0, t)}{\partial x} = 0$	$\frac{dY_i(x_0)}{dx} = 0$
Flexible		$T \frac{\partial v(x_0, t)}{\partial x} - kv(x_0, t) = 0$	$T \frac{dY_i(x_0)}{dx} - kY_i(x_0) = 0$
Flexible and inertial		$T \frac{\partial v(x_0, t)}{\partial x} - kv(x_0, t) = M \frac{\partial^2 v(x_0, t)}{\partial t^2}$	$T \frac{dY_i(x_0)}{dx} - (k - \omega_i^2 M)Y_i(x_0) = 0$

Equation 4.18 represents a simple harmonic motion with the *modal natural frequencies* ω_i given by Equation 4.19. It follows that there are an infinite number of natural frequencies, as mentioned earlier. The general solution of Equation 4.19 is given by

$$q_i(t) = c_i \sin(\omega_i t + \phi_i) \quad (4.20)$$

where the amplitude parameter c_i and the phase parameter ϕ_i are determined using two of the initial conditions of the system. It should be clear that it is redundant to use a separate constant C_i for $Y_i(x)$ in Equation 4.17, and that this may be absorbed into the amplitude constant in Equation 4.20 to express the general free response of the cable as

$$v(x, t) = \sum c_i \sin \frac{i\pi x}{l} \sin(\omega_i t + \phi_i) \quad (4.21)$$

In this manner, the complete solution has been expressed as a summation of the modal solutions. This is known as the modal series expansion. Such a solution is quite justified because of the fact that the mode shapes are *orthogonal* in some sense, and what we obtained above were a complete set of *normal modes* (normal in the sense of perpendicular or orthogonal). The system is able to move in each mode independently, with a unique spatial shape, at the corresponding natural frequency, because each modal solution is separable into a space function, $Y_i(x)$, and a time function (generalized coordinate), $q_i(t)$. Of course, the system will be able to simultaneously move in a linear combination of two modes (say, $C_1 Y_1(x)q_1(t) + C_2 Y_2(x)q_2(t)$), since this combination satisfies the original system Equation 4.3 because of its linearity and because each modal component satisfies the equation. However, clearly, this solution, with two modes, is not separable into a product of a space function and a time function. Hence, it is not a modal solution. In this manner, it can be argued that the infinite sum of modal solutions $\sum c_i Y_i(x)q_i(t)$ is the most general solution to the system (Equation 4.3). The orthogonality of mode shapes plays a key role in this argument and, furthermore, it is useful in the analysis of the system, as we shall see. In particular, in Equation 4.21, the unknown constants c_i and ϕ_i are determined using the system initial conditions, and the orthogonality property of modes is useful in that procedure.

4.2.4 Orthogonality of Natural Modes

A cable can vibrate at frequency ω_i while maintaining a unique natural shape $Y_i(x)$, called the mode shape of the cable. We have shown that, for the fixed-ended cable, the natural mode shapes are given by $\sin(i\pi x/l)$ with the corresponding natural frequencies, ω_i . It can be easily verified that

$$\int_0^l \sin \frac{i\pi x}{l} \sin \frac{j\pi x}{l} dx = \begin{cases} 0 & \text{for } i \neq j \\ \frac{l}{2} & \text{for } i = j \end{cases} \quad (4.22)$$

In other words, the natural modes are orthogonal. Equation 4.22 represents the principle of orthogonality of natural modes in this case.

Orthogonality makes the modal solutions independent and the corresponding mode shapes “normal.” It also makes the infinite set of modal solutions a complete set, or a *basis*, so that any arbitrary response can be formed as a linear combination of these normal mode solutions.

Orthogonality holds for other types of BCs as well. To show this, we observe from Equation 4.9 that

$$\frac{d^2 Y_i(x)}{dx^2} + \lambda_i^2 Y_i(x) = 0 \quad \text{for mode } i \quad (4.23)$$

$$\frac{d^2 Y_j(x)}{dx^2} + \lambda_j^2 Y_j(x) = 0 \quad \text{for mode } j \quad (4.24)$$

Multiply Equation 4.23 by $Y_j(x)$, Equation 4.24 by $Y_i(x)$, subtract that second result from the first, and integrate with respect to x along the cable length from $x = 0$ to l . We obtain

$$\int_0^l \left[Y_j \frac{d^2 Y_i}{dx^2} - Y_i \frac{d^2 Y_j}{dx^2} \right] dx + (\lambda_i^2 - \lambda_j^2) \int_0^l Y_i Y_j dx = 0 \quad (4.25)$$

Integrating by parts, we obtain the results

$$\begin{aligned} \int_0^l Y_j \frac{d^2 Y_i}{dx^2} dx &= Y_j \frac{dY_i}{dx} \Big|_0^l - \int_0^l \frac{dY_i}{dx} \frac{dY_j}{dx} dx \\ \int_0^l Y_i \frac{d^2 Y_j}{dx^2} dx &= Y_i \frac{dY_j}{dx} \Big|_0^l - \int_0^l \frac{dY_j}{dx} \frac{dY_i}{dx} dx \end{aligned}$$

Hence, the first term of Equation 4.25 becomes

$$\left[Y_j \frac{dY_i}{dx} - Y_i \frac{dY_j}{dx} \right]_0^l$$

which will vanish for common BCs. Then, since $\lambda_i \neq \lambda_j$ for $i \neq j$, we have

$$\int_0^l Y_i(x) Y_j(x) dx = 0 \quad \text{for } i \neq j$$

We can pick the value of the multiplication constant in the general solution for $Y(x)$, given by Equation 4.13, so as to *normalize* the mode shapes such that

$$\int_0^l Y_i^2(x) dx = \frac{l}{2}$$

which is consistent with the result 4.22. Hence, the general condition of orthogonality of natural modes may be expressed as

$$\int_0^l Y_i(x) Y_j(x) dx = \begin{cases} 0 & \text{for } i \neq j \\ \frac{l}{2} & \text{for } i = j \end{cases} \quad (4.26)$$

4.2.4.1 Nodes

When vibrating in a particular mode, one or more points of the system (cable) that are not physically fixed may remain stationary at all times. These points are called the *nodes* of that mode. For example, in the second mode of a cable with its ends fixed, there will be a node at the midspan. This should be clear from the fact that the mode shape of the second mode is $\sin 2\pi x/l$ which becomes zero at $x = l/2$. Similarly, in the third mode, with mode shape $\sin 3\pi x/l$, there will be nodes at $x = l/3$ and $2l/3$.

Example 4.1

If the cable tension varies along the length x , what is the corresponding equation of free lateral vibration? A hoist mechanism has a rope of freely hanging length l in a particular equilibrium configuration and carrying a load of mass M , as shown in Figure 4.2(a). Determine the equation of lateral vibration and the applicable BCs for the rope segment.

Solution

With reference to Figure 4.1(b), Equation 4.1 may be modified for the case of variable T as

$$-T \sin \theta + (T + dT) \sin(\theta + d\theta) = m dx \frac{\partial^2 v}{\partial t^2} \quad (4.27)$$

where $f(x, t) = 0$ for free vibration. Now, with the assumption of small θ , and by neglecting the second-order product term $dT d\theta$, we obtain

$$T d\theta + \theta dT = m \frac{\partial^2 v}{\partial x^2} dx$$

Next, using

$$\theta = \frac{\partial v}{\partial x}, \quad d\theta = \frac{\partial^2 v}{\partial x^2} dx, \quad \text{and} \quad dT = \frac{\partial T}{\partial x} dx$$

and canceling dx , we obtain the equation of lateral vibration of a cable as

$$m \frac{\partial^2 v}{\partial t^2} = T \frac{\partial^2 v}{\partial x^2} + \frac{\partial T}{\partial x} \frac{\partial v}{\partial x} \quad (4.28)$$

Longitudinal (axial) dynamics of the rope are negligible for the case of a stationary hoist. Then, longitudinal equilibrium (in the x direction) of the small element of rope shown in Figure 4.2(b) gives

$$(T + dT) \cos(\theta + d\theta) - T \cos \theta - mg dx = 0$$

For small θ , we have $\cos \theta \cong 1$ and $\cos(\theta + d\theta) \cong 1$ up to the first-order term in the Taylor series expansion. Hence,

$$dT = mg dx \quad (4.29)$$

Integration gives

$$T = T_0 + mgx \quad (4.30)$$

with the end condition

$$T = Mg \quad \text{at} \quad x = 0$$

Hence,

$$T = Mg + mgx \quad (4.31)$$

Note from Equation 4.29 that $\partial T / \partial x = dT / dx = mg$ for this problem. Substitute in (Equation 4.28) this fact and Equation 4.31 to obtain

$$m \frac{\partial^2 v}{\partial t^2} = (M + mx)g \frac{\partial^2 v}{\partial x^2} + mg \frac{\partial v}{\partial x}$$

or

$$\frac{\partial^2 v}{\partial t^2} = \left(\frac{M}{m} + x \right) g \frac{\partial^2 v}{\partial x^2} + g \frac{\partial v}{\partial x} \quad (4.32)$$

The BC at $x = 0$ is obtained by applying Newton's Second Law to the end mass in the lateral (y) direction. This gives

$$T_0 \frac{\partial v(0, t)}{\partial x} = M \frac{\partial^2 v(0, t)}{\partial t^2}$$

Now, using the fact that $T_0 = Mg$, we have the boundary condition

$$g \frac{\partial v(0, t)}{\partial x} = \frac{\partial^2 v(0, t)}{\partial t^2}$$

FIGURE 4.2 (a) Free segment of a stationary hoist; (b) a small element of the rope.

For mode i :

$$\frac{\partial v(0, t)}{\partial x} = \frac{dY_i(0)}{dx} q_i(t)$$

and

$$\frac{\partial^2 v(0, t)}{\partial t^2} = Y_i(0) \frac{d^2 q_i(t)}{dt^2} = -\omega_i^2 Y_i(0) q_i(t)$$

which holds for all t and where ω_i is the i th natural frequency of vibration. Hence, the modal BC at $x = 0$ is

$$g \frac{dY_i(0)}{dx} + \omega_i^2 Y_i(0) = 0 \quad \text{for } i = 1, 2, \dots \quad (4.33)$$

The BC at $x = l$ is

$$v(l, t) = 0 \quad (4.34)$$

which holds for all t . Hence, the corresponding modal BC is

$$Y_i(l) = 0 \quad \text{for } i = 1, 2, \dots \quad (4.35)$$

4.2.5 Application of Initial Conditions

The general solution to the cable vibration problem is given by

$$v(x, t) = \sum c_i Y_i(x) \sin(\omega_i t + \phi_i) \quad (4.36)$$

where $Y_i(x)$ are the *normalized* mode shapes which satisfy the orthogonality property (Equation 4.26). The unknown constants c_i and ϕ_i are determined using the initial conditions

$$v(x, 0) = d(x) \quad (4.37)$$

$$\frac{\partial v(x, 0)}{\partial t} = s(x) \quad (4.38)$$

By substituting Equation 4.36 into Equation 4.37 and Equation 4.38, we obtain

$$d(x) = \sum c_i Y_i(x) \sin \phi_i \quad (4.39)$$

$$s(x) = \sum c_i \omega_i Y_i(x) \cos \phi_i \quad (4.40)$$

Multiply Equation 4.39 and Equation 4.40 by $Y_j(x)$ and integrate with respect to x from 0 to l , making use of the orthogonality condition (Equation 4.26). We obtain

$$\int_0^l d(x) Y_j(x) dx = c_j \frac{l}{2} \sin \phi_j$$

$$\int_0^l s(x) Y_j(x) dx = c_j \omega_j \frac{l}{2} \cos \phi_j$$

Solving these two equations, we obtain

$$\tan \phi_j = \omega_j \frac{\int_0^l d(x) Y_j(x) dx}{\int_0^l s(x) Y_j(x) dx} \quad \text{for } j = 1, 2, 3, \dots \quad (4.41)$$

Once ϕ_j is determined in this manner, we can obtain c_j by using

$$c_j = \frac{2}{l \sin \phi_j} \int_0^l d(x) Y_j(x) dx \quad \text{for } j = 1, 2, 3, \dots \quad (4.42)$$

Example 4.2

Consider a taut horizontal cable of length l and mass m per unit length, as shown in Figure 4.3, excited by a transverse point force $f_0 \sin \omega t$ at location $x = a$, where ω is the frequency of (harmonic) excitation and f_0 is the forcing amplitude. Determine the resulting response of the cable under general end conditions and initial conditions. For the special case of fixed ends, what is the steady-state response of the cable?

FIGURE 4.3 A cable excited by a point harmonic force.

Solution

We have shown that the forced transverse response of a cable is given by Equation 4.2:

$$\frac{\partial^2 v(x, t)}{\partial t^2} = c^2 \frac{\partial^2 v(x, t)}{\partial x^2} + \frac{f(x, t)}{m} \quad (4.2)$$

where $v(x, t)$ is the transverse displacement and $f(x, t)$ is the external force per unit length of the cable. For the point force F at $x = a$, an analytical representation of the equivalent distributed force per unit length is

$$f(x, t) = F \delta(x - a) \quad (4.43)$$

where the Dirac delta function (unit impulse function) $\delta(x)$ is such that

$$\int_{a_1}^{a_2} g(x) \delta(x - a) dx = g(a) \quad (i)$$

for an arbitrary function $g(x)$, provided that the point a is within the interval of integration $[a_1, a_2]$. We seek a “modal superposition” solution of the form

$$v(x, t) = \sum Y_i(x) \bar{q}_i(t) \quad (4.44)$$

where $\bar{q}_i(t)$ are the generalized coordinates of the forced response solution (which are generally different from those for the free solution; i.e., $q_i(t)$).

Substitute the solution (Equation 4.44) into the system Equation 4.2 and make use of the governing equation of the mode shapes (see Equation 4.10)

$$\frac{d^2 Y_i(x)}{dx^2} = -\lambda_i^2 Y_i(x) \quad (4.45)$$

we obtain

$$m \sum Y_i(x) \ddot{\bar{q}}_i(t) = -T \sum \lambda_i^2 Y_i(x) \bar{q}_i(t) + f_0 \sin \omega t \delta(x - a) \quad (ii)$$

Multiply Equation (ii) by $Y_j(x)$, and integrate from $x = 0$ to l using the orthogonality property (Equation 4.26) and also Equation (i). We obtain

$$m \frac{l}{2} \ddot{\bar{q}}_i(t) = -T \frac{l}{2} \lambda_j^2 \bar{q}_j(t) + f_0 Y_j(a) \sin \omega t$$

Now since $\omega_j = \lambda_j \sqrt{T/m}$ (see Equation 4.19), we obtain

$$\ddot{q}_j(t) + \omega_j^2 \bar{q}_j(t) = \frac{2f_0}{lm} Y_j(a) \sin \omega t \quad \text{for } j = 1, 2, 3, \dots \quad (4.46)$$

This has the familiar form of a simple oscillator excited by a harmonic force and its solution is well known. The initial conditions $\bar{q}_j(0)$ and $\dot{\bar{q}}_j(0)$ are needed. Suppose that the initial transverse displacement and the speed of the cable are

$$v(x, 0) = d(x) \quad \text{and} \quad \dot{v}(x, 0) = s(x)$$

Then, in view of Equation 4.45, we can write

$$\sum Y_i(x) \bar{q}_i(0) = d(x) \quad (4.47)$$

$$\sum Y_i(x) \dot{\bar{q}}_i(0) = s(x) \quad (4.48)$$

Multiply Equation 4.47 and Equation 4.48 by $Y_j(x)$, and integrate from $x = 0$ to l using the orthogonality property 4.26. We obtain the necessary initial conditions

$$\bar{q}_j(0) = \frac{2}{l} \int_0^l d(x) Y_j(x) dx \quad (4.49)$$

$$\dot{\bar{q}}_j(0) = \frac{2}{l} \int_0^l s(x) Y_j(x) dx \quad (4.50)$$

which will provide the complete solution for Equation 4.46 and hence will completely determine Equation 4.44.

For a fixed-ended cable, we have

$$Y_i(x) = \sin \frac{i\pi x}{l} \quad (\text{iii})$$

and, at steady state, the time response $\bar{q}_j(t)$ will be harmonic at the same frequency as the excitation frequency ω . Hence, we have

$$\bar{q}_j(t) = q_{0j} \sin(\omega t + \phi_j) \quad (4.51)$$

We see that, for Equation 4.51 to satisfy Equation 4.46 in this undamped problem, we must have $\phi_j = 0$. Direct substitution gives

$$[-\omega^2 + \omega_j^2] q_{0j} = \frac{2f_0}{lm} Y_j(a)$$

which determines q_{0j} . Hence, from Equation 4.45, the complete solution for the fixed-ended problem, at steady state, is

$$v(x, t) = \frac{2f_0}{lm} \sin \omega t \sum \frac{\sin i\pi a/l}{(\omega_i^2 - \omega^2)} \sin \frac{i\pi x}{l} \quad (4.52)$$

Some important results for transverse vibration of strings and cables are summarized in Box 4.1.

4.3 Longitudinal Vibrations of Rods

It can be shown that the governing equation of the longitudinal vibration of line structures such as rods and bars is identical to that of the transverse vibration of cables and strings. Hence, it is not necessary to repeat the complete analysis here. We will first develop the equation of motion, then consider BCs, next identify the similarity with the cable vibration problem, and will conclude with an illustrative example.

Box 4.1

TRANSVERSE VIBRATION OF STRINGS AND CABLES

Equation of motion:

$$m(x) \frac{\partial^2 v(x, t)}{\partial t^2} = T \frac{\partial^2 v(x, t)}{\partial x^2} + f(x, t)$$

Separable (modal) solution for free vibration:

$$v(x, t) = \sum Y_i(x) q_i(t)$$

with

$$\frac{d^2 Y_i(x)}{dx^2} + \lambda_i^2 Y_i(x) = 0 \quad (\text{needs two boundary conditions})$$

and

$$\frac{d^2 q_i(t)}{dt^2} + \omega_i^2 q_i(t) = 0 \quad (\text{needs two initial conditions})$$

Natural frequency: $\omega_i = \lambda_i c$

$$\text{Wave speed: } c = \sqrt{\frac{T}{m}}$$

Traveling-wave solution (long cable, independent of end conditions):

$$v(x, t) = v_1(x - ct) + v_2(x + ct)$$

Orthogonality:

$$\int_0^l Y_i(x) Y_j(x) dx = \begin{cases} 0 & \text{for } i \neq j \\ \frac{l}{2} & \text{for } i = j \end{cases}$$

Initial conditions:

(for initial displacement $d(x)$ and speed $s(x)$)

$$q_i(0) = \frac{2}{l} \int_0^l d(x) Y_i(x) dx$$

$$\dot{q}_i(0) = \frac{2}{l} \int_0^l s(x) Y_i(x) dx$$

Variable-tension problem:

$$m \frac{\partial^2 v}{\partial t^2} = T \frac{\partial^2 v}{\partial x^2} + \frac{\partial T}{\partial x} \frac{\partial v}{\partial x}$$

4.3.1 Equation of Motion

Consider a rod that is mounted horizontally (so that the gravitational effects can be neglected) as shown in Figure 4.4(a). A small element of length dx (the limiting case of δx) at position x is shown in Figure 4.4(b). The longitudinal strain at x is given by

$$\varepsilon = \frac{\partial u}{\partial x} \quad (4.53)$$

where $u(x, t)$ = longitudinal displacement of the rod at x from a fixed reference.

Note that the fixed reference may be chosen arbitrarily but, if the assumption of small u is needed, the relaxed (unstrained) position of the element must be chosen as the reference. The longitudinal stress at the cross section at x is $\sigma = E\varepsilon$ and, hence, the longitudinal force is

$$P = EA \frac{\partial u}{\partial x} \quad (4.54)$$

where

E = Young's modulus of the rod

A = area of cross section

It is not necessary at this point to assume a uniform rod. Hence, A may depend on x .

The equation of motion for the small element shown in Figure 4.4(b) is

$$\rho A \, dx \frac{\partial^2 u(x, t)}{\partial t^2} = P + dP - P + f(x, t)dx$$

or

$$\rho A \frac{\partial^2 u}{\partial t^2} dx = dP + f(x, t)dx \quad (4.55)$$

Now, from Equation 4.54, we have

$$dP = \frac{\partial}{\partial x} EA(x) \frac{\partial u}{\partial x} dx \quad (4.56)$$

FIGURE 4.4 (a) A rod with distributed loading and in longitudinal vibration; (b) a small element of the rod.

which when substituted into Equation 4.55 gives

$$\rho A \frac{\partial^2 u(x, t)}{\partial t^2} = \frac{\partial}{\partial x} EA(x) \frac{\partial u(x, t)}{\partial x} + f(x, t) \quad (4.57)$$

For the case of a uniform rod (constant A) in free vibration ($f(x, t) = 0$), we have

$$\frac{\partial^2 u}{\partial t^2} = c^2 \frac{\partial^2 u(x, t)}{\partial x^2} \quad (4.58)$$

which is identical to the cable vibration equation 4.3, but with the wave speed parameter given by

$$c = \sqrt{\frac{E}{\rho}} \quad (4.59)$$

which should be compared with Equation 4.4. The analysis of the present problem may be carried out exactly as for the cable vibration. In particular, the traveling wave solution will hold. Mode shape orthogonality will hold also. Even the BCs are similar to those of the cable vibration problem.

4.3.2 Boundary Conditions

As for the cable vibration problem, two BCs will be needed along with two initial conditions in order to obtain the complete solution to the longitudinal vibration of a rod. Both free and forced vibration may be analyzed as before. For a fixed end at $x = x_0$, we will have no deflection. Hence,

$$u(x_0, t) = 0 \quad (4.60)$$

with the corresponding modal end condition

$$X_i(x_0) = 0 \quad \text{for } i = 1, 2, 3, \dots \quad (4.61)$$

For a free end at $x = x_0$, there will not be an end force. Hence, in view of Equation 4.54, the applicable BC will be

$$\frac{\partial u(x_0, t)}{\partial x} = 0 \quad (4.62)$$

with the corresponding modal boundary condition

$$\frac{dX_i(x_0)}{dx} = 0 \quad \text{for } i = 1, 2, 3, \dots \quad (4.63)$$

The mode shapes $X_i(x)$ will satisfy the orthogonality property

$$\int_0^l X_i(x) X_j(x) dx = \begin{cases} 0 & \text{for } i \neq j \\ l_j & \text{for } i = j \end{cases} \quad (4.64)$$

as before. It can be easily verified, for example, that, for a rod with both ends fixed

$$X_i(x) = \sin \frac{i\pi x}{l} \quad (4.65)$$

Example 4.3

A uniform structural column of length l , mass M , and area of cross section A hangs from a rigid platform and is supported on a flexible base of stiffness k . A model is shown in [Figure 4.5](#). Initially, the system remains stationary, in static equilibrium. Suddenly an axial (vertical) speed of u_0 is imparted uniformly

on the entire column due to a seismic jolt. Determine the subsequent vibration motion of the column from its initial equilibrium configuration.

Solution

The gravitational force corresponds to a force per unit length

$$f(x, t) = \frac{Mg}{l}$$

and Equation 4.57 becomes

$$\frac{\partial^2 u(x, t)}{\partial t^2} = c^2 \frac{\partial^2 u(x, t)}{\partial x^2} + \frac{Mg}{\rho Al}$$

Since $M = \rho Al$, we have

$$\frac{\partial^2 u(x, t)}{\partial t^2} = c^2 \frac{\partial^2 u(x, t)}{\partial x^2} + g \quad (4.66)$$

Boundary conditions are

$$u(0, t) = 0 \quad (4.67)$$

$$EA \frac{\partial u(l, t)}{\partial x} + ku(l, t) = 0 \quad (4.68)$$

Initial conditions are

$$u(x, 0) = 0 \quad (4.69)$$

$$\frac{\partial u(x, 0)}{\partial t} = u_0 \quad (4.70)$$

We seek the modal summation solution

$$u(x, t) = \sum X_i(x)q_i(t) \quad (4.71)$$

where the mode shapes $X_i(x)$ satisfy

$$\frac{d^2 X_i(x)}{dx^2} + \lambda_i^2 X_i(x) = 0 \quad (4.72)$$

whose solution is

$$X_i(x) = C_1 \sin \lambda_i x + C_2 \cos \lambda_i x \quad (4.73)$$

According to Equation 4.67 and Equation 4.68, the modal BCs are

$$X_i(0) = 0 \quad (4.74)$$

$$EA \frac{dX_i(l)}{dx} + kX_i(l) = 0 \quad (4.75)$$

Substitute Equation 4.74 into Equation 4.73. We have $C_2 = 0$. Next, use Equation 4.75. We obtain

$$EA\lambda_i C_1 \cos \lambda_i l + kC_1 \sin \lambda_i l = 0$$

Since, $C_1 \neq 0$ for a nontrivial solution, the required condition is

$$EA\lambda_i \cos \lambda_i l + k \sin \lambda_i l = 0$$

FIGURE 4.5 A column suspended from a fixed platform and supported on a flexible base.

which may be expressed as

$$\tan \lambda_i l + \frac{EA}{k} \lambda_i = 0 \quad (4.76)$$

This *transcendental equation* has an infinite number of solutions λ_i , which correspond to the modes of vibration. The solution may be made computationally and the corresponding natural frequencies are obtained using

$$\omega_i = \lambda_i c = \lambda_i \sqrt{\frac{E}{\rho}} = \lambda_i \sqrt{\frac{EAl}{M}} \quad (4.77)$$

Substitute Equation 4.71 into Equation 4.66 and use Equation 4.72 to obtain

$$\sum X_i(x) \ddot{q}_i(t) = -c^2 \sum \lambda_i^2 X_i(x) q_i(t) + g \quad (4.78)$$

Multiply Equation 4.78 by $X_j(x)$ and integrate from $x = 0$ to l , using the orthogonality property (Equation 4.64), to obtain

$$l_j \ddot{q}_j(t) + c^2 \lambda_j^2 l_j q_j(t) = g \int_0^l X_j(x) dx \quad (4.79)$$

We normalize the mode shapes as

$$X_i(x) = \sin \lambda_i x \quad (4.80)$$

where the constant multiplier (C_1) has been absorbed into $q_i(t)$ in Equation 4.71. Then,

$$l_j = \int_0^l \sin^2 \lambda_j x dx = \int_0^l \frac{1}{2} [1 - \cos 2\lambda_j x] dx = \frac{1}{2} \left[x - \frac{1}{2\lambda_j} \sin 2\lambda_j x \right]_0^l = \frac{1}{2} \left[l - \frac{1}{2\lambda_j} \sin 2\lambda_j l \right] \quad (4.81)$$

and

$$\int_0^l \sin \lambda_j x dx = \frac{1}{\lambda_j} [1 - \cos \lambda_j l]$$

Accordingly, Equation 4.79 becomes

$$\ddot{q}_j(t) + \omega_j^2 q_j(t) = \frac{g}{l_j \lambda_j} [1 - \cos \lambda_j l] \quad (4.82)$$

where the right-hand side is a constant and is completely known from Equation 4.81 and Equation 4.76, and ω_j is given by Equation 4.77. Now Equation 4.82, which corresponds to a simple oscillator with a constant force input, may be solved using any convenient approach. For example, the particular solution is

$$q_{jp} = \frac{g}{\omega_j^2 l_j \lambda_j} [1 - \cos \lambda_j l] \quad (4.83)$$

and the overall solution is

$$q_j(t) = A_j \sin \omega_j t + B_j \cos \omega_j t + q_{jp} \quad (4.84)$$

The constants A_j and B_j are determined using the initial conditions $q_j(0)$ and $\dot{q}_j(0)$. These are obtained by substituting Equation 4.71 into Equation 4.67 and Equation 4.68, multiplying by $X_j(x)$, and integrating from $x = 0$ to l , making use of the orthogonality property (Equation 4.64). Specifically, we obtain

$$q_j(0) = 0 \quad (4.85)$$

and

$$\dot{q}_j(0) = \frac{u_0}{l_j} \int_0^l \sin \lambda_j x \, dx = \frac{u_0}{l_j \lambda_j} [1 - \cos \lambda_j l] \quad (4.86)$$

4.4 Torsional Vibration of Shafts

Torsional vibrations are oscillating angular motions of a device about some axis of rotation. Examples are vibration in shafts, rotors, vanes, and propellers. The governing PDE of the torsional vibration of a shaft is quite similar to that we previously encountered of the transverse vibration of a cable in tension and the longitudinal vibration of a rod. However, in the present case, the vibrations are rotating (angular) motions with resulting shear strains, shear stresses, and torques in the torsional member. Furthermore, the parameters of the equation of motion will take different meanings. When bending and torsional motions occur simultaneously, there can be some interaction, thereby making the analysis more difficult. Here, we neglect such interactions by assuming that only the torsional effects are present or that the motions are quite small.

Since the form of the torsional vibration equation is similar to forms we have studied before, the same procedures of analysis may be employed and, in particular, the concepts of modal analysis will be similar. However, the torsional parameters will be rather complex for members with noncircular cross sections. Nevertheless, vast majority of torsional devices have circular cross sections.

4.4.1 Shaft with Circular Cross Section

Here, we will formulate the problem of the torsional vibration of a shaft having a circular cross section. The general case of a nonuniform cross section along the shaft is considered, but the usual assumptions such as homogeneous, isotropic, and elastic material are made.

First, we will obtain a relationship between torque (T) and angular deformation or twist (θ) for a circular shaft. Consider a small element of length dx along the shaft axis and the cylindrical surface at a general radius r (in the interior of the shaft segment), as shown in Figure 4.6(a). During vibration, this element will deform (twist) through a small angle $d\theta$.

A point on the circumference will deform through $r \, d\theta$ as a result, and a longitudinal line on the cylindrical surface will deform through angle γ , as shown in Figure 4.6(a). From the strength of materials and elasticity theory of solid mechanics, we know that γ is the shear strain. Hence,

$$\text{Shear strain } \gamma = \frac{r \, d\theta}{dx}$$

FIGURE 4.6 (a) Small element of a circular shaft in torsion; (b) shear stresses in a small annular cross section carrying torque.

However, allowing for the fact that the angular shift θ is a function of t as well as x in the general case of dynamics, we use partial derivatives and write

$$\gamma = r \frac{\partial \theta}{\partial x} \quad (4.87)$$

The corresponding shear stress at the deformed point at radius r is

$$\tau = G\gamma = Gr \frac{\partial \theta}{\partial x} \quad (4.88)$$

where G = shear modulus.

This shear stress acts tangentially. Consider a small annular cross section of width dr at radius r of the shaft, as shown in Figure 4.6(b). By symmetry, the shear stress will be the same throughout this region and will form a torque of $r\tau \times 2\pi r dr = 2\pi r^2 \tau dr$. Hence, the overall torque at the shaft cross section is

$$T = \int 2\pi r^2 \tau dr$$

which, in view of Equation 4.88, is written as

$$T = G \frac{\partial \theta}{\partial x} \int 2\pi r^3 dr \quad (4.89)$$

It is clear that the integral term is the *polar moment of area* of the shaft cross section:

$$J = \int 2\pi r^3 dr \quad (4.90)$$

In particular, for a solid shaft of radius r

$$J = \frac{\pi r^4}{2} \quad (4.91)$$

and, for a hollow shaft of inner radius r_1 and the outer radius r_2

$$J = \frac{\pi}{2}(r_2^4 - r_1^4) \quad (4.92)$$

So, we write Equation 4.89 as

$$T = GJ(x) \frac{\partial \theta}{\partial x} \quad (4.93)$$

The combined parameter GJ is termed the *torsional rigidity* of the shaft. We have emphasized that the shaft may be nonuniform and hence J is a function of x . Consider a uniform shaft segment of length l , with associated overall angular deformation θ . Equation 4.93 can be written as

$$\text{Torsional stiffness } K = \frac{T}{\theta} = \frac{GJ}{l} \quad (4.94)$$

Note: For a shaft with noncircular cross section, replace J by J_t in this equation. It follows that, the larger the torsional rigidity GJ , the higher the torsional stiffness K , as expected. Furthermore, longer members have a lower torsional stiffness (and smaller natural frequencies).

Now, we apply Newton's Second Law for rotatory motion of the small element dx , shown in Figure 4.6(a). The *polar moment of inertia* of the element is $\int r^2 dm = \int r^2 \rho dx dA = \rho dx \int r^2 dA = \rho J dx$, where J is the polar moment of area, as discussed before. Also, suppose that a distributed external torque of $\tau(x, t)$ per unit length is applied along the shaft. Hence, the equation of motion is

$$\rho J dx \frac{\partial^2 \theta}{\partial t^2} = T + dT - T + \tau(x, t)dx = \frac{\partial T}{\partial x} dx + \tau(x, t)dx$$

Substitute Equation 4.93 and cancel dx to obtain the equation of torsional vibration of a circular shaft as

$$\rho J \frac{\partial^2 \theta(x, t)}{\partial t^2} = \frac{\partial}{\partial x} GJ(x) \frac{\partial \theta(x, t)}{\partial x} + \tau(x, t) \quad (4.95)$$

For the case of a uniform shaft (constant J) in free vibration ($\tau(x, t) = 0$), we have

$$\frac{\partial^2 \theta(x, t)}{\partial t^2} = c^2 \frac{\partial^2 \theta(x, t)}{\partial x^2} \quad (4.96)$$

with

$$c = \sqrt{\frac{G}{\rho}} \quad (4.97)$$

Note that Equation 4.96 is quite similar to that for transverse vibration of a cable in tension and the longitudinal vibration of a rod. Hence, the same concepts and procedures of analysis may be used. In particular, two boundaries conditions will be needed in the solution; for example

$$\text{Fixed end at } x = x_0: \theta(x_0, t) = 0 \quad (4.98)$$

$$\text{Free end at } x = x_0: \frac{\partial \theta(x_0, t)}{\partial x} = 0 \quad (4.99)$$

The orthogonality property of mode shapes $\Theta_i(x)$:

$$\int_0^l \Theta_i(x) \Theta_j(x) dx = \begin{cases} 0 & \text{for } i \neq j \\ l_j & \text{for } i = j \end{cases} \quad (4.100)$$

4.4.2 Torsional Vibration of Noncircular Shafts

Unlike the longitudinal and transverse vibrations of rods and beams, when considering the torsional vibration of shafts, the equation of motion for circular shafts (Equation 4.95 and Equation 4.96) cannot be used for shafts with noncircular cross sections. The reason is that the shear stress distributions in the two cases can be quite different, and Equation 4.88 does not hold for noncircular sections. Hence, the parameter J in the torque–deflection relations (e.g., Equation 4.93 and Equation 4.94) is not the polar moment of area in the case of noncircular sections. In the noncircular case, we write

$$T = GJ_t \frac{\partial \theta}{\partial x} \quad (4.101)$$

where J_t = torsional parameter.

The Saint-Venant theory of torsion and the related membrane analogy, developed by Prandtl, have provided equations for J_t in special cases. For example, for a thin hollow section

$$J_t = \frac{4tA_s^2}{p} \quad (4.102)$$

where

A_s = enclosed (contained) area of the hollow section

p = perimeter of the section

t = wall thickness of the section

For a thin, solid section, we have

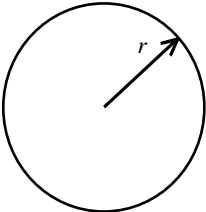

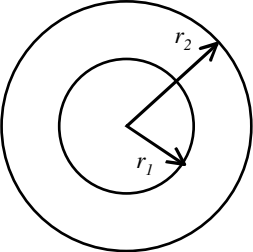

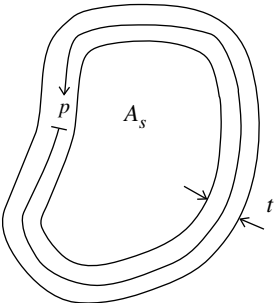

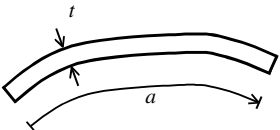

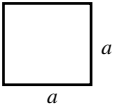

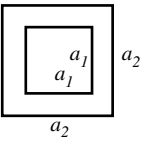

$$J_t = \frac{t^3 a}{3} \quad (4.103)$$

where

- a = length of the narrow section
- t = thickness of the narrow section

Torsional parameters for some useful sections are given in Table 4.2.

TABLE 4.2 Torsional Parameters for Several Sections

Section	Shape	Torsional Parameter J_t
Solid circular		$\frac{\pi}{2} r^4$
Hollow circular		$\frac{\pi}{2} (r_2^4 - r_1^4)$
Thin closed		$\frac{4tA_s^2}{p}$
Thin open		$\frac{t^3 a}{3}$
Solid square		$0.1406a^4$
Hollow square		$0.1406(a_2^4 - a_1^4)$

Example 4.4

Consider a thin, rectangular hollow section of thickness t , height a , and width $a/2$, as shown in Figure 4.7(a). Suppose that the section is opened by making a small slit as in Figure 4.7(b). Study the affect on the torsional parameter J_t and torsional stiffness K of the member due to the opening.

Solution

(a) Closed section:

The contained area of the section is $A_s = a^2/2$

The perimeter of the section $p = 3a$

Using Equation 4.102, the torsional parameter is

$$J_{tc} = \frac{ta^3}{3}$$

(b) Open section:

The solid length of the section $= 3a$

Using Equation 4.103, the torsional parameter is

$$J_{to} = at^3$$

The ratio of the torsional parameters is

$$\frac{J_{to}}{J_{tc}} = \frac{3t^2}{a^2}$$

For members of equal length, torsional stiffness will also be in the same ratio as is given by this expression. Since t is small compared with a , there will be a significant drop in torsional stiffness due to the opening (cutout).

Example 4.5

An innovative automated transit system uses an elevated guideway with cars whose suspension is attached to (and slides on) the side of the guideway. Owing to this eccentric loading on the guideway,

FIGURE 4.7 (a) A thin closed section; (b) a thin open section.

FIGURE 4.8 A torsional-guideway transit system.

there is a significant component of torsional dynamics in addition to bending. Assume that the torque T_j acting on the guideway due to the j th suspension of the vehicle to be constant, acting at a point x_j as measured from one support pier, and moving at speed v_j . A schematic representation is given in Figure 4.8. The guideway span shown has a length L and a cross section which is a thin-walled rectangular box of height a , width b , and thickness t . The ends of the guideway span are restrained for angular motion (i.e., fixed):

- Formulate and analyze the torsional (angular) motion of the guideway.
- For a single point vehicle entering a guideway that is at rest, what is the resulting dynamic response of the guideway? What is the critical speed that should be avoided?
- Given the parameter values

$$l = 60 \text{ ft (18.3 m)}$$

$$abt = 5 \text{ ft} \times 2.2 \text{ ft} \times \frac{1}{2} \text{ ft (1.52 m} \times 0.67 \text{ m} \times 0.15 \text{ m)}$$

$$\rho = 4.66 \text{ slugs/ft}^3 (2.4 \times 10^3 \text{ kg/m}^3)$$

$$G = 1.55 \times 10^6 \text{ lb/in.}^2 (1.07 \times 10^{10} \text{ N/m}^2)$$

and vehicle speed

$$v = 60 \text{ mi/h (26.8 m/sec)}$$

Compute the crossing frequency ratio given by

$$v_c = \frac{\text{Rate of span crossing}}{\text{Fundamental natural frequency of guideway}}$$

and discuss its implications.

Solution

- For a uniform guideway with distributed torque load $\tau(x, t)$ and a noncircular cross section having torsional parameter J_t , the governing equation is

$$\rho J \frac{\partial^2 \theta(x, t)}{\partial t^2} = G J_t \frac{\partial^2 \theta}{\partial x^2} + \tau(x, t) \quad (4.104)$$

As usual, the mode shapes are obtained by solving

$$\frac{d^2 \Theta}{dx^2} + \lambda^2 \Theta = 0 \quad (4.105)$$

and the corresponding natural frequencies are given by

$$\omega_i = \lambda_i \sqrt{G J_t / \rho J_t} \quad (4.106)$$

The general solution of Equation 4.105 is

$$\Theta(x) = A_1 \sin \lambda x + A_2 \cos \lambda x$$

where A_i ($i = 1, 2$) are the constants of integration. The torsional BCs corresponding to the fixed ends (no twist) are

$$\Theta(0) = \Theta(l) = 0$$

where l = guideway span length. For a nontrivial solution, we need

$$A_2 = 0$$

and

$$\lambda_i = \frac{\pi}{l} \quad i = 1, 2, \dots \quad (4.107)$$

The solution corresponds to an infinite set of eigenfunctions $\Theta_i(x)$ satisfying Equation 4.105. Each of these represents a *natural mode* in which the beam can undergo free torsional vibrations. The actual motion consists of a linear combination of the normal modes depending on beam initial conditions and the forcing term $\tau(x, t)$. The integration constant A_1 may be incorporated (partially) into the generalized coordinate q , which is still unknown and is determined through initial conditions. Here, we use the normalized eigenfunctions

$$\Theta_i(x) = \sqrt{2} \sin \frac{i\pi x}{l} \quad i = 1, 2, \dots \quad (4.108)$$

The orthogonality condition given by

$$\frac{1}{l} \int_0^l \Theta_i \Theta_j dx = \begin{cases} 0 & \text{for } i \neq j \\ 1 & \text{for } i = j \end{cases} \quad (4.109)$$

is satisfied. In view of the relations (Equation 4.106 and Equation 4.107) the natural frequencies corresponding to different eigenfunctions (natural mode shapes) are

$$\omega_i = \frac{i\pi}{l} \sqrt{GJ/\rho J_i} \quad i = 1, 2, \dots \quad (4.110)$$

For n number of vehicle's suspensions located on the analyzed span

$$\tau(x, t) = \sum_{j=1}^n T_j \delta(x - x_{0j} - v_j t) \quad (4.111)$$

where

T_j = torque exerted on guideway by the j th suspension

v_j = speed of the j th suspension

x_{0j} = initial position (at $t = 0$) along the guideway of the j th suspension

$\delta(\cdot)$ = Dirac delta function

The forced motion can be represented in terms of the normalized eigenfunction as

$$\theta(x, t) = \sum_{i=1}^{\infty} q_i(t) \Theta_i(x) \quad (4.112)$$

where $q_i(t)$ = the generalized coordinate for forced motion in the i th mode. On substituting the relations (Equation 4.111 and Equation 4.112) into Equation 4.104, and integrating the result over the span length, after multiplying by a general eigenfunction while making use of the

orthogonality relation (Equation 4.109), one obtains

$$\frac{d^2 q_i}{dt^2} + \omega_i^2 q_i = \frac{1}{\rho J_t l} \sum_{j=1}^n T_j \Theta_i(x_{0j} + v_j t) \quad i = 1, 2, \dots \quad (4.113)$$

- (b) For a single suspension entering the guideway at $t = 0$, with the guideway initially at rest ($q_i(0) = \dot{q}_i(0) = 0$), we have $n = 1$ and $x_{01} = 0$. Then, the complete solution of Equation 4.113 is

$$q_i(t) = \frac{\sqrt{2} l T \left[\sin \frac{i \pi v t}{l} - 2 v_c \sin \omega_i t \right]}{G J_t \pi^2 i^2 (1 - v_c^2)} \quad i = 1, 2, \dots \quad (4.114)$$

where the crossing-frequency ratio v_c is given by

$$v_c = \frac{v}{l \omega_1} \quad (4.115)$$

Note from Equation 4.114 that the critical speed corresponds to $v_c = 1$ and should be avoided. In typical transit systems, v_c is considerably less than 1.

- (c) For the given numerical values, by straightforward computations, it can be shown that

$$J_t = 3.485 \times 10^5 \text{ in.}^4 \quad (1.451 \times 10^7 \text{ cm}^4)$$

$$J = 4.574 \times 10^5 \text{ in.}^4 \quad (2.736 \times 10^7 \text{ cm}^4)$$

$$\omega_1 = 263.8 \text{ rad/sec} = 42.0 \text{ Hz}$$

Note: We used the expression for a thin, hollow section, given in Table 4.2, in computing J_t . Finally, the crossing-frequency ratio is computed to be $v_c = 0.017$, which is much less than 1.0, as expected.

4.5 Flexural Vibration of Beams

In this section, we will study a beam (or rod or shaft) in flexural vibration. The vibration is in the *transverse* or *lateral* direction, which is accompanied by bending (or flexure) of the member. Hence, the vibrations are perpendicular to the main axis of the member, as in the case of a cable or string, which we studied in Section 4.2. However, a beam, unlike a string, can support shear forces and bending moments at its cross section. In the initial analysis of bending vibration, we will assume that there is no axial force at the ends of the beam. We will make further simplifying assumptions that will be clear in the development of the governing equation of motion. The analysis procedure will be quite similar to that we have followed in the previous sections.

The study of the bending vibration (or lateral or transverse vibration) of beams is very important in a variety of practical situations. Noteworthy are the vibration analyses of structures like bridges, vehicle guideways, tall buildings, and space stations; the ride quality and structural integrity analysis of buses, trains, ships, aircraft and spacecraft; the dynamics and control of rockets, missiles, machine tools and robots; and the vibration testing, evaluation, and qualification of products with continuous members.

4.5.1 Governing Equation for Thin Beams

Now, we will develop the *Bernoulli–Euler equation*, which governs the transverse vibration of thin beams. Consider a beam bending in the x – y plane, with x as the longitudinal axis and y as the transverse axis of bending deflection, as shown in Figure 4.9. We will develop the required equation by considering the moment–deflection relation, rotational equilibrium, and transverse dynamics of a beam element.

FIGURE 4.9 A thin beam in bending.

(1) *Moment–deflection relation*

A small beam element of length δx subjected to bending moment M is shown. Neglect any transverse deflections due to shear stresses. Consider a lateral area element δA in the cross section A of the beam element, at a distance w (measure parallel to y) from the neutral axis of bending.

Normal strain (at δA)

$$\varepsilon = \frac{(R + w)\delta\theta - R\delta\theta}{R\delta\theta}$$

Note that the neutral axis joins the points along the beam when the normal strain and stress are zero. Hence,

$$\varepsilon = \frac{w}{R} \quad (4.116)$$

where R = radius of curvature of the bent element. Normal stress in the axial direction

$$\sigma = E\varepsilon = E\frac{w}{R} \quad (4.117)$$

where E = Young's modulus (of elasticity). Then, bending moment

$$M = \int_A w\sigma dA = \int w^2 \frac{E}{R} dA = \frac{E}{R} \int w^2 dA = \frac{EI}{R}$$

where I = second moment of area of the beam cross section about the neutral axis. So, we have

$$M = \frac{EI}{R} \quad (4.118)$$

Slope at $A = \partial v / \partial x$; slope at $B = (\partial v / \partial x) + (\partial^2 v / \partial x^2) \delta x$; where v = lateral deflection of the beam at element δx . Hence, the change in slope = $(\partial^2 v / \partial x^2) \delta x = \delta\theta$, where $\delta\theta$ is the arc angle of bending for the beam element δx , as shown in Figure 4.9.

Also, we have $\delta x = R \delta \theta$. Hence, $(\partial^2 v / \partial x^2) R \delta \theta = \delta \theta$. Cancel $\delta \theta$. We obtain

$$\frac{1}{R} = \frac{\partial^2 v}{\partial x^2} \quad (4.119)$$

Substitute Equation 4.119 into Equation 4.118. We obtain

$$M = EI \frac{\partial^2 v}{\partial x^2} \quad (4.120)$$

(2) *Rotatory dynamics (equilibrium)*

Again, consider the beam element δx , as shown in Figure 4.10, where forces and moments acting on the element are indicated. Here, $f(x, t)$ = excitation force per unit length acting on the beam, in the transverse direction, at location x . Disregard the rotatory inertia of the beam element.

Hence, the equation of angular motion is given by the equilibrium condition of moments:

$$M + Q \delta x - \left(M + \frac{\partial M}{\partial x} \delta x \right) = 0$$

or

$$Q = \frac{\partial M}{\partial x} = \frac{\partial}{\partial x} \left(EI \frac{\partial^2 v}{\partial x^2} \right) \quad (4.121)$$

where the previously obtained result (Equation 4.120) for M has been substituted. Note that we have not assumed a uniform beam and hence $I = I(x)$ will be variable along the beam length.

(3) *Transverse dynamics*

The equation of transverse motion (Newton's Second Law) for element δx is

$$(\rho A \delta x) \frac{\partial^2 v}{\partial t^2} = f(x, t) \delta x + Q - \left(Q + \frac{\partial Q}{\partial x} \delta x \right)$$

Here, ρ = mass density of the beam material. So, we obtain

$$\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial Q}{\partial x} = f(x, t)$$

or, in view of Equation 4.121, we have the governing equation of forced transverse motion for the beam as

$$\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) = f(x, t) \quad (4.122)$$

FIGURE 4.10 Dynamics of a beam element in bending.

4.5.2 Modal Analysis

The solution to the flexural vibration problem given by Equation 4.122 may be obtained exactly as for other continuous members. Specifically, we first obtain the natural frequencies and mode shapes and express the general solution as a summation of the modal responses. The approach is similar for both free and forced problems, but the associated generalized coordinates will be different. This approach is followed here.

For modal (natural) vibration, consider the free motion described by

$$\frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) + \rho A \frac{\partial^2 v}{\partial t^2} = 0 \quad (4.123)$$

For a uniform beam, EI will be constant and Equation 4.123 can be expressed as

$$\frac{\partial^2 v(x, t)}{\partial t^2} = -c^2 \frac{\partial^4 v(x, t)}{\partial x^4} \quad (4.124)$$

where

$$c = \sqrt{\frac{EI}{\rho A}} \quad (4.125)$$

Observe from Equation 4.124 that it is fourth order in x and second order in t , whereas the governing equations for the transverse vibration of a cable, longitudinal vibration of a rod, and torsional vibration of a shaft, are all identical in fourth and second order in x . So the behavior of transverse vibrations of beams will not be exactly identical to that of these other three types of continuous system. In particular, the traveling wave solution 4.7 will not be satisfied. However, there are also many similarities.

In each mode the system will vibrate in a fixed shape ratio. Hence, the time and space functions will be separable for a modal motion; we seek a solution of the form

$$v(x, t) = Y(x)q(t) \quad (4.126)$$

This separable solution for a modal response has been justified previously. Note that, even in the lumped parameter case, we make the same assumption, except in that case we have a modal vector

$$\mathbf{Y} = \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_n \end{bmatrix}$$

instead of a mode shape function $Y(x)$. For a given mode of a lumped parameter system, Y_i values denote the *relative* displacements of various inertia elements m_i , as shown in Figure 4.11. Hence, the vector \mathbf{Y} corresponds to the *mode shape*. Note that Y_i can be either positive or negative. Also, $q(t)$ is the harmonic function corresponding to the natural frequency.

It should be clear that \mathbf{Y} and $q(t)$ are separable in this lumped-parameter case of modal motion. Then, in the limit, $Y(x)$ and $q(t)$ should also be separable for the distributed parameter case.

Substitute Equation 4.124 into Equation 4.123, and bring the terms containing x to the left-hand side (LHS) and terms containing t to the right-hand side (RHS).

$$\frac{1}{\rho A Y} \frac{d^2}{dx^2} \left(EI \frac{d^2 Y}{dx^2} \right) = -\frac{1}{q(t)} \frac{d^2 q}{dt^2} = \omega^2 \quad (4.127)$$

Since a function of x cannot be equal to a function of t in general, unless each function is equal to the same constant, we have defined ω^2 as a constant.

FIGURE 4.11 Modal motions of a lumped-parameter system.

We have not shown that this *separation constant* (ω^2) should be positive. This requirement can be verified due to the nature of the particular vibration problem; that is, $q(t)$ should have an oscillatory solution in general. It is also clear that the physical interpretation of ω is a natural frequency of the system. Equation 4.127 corresponds to the two ODEs, one in t and the other in x , as

$$\frac{d^2 q(t)}{dt^2} + \omega^2 q(t) = 0 \quad (4.128)$$

$$\frac{d^2}{dx^2} EI \frac{d^2 Y(x)}{dx^2} - \omega^2 \rho A Y(x) = 0 \quad (4.129)$$

The solution of these two equations will provide the natural frequencies ω and the corresponding mode shapes $Y(x)$ of the beam.

For further analysis of the modal behavior, assume a uniform beam. Then, EI will be constant and Equation 4.129 may be expressed as

$$\frac{d^4 Y(x)}{dx^4} - \lambda^4 Y(x) = 0 \quad (4.130)$$

where

$$\omega = \lambda^2 c = \lambda^2 \sqrt{\frac{EI}{\rho A}} \quad (4.131)$$

The positive parameter λ is yet to be determined, and will come from the mode shape analysis.

The characteristic equation corresponding to Equation 4.130 is

$$p^4 - \lambda^4 = 0; \quad \text{or,} \quad (p^2 - \lambda^2)(p^2 + \lambda^2) = 0 \quad (4.132)$$

The roots are

$$p = \pm \lambda, \pm j\lambda \quad (4.133)$$

Hence, the general solution for a mode shape (eigenfunction) is given by

$$Y(x) = A_1 e^{\lambda x} + A_2 e^{-\lambda x} + A_3 e^{+j\lambda x} + A_4 e^{-j\lambda x} = C_1 \cosh \lambda x + C_2 \sinh \lambda x + C_3 \cos \lambda x + C_4 \sin \lambda x \quad (4.134)$$

There are five unknowns (C_1, C_2, C_3, C_4 , and λ) here. The mode shapes can be normalized and one of the first four unknowns can be incorporated into $q(t)$ as usual. The remaining four unknowns are determined by the end conditions of the beam. So, four BCs will be needed.

Note:

$$\begin{aligned} \cosh \lambda x &= \frac{e^{\lambda x} + e^{-\lambda x}}{2}; & \sinh \lambda x &= \frac{e^{\lambda x} - e^{-\lambda x}}{2} \\ \cos \lambda x &= \frac{e^{j\lambda x} + e^{-j\lambda x}}{2}; & \sin \lambda x &= \frac{e^{j\lambda x} - e^{-j\lambda x}}{2j} \\ \frac{d}{dx} \cosh \lambda x &= \lambda \sinh \lambda x; & \frac{d}{dx} \sinh \lambda x &= \lambda \cosh \lambda x \end{aligned}$$

4.5.3 Boundary Conditions

The four modal BCs that are needed can be derived in the usual manner, depending on the conditions at the two ends of the beam. The procedure is to apply the separable (modal) solution Equation 4.126 to the end relation with the understanding that this relation has to be true for all possible values of $q(t)$. The relation (Equation 4.128) may be substituted as well, if needed.

For example, consider an end $x = x_0$ that is completely free. Then, both bending moment and shear force have to be zero at this end. From Equation 4.120 and Equation 4.121, we have

$$EI \frac{\partial^2 v(x_0, t)}{\partial x^2} = 0 \quad (4.135)$$

$$\frac{\partial}{\partial x} \left(EI \frac{\partial^2 v(x_0, t)}{\partial x^2} \right) = 0 \quad (4.136)$$

Substitute Equation 4.126 into Equation 4.135 and Equation 4.136:

$$EI \frac{d^2 Y(x_0)}{dx^2} q(t) = 0$$

$$\frac{d}{dx} EI \frac{d^2 Y(x_0)}{dx^2} q(t) = 0$$

which are true for all $q(t)$. Hence, the following modal BCs result for a free end:

$$\frac{d^2 Y(x_0)}{dx^2} = 0 \quad (4.137)$$

$$\frac{d}{dx} EI \frac{d^2 Y(x_0)}{dx^2} = 0 \quad (4.138)$$

For a uniform beam, Equation 4.137 becomes

$$\frac{d^3 Y(x_0)}{dx^3} = 0$$

Some common conditions and the corresponding modal BC equations for the bending vibration of a beam are listed in Box 4.2.

4.5.4 Free Vibration of a Simply Supported Beam

To illustrate this approach, consider a uniform beam of length l that is pinned (simply supported) at both ends. In this case, both displacement and the bending moment will be zero at each end. Accordingly, we have the modal boundary conditions

$$Y(0) = 0 = Y(l) \quad (4.139)$$

$$\frac{d^2 Y(0)}{dx^2} = 0 = \frac{d^2 Y(l)}{dx^2} \quad (4.140)$$

where l = length of the beam. Substitute Equation 4.134 into Equation 4.139:

$$C_1 + C_3 = 0 \quad (4.141)$$

$$C_1 \cosh \lambda l + C_2 \sinh \lambda l + C_3 \cos \lambda l + C_4 \sin \lambda l = 0 \quad (4.142)$$

To apply the bending moment BCs, first differentiate Equation 4.134 to obtain

$$\frac{dY}{dx} = \lambda C_1 \sinh \lambda x + \lambda C_2 \cosh \lambda x - \lambda C_3 \sin \lambda x + \lambda C_4 \cos \lambda x$$

$$\frac{d^2 Y}{dx^2} = \lambda^2 C_1 \cosh \lambda x + \lambda^2 C_2 \sinh \lambda x - \lambda^2 C_3 \cos \lambda x - \lambda^2 C_4 \sin \lambda x$$

and the substitute these into the bending moment BCs (Equation 4.140). We obtain

$$C_1 - C_3 = 0 \quad (4.143)$$

$$C_1 \cosh \lambda l + C_2 \sinh \lambda l - C_3 \cos \lambda l - C_4 \sin \lambda l = 0 \quad (4.144)$$

Box 4.2

BOUNDARY CONDITIONS FOR TRANSVERSE VIBRATION OF BEAMS

1.	Simply supported (pinned)	Deflection = 0 $\Rightarrow Y = 0$ Bending moment = 0 $\Rightarrow \frac{d^2 Y}{dx^2} = 0$
2.	Clamped (fixed)	Deflection = 0 $\Rightarrow Y = 0$ Slope = 0 $\Rightarrow \frac{dY}{dx} = 0$
3.	Free	Bending moment = 0 $\Rightarrow \frac{d^2 Y}{dx^2} = 0$ Shear force = 0 $\Rightarrow \frac{d}{dx} EI \frac{d^2 Y}{dx^2} = 0$
4.	Sliding	Slope = 0 $\Rightarrow \frac{dY}{dx} = 0$ Shear force = 0 $\Rightarrow \frac{d}{dx} EI \frac{d^2 Y}{dx^2} = 0$
5.	Dynamic (flexible, inertial, etc.)	Transverse equation of motion (or force balance) Substitute Equation 4.128, if needed Rotatory equation of motion (or moment balance)

as $\lambda \neq 0$ in general, due to the oscillatory nature of most modes. Equation 4.141 and Equation 4.143 give $C_1 = 0 = C_3$. Then,

Equation 4.142 becomes:

Equation 4.144 becomes: $C_2 \sinh \lambda l + C_4 \sin \lambda l = 0$

Add $C_2 \sinh \lambda l - C_4 \sin \lambda l = 0$

Add

$$C_2 \sinh \lambda l = 0$$

However, $\sinh \lambda l = 0$ if and only if $\lambda = 0$. This corresponds to zero-frequency conditions (no oscillations), and is rejected as it is not true in general. Hence, we have $C_2 = 0$. Accordingly, we are left

with the remaining equation:

$$C_4 \sin \lambda l = 0 \quad (4.145)$$

However, if $C_4 = 0$ then $Y(x) = 0$, which corresponds to a stationary beam with no oscillations, and is rejected as the trivial solution. Hence, the valid solution is given by $\sin \lambda l = 0$ which gives the infinite set of solutions:

$$\lambda_i l = i\pi \quad \text{for } i = 1, 2, 3, \dots \quad (4.146)$$

Note that we must have $i > 0$ because λ has to be nonzero, thereby giving nonzero natural frequencies according to Equation 4.131, as required for the given problem.

4.5.4.1 Normalization of Mode Shape Functions

For absorbing the yet unknown constant C_4 into $q(t)$, we will normalize the mode shape functions. The commonly used normalization condition is

$$\int_0^l Y_i^2 dx = \frac{l}{2} \quad (4.147)$$

Hence,

$$\frac{l}{2} = \int_0^l C_4^2 \sin^2 \frac{i\pi x}{l} dx = C_4^2 \int_0^l \sin^2 \frac{i\pi x}{l} dx = \frac{C_4^2}{2} l$$

Note that we used $\cos 2\theta = 1 - 2 \sin^2 \theta$ prior to integration. Then, for normalized mode shape functions, we have $C_4 = 1$. Hence, the normalized eigenfunctions (mode shape functions) for various modes are given by

$$Y_i(x) = \sin \frac{i\pi x}{l} \quad \text{for } i = 1, 2, 3, \dots \quad (4.148)$$

Using the result (Equation 4.146) in Equation 4.131, the natural frequencies of the i th mode are

$$\omega_i = \frac{i^2 \pi^2}{l^2} \sqrt{\frac{EI}{\rho A}} \quad \text{for } i = 1, 2, 3, \dots \quad (4.149)$$

In this manner, we have obtained an infinite set of mode shape functions $Y_i(x)$ for a simply supported beam. Hence, according to the solution (Equation 4.126), we have a corresponding infinite set of generalized coordinates $q_i(t)$, $i = 1, 2, 3, \dots$, which satisfy Equation 4.128. It follows that the overall response of the beam is

$$v(x, t) = \sum Y_i(x) q_i(t) \quad (4.150)$$

4.5.4.2 Initial Conditions

We have yet to solve Equation 4.128 for determining $q_i(t)$. To do so, we need to know the initial conditions $q_i(0)$ and $\dot{q}_i(0)$. These are determined from the beam initial conditions of displacement and speed, which have to be known:

$$v(x, 0) = d(x) \quad (4.151)$$

$$\frac{\partial v(x, 0)}{\partial t} = s(x) \quad (4.152)$$

Substitute Equation 4.150 into Equation 4.151 and Equation 4.152 to obtain

$$\sum Y_i(x) q_i(0) = d(x) \quad (4.153)$$

$$\sum Y_i(x) \dot{q}_i(0) = s(x) \quad (4.154)$$

Multiply by $Y_j(x)$ and integrate from $x = 0$ to l , using the orthogonality property of $Y_i(x) = \sin(i\pi x/l)$; namely

$$\int_0^l \sin \frac{i\pi x}{l} \sin \frac{j\pi x}{l} dx = \begin{cases} 0 & \text{for } i \neq j \\ \frac{l}{2} & \text{for } i = j \end{cases} \quad (4.155)$$

We obtain

$$q_j(0) = \frac{2}{l} \int_0^l d(x) Y_j(x) dx \quad (4.156)$$

$$\dot{q}_j(0) = \frac{2}{l} \int_0^l s(x) Y_j(x) dx \quad (4.157)$$

In this manner, $q_i(t)$ is completely determined for each ω_i by solving Equation 4.128, using the initial conditions (Equation 4.156 and Equation 4.157). Hence, the complete solution (Equation 4.150) is determined for the free bending vibration of a simply supported beam.

4.5.5 Orthogonality of Mode Shapes

We have seen that the mode shapes of simply supported beams in bending vibrations are orthogonal (see Equation 4.155). This property is not limited to simply supported beams but holds for most BCs, as we will show now. First, from integration by parts, twice, we have

$$\int_0^l Y_i \frac{d^4 Y_j}{dx^4} dx = Y_i \frac{d^3 Y_j}{dx^3} \Big|_0^l - \int_0^l \frac{dY_i}{dx} \frac{d^3 Y_j}{dx^3} dx = \left[Y_i \frac{d^3 Y_j}{dx^3} - \frac{dY_i}{dx} \frac{d^2 Y_j}{dx^2} \right]_0^l + \int_0^l \frac{d^2 Y_i}{dx^2} \frac{d^2 Y_j}{dx^2} dx \quad (4.158)$$

Now consider two separate modes, i and j , which have the modal equations

$$\text{Mode } i: \frac{d^4 Y_i}{dx^4} = \lambda_i^4 Y_i \quad (a)$$

$$\text{Mode } j: \frac{d^4 Y_j}{dx^4} = \lambda_j^4 Y_j \quad (b)$$

Multiply Equation (a) by Y_j , multiply Equation (b) by Y_i , integrate both with respect to x from 0 to l , make use of Equation 4.158 and subtract the second result from the first. We obtain

$$\begin{aligned} (\lambda_i^4 - \lambda_j^4) \int_0^l Y_i Y_j dx &= \int_0^l \left(Y_j \frac{d^4 Y_i}{dx^4} - Y_i \frac{d^4 Y_j}{dx^4} \right) dx \\ &= \left[Y_j \frac{d^3 Y_i}{dx^3} - \frac{dY_j}{dx} \frac{d^2 Y_i}{dx^2} \right]_0^l - \left[Y_i \frac{d^3 Y_j}{dx^3} - \frac{dY_i}{dx} \frac{d^2 Y_j}{dx^2} \right]_0^l \end{aligned} \quad (4.159)$$

Clearly, the two RHS terms are zero for typical BCs, such as pinned, fixed, free, and sliding. Now, since $\lambda_i \neq \lambda_j$ for $i \neq j$ (unequal modes), we have

$$\int_0^l Y_i Y_j dx = 0 \quad \text{for } i \neq j \quad l_j \quad \text{for } i = j \quad (4.160)$$

Note that normalized mode shape functions may be used here to obtain the constant $l_j = l/2$.

4.5.5.1 Case of Variable Cross Section

The orthogonality of mode shapes holds for nonuniform beams as well. Here, EI is not constant. We use integration by parts:

$$\int_0^l Y_j \frac{d^2}{dx^2} EI \frac{d^2 Y_i}{dx^2} dx = \left[Y_j \underbrace{\frac{d}{dx} EI \frac{d^2 Y_i}{dx^2}}_Q \right]_0^l - \left[\frac{dY_j}{dx} \underbrace{EI \frac{d^2 Y_i}{dx^2}}_M \right]_0^l + \int_0^l EI \frac{d^2 Y_j}{dx^2} \frac{d^2 Y_i}{dx^2} dx \quad (4.161)$$

Again, the first two terms on the RHS are zero for typical BCs. Then, as before, we use the modal equations (Equation 4.129) for two different modes, i and j :

$$\frac{d^2}{dx^2} EI \frac{d^2 Y_i}{dx^2} = \omega_i^2 \rho A Y_i$$

$$\frac{d^2}{dx^2} EI \frac{d^2 Y_j}{dx^2} = \omega_j^2 \rho A Y_j$$

Multiply the first equation by Y_j , the second equation by Y_i , subtract the second result from the first, integrate the result from $x = 0$ to l , and finally use Equation 4.161 to cancel the equal terms. We obtain

$$\begin{aligned} (\omega_i^2 - \omega_j^2) \int_0^l \rho A Y_i Y_j dx - \left[Y_j \frac{d}{dx} EI \frac{d^2 Y_i}{dx^2} - Y_i \frac{d}{dx} EI \frac{d^2 Y_j}{dx^2} \right]_0^l \\ + \left[\frac{dY_j}{dx} EI \frac{d^2 Y_i}{dx^2} - \frac{dY_i}{dx} EI \frac{d^2 Y_j}{dx^2} \right]_0^l = 0 \end{aligned} \quad (4.162)$$

Now, as before, for common BCs, the second and third boundary terms in Equation 4.162 will vanish. Hence, after canceling the term $\omega_i^2 - \omega_j^2$, which is $\neq 0$ $i \neq j$, we obtain the orthogonality condition for nonuniform beams as

$$\int_0^l \rho A Y_i Y_j dx = \begin{cases} 0 & \text{for } i \neq j \\ \alpha_j & \text{for } i = j \end{cases} \quad (4.163)$$

The general steps for the modal analysis of a distributed-parameter vibrating system are summarized in Box 4.3.

4.5.6 Forced Bending Vibration

The equation of motion is

$$\frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} + \rho A \frac{\partial^2 v}{\partial t^2} = f(x, t) \quad (4.164)$$

Assume a separable, forced response:

$$v(x, t) = \sum_i \bar{q}_i(t) Y_i(x) \quad (4.165)$$

where $\bar{q}_i(t)$ are the generalized coordinates in the forced case. Substitute Equation 4.165 into Equation 4.164 in the beam equation:

$$\sum_i \bar{q}_i(t) \frac{d^2}{dx^2} EI \frac{d^2 Y_i(x)}{dx^2} + \rho A \sum_i \ddot{\bar{q}}_i(t) Y_i(x) = f(x, t)$$

Box 4.3

MODAL ANALYSIS OF CONTINUOUS SYSTEMS

Equation of free (unforced) motion:

$$L(x, t)v(x, t) = 0 \quad (i)$$

where

$v(x, t)$ = system response

$L(x, t)$ = partial differential operator in space (x) and time (t)

Model solution:

Assume a separable solution

$$v(x, t) = Y(x)q(t) \quad (ii)$$

because a modal response is separable in time and space.

Note:

$Y(x)$ = mode shape

$q(t)$ = generalized coordinate for free response

Note: For two- and three-dimensional space systems, time and space will still be separable for a modal response. However, the space function itself may not be separable along each coordinate direction.

Steps:

1. Substitute Equation (ii) in Equation (i) and separate the space function (of x) and the time function (of t), each of which should be equal to the same constant.
2. Solve the resulting ODE for $Y(x)$ using system boundary conditions. We obtain an infinite set of mode shapes $Y_i(x)$, up to one unknown (removed by normalization), and natural frequencies ω_i .
3. Solve the ODE for $q(t)$ using system initial conditions to determine $q_i(t)$ for mode i . (The orthogonality of $Y_i(x)$ will be needed to establish the initial conditions for $q_i(t)$.)
4. Overall response

$$v(x, t) = \sum_i Y_i(x)q_i(t)$$

The first term on the LHS, on using the mode shape equation 4.129, becomes $\bar{q}_i(t)\rho A\omega_i^2 Y_i(x)$. Multiply the result by $Y_j(x)$ and integrate with respect to $x[0, l]$. We obtain

$$\omega_j^2 \bar{q}_j(t) \int_0^l \rho A Y_j^2(x) dx + \ddot{\bar{q}}_j(t) \int_0^l \rho A Y_j^2(x) dx = \underbrace{\int_0^l Y_j(x) f(x, t) dx}_{f_j(t)}$$

Each of the two integrals on the LHS evaluates α_j according to Equation 4.163. Hence,

$$\ddot{\bar{q}}_j(t) + \omega_j^2 \bar{q}_j(t) = \frac{1}{\alpha_j} f_j(t) \quad \text{for } j = 1, 2, 3, \dots \quad (4.166)$$

We can then solve this equation to determine the generalized coordinates $\bar{q}_j(t)$, using the knowledge of the forcing function $f_j(t)$ and the initial conditions $\bar{q}_j(0)$ and $(d\bar{q}_j/dt)(0)$. Specifically, if the initial displacement and speed of the beam are given by Equation 4.151 and Equation 4.152, respectively, by following the procedure that was adopted to obtain the results (Equation 4.156 and Equation 4.157), we determine

$$\bar{q}_j(0) = \frac{1}{\alpha_j} \int_0^l \rho A d(x) Y_j(x) dx \quad (4.167)$$

$$\frac{d\bar{q}_j(0)}{dt} = \frac{1}{\alpha_j} \int_0^l \rho A s(x) Y_j(x) dx \quad (4.168)$$

Finally, we obtain the overall response of the forced system as

$$v(x, t) = \sum_i \bar{q}_j(t) Y_j(x) \quad (4.169)$$

The main steps in the forced response analysis are summarized in Box 4.4.

Box 4.4

FORCED RESPONSE OF CONTINUOUS SYSTEMS

Equation of forced motion:

$$L(x, t)v(x, t) = L_1(x, t)f(x, t) \quad (i)$$

where

$v(x, t)$ = forced response of the system

$f(x, t)$ = distributed force per unit space

L and L_1 are partial differential operators in space and time

Steps:

1. Substitute the modal expansion

$$v(x, t) = \sum Y_i(x) \bar{q}_i(t) \quad (ii)$$

in Equation (i), where

$Y_i(x)$ = mode shapes

$\bar{q}_i(t)$ = generalized coordinates for forced motion

2. Multiply by $Y_j(x)$ and integrate with respect to space (x) using orthogonality

$$\int_0^l m(x) Y_i(x) Y_j(x) dx = 0 \quad \text{for } i \neq j \quad (iii)$$

Note: Additional boundary terms are present in Equation (iii) when there are lumped elements at the system boundary.

3. Determine the initial conditions for $\bar{q}_j(t)$. We require Equation (iii) for this.
4. Solve the ODE for $\bar{q}_j(t)$ using the initial conditions.
5. Substitute the results into Equation (ii).

FIGURE 4.12 A pump mounted on a simply supported beam.

Example 4.6

A pump is mounted at the midspan of a simply supported thin beam of uniform cross section and length l . The pump rotation generates a transverse force $f_0 \cos \omega t$, as schematically shown in Figure 4.12. Initially, the system starts from rest, from the static equilibrium position of the beam, such that

$$v(x, t) = 0 \quad \text{and} \quad \frac{\partial v(x, t)}{\partial t} = 0 \quad \text{at } t = 0$$

It is necessary to obtain the transverse response $v(x, t)$ of the beam in the form of a modal summation during operation of the pump.

First, determine $q_j(t)$ in terms of f_0 , ω , ω_j and the beam parameters ρ , A , and l , assuming that the beam is completely undamped. Are all modes of the beam excited by the pump? If the beam is lightly damped, what would be its steady-state response?

In particular, what is the steady-state response of the beam at the pump location? Sketch its amplitude as a function of the excitation frequency ω .

Solution

Using the Dirac delta function $\delta(x)$, we can express the equation of forced motion of the beam as

$$EI \frac{\partial^4 v}{\partial x^4} + \rho A \frac{\partial^2 v}{\partial t^2} = f_0 \cos \omega t \delta\left(x - \frac{l}{2}\right) \quad (4.170)$$

Substitute $v(x, t) = \sum_i Y_i(x) q_i(t)$, where normalized mode shapes for the simply supported beam are $Y_i(x) = \sin i\pi x/l$, multiply by $Y_j(x)$, integrate over $x = [0, l]$ and use the orthogonality of mode shapes. We obtain

$$EI \left(\frac{i\pi}{l}\right)^4 \frac{l}{2} q_j(t) + \rho A \frac{l}{2} \ddot{q}_j = f_0 \cos \omega t \sin \frac{j\pi}{2}$$

Note:

$$\int_{a^-}^{a^+} p(x) \delta(x - a) dx = p(a)$$

Hence, from Equation 4.149, we obtain

$$\ddot{q}_j + \omega_j^2 q_j = \alpha_j \cos \omega t \quad (4.171)$$

where

$$\alpha_j = \frac{2f_0}{\rho A l} \sin j \frac{\pi}{2}$$

The given initial conditions are satisfied if and only if $q_j(0) = 0$ and $\dot{q}_j(0) = 0$ for all j .

Hence, the complete solution is

$$q_j(t) = \frac{\alpha_j}{(\omega_j^2 - \omega^2)} [\cos \omega t - \cos \omega_j t] \quad (4.172)$$

It follows that the total response is

$$v(x, t) = \frac{2f_0}{\rho A l} \sum \frac{\sin j\pi/2}{(\omega_j^2 - \omega^2)} \sin j \frac{\pi x}{l} [\cos \omega t - \cos \omega_j t] \quad (4.173)$$

Clearly, $\sin(j\pi/2) = 0$ for even values of j . We see that even modes of the beam are not excited by the pump. This is to be expected because, for even modes, the midspan is a node point and has no motion. If the beam is lightly damped, its natural response terms ($\cos \omega_j t$) will decay to zero with time. Hence, the steady-state response will be

$$v_{ss}(x, t) = \frac{2f_0}{\rho A l} \cos \omega t \sum \frac{\sin j\pi/2 \sin j\pi x/l}{(\omega_j^2 - \omega^2)} \quad (4.174)$$

At the pump location ($x = l/2$), the steady-state response is

$$v_{ss}(l/2, t) = \frac{2f_0}{\rho A l} \cos \omega t \sum \frac{\sin^2 j\pi/2}{(\omega_j^2 - \omega^2)} = \frac{2f_0}{\rho A l} \cos \omega t \left[\frac{1}{(\omega_1^2 - \omega^2)} + \frac{1}{(\omega_3^2 - \omega^2)} + \frac{1}{(\omega_5^2 - \omega^2)} + \cdots \right]$$

Note again that only the odd modes contribute to the response. Furthermore, for a simply supported beam

$$\omega_j = j^2 \omega_1 \quad \text{for } j = 1, 2, 3, \dots$$

where

$$\omega_1 = \left(\frac{\pi}{l} \right)^2 \sqrt{\frac{EI}{\rho A}}$$

Nondimensionalize the midspan response at steady state as

$$\bar{v} = \frac{\rho A l \omega_1^2}{2f_0} v_{ss}(l/2, t) = \left[\frac{1}{(1^4 - \bar{\omega}^2)} + \frac{1}{(3^4 - \bar{\omega}^2)} + \frac{1}{(5^4 - \bar{\omega}^2)} + \cdots \right] \cos \omega t$$

Its amplitude is

$$v_0(\bar{\omega}) = \left| \frac{1}{(1^4 - \bar{\omega}^2)} + \frac{1}{(3^4 - \bar{\omega}^2)} + \frac{1}{(5^4 - \bar{\omega}^2)} + \cdots \right|$$

The characteristic of the amplitude as a function of the nondimensional excitation frequency is sketched in [Figure 4.13](#).

Example 4.7

Perform a modal analysis to determine natural frequencies and mode shapes of transverse vibration of a thin cantilever (i.e., a beam with “fixed–free” or “clamped–free” end conditions). The coordinate system and the beam parameters are as shown in [Figure 4.14](#).

Solution

As usual, the mode shapes are given by

$$Y(x) = C_1 \cosh \lambda x + C_2 \sinh \lambda x + C_3 \cos \lambda x + C_4 \sin \lambda x \quad (4.134)$$

FIGURE 4.13 Amplitude of the steady response at the pump as a function of excitation frequency.

Its first three derivatives are

$$\frac{dY(x)}{dx} = C_1 \lambda \sinh \lambda x + C_2 \lambda \cosh \lambda x - C_3 \lambda \sin \lambda x + C_4 \lambda \cos \lambda x \quad (4.175)$$

$$\frac{d^2 Y(x)}{dx^2} = C_1 \lambda^2 \cosh \lambda x + C_2 \lambda^2 \sinh \lambda x - C_3 \lambda^2 \cos \lambda x - C_4 \lambda^2 \sin \lambda x \quad (4.176)$$

$$\frac{d^3 Y(x)}{dx^3} = C_1 \lambda^3 \sinh \lambda x + C_2 \lambda^3 \cosh \lambda x + C_3 \lambda^3 \sin \lambda x - C_4 \lambda^3 \cos \lambda x \quad (4.177)$$

The BCs of the beam are

$$\text{At } x = 0 : v(0, t) = 0 \quad \text{and} \quad \frac{\partial v(0, t)}{\partial x} = 0$$

$$\text{At } x = l : EI \frac{\partial^2 v(l, t)}{\partial x^2} = 0 \quad \text{and} \quad EI \frac{\partial^3 v(l, t)}{\partial x^3} = 0$$

The corresponding modal BCs are

$$Y(0) = 0; \quad \frac{dY(0)}{dx} = 0; \quad \frac{d^2 Y(l)}{dx^2} = 0; \quad \frac{d^3 Y(l)}{dx^3} = 0 \quad (4.178)$$

Substitute Equation 4.134, Equation 4.175 to Equation 4.177 into Equation 4.178. We obtain

$$C_1 + C_3 = 0 \quad (i)$$

$$C_2 + C_4 = 0 \quad (ii)$$

FIGURE 4.14 A cantilever in bending vibration.

$$C_1 \cosh \lambda l + C_2 \sinh \lambda l - C_3 \cos \lambda l - C_4 \sin \lambda l = 0 \quad (\text{iii})$$

$$C_1 \sinh \lambda l + C_2 \cosh \lambda l + C_3 \sin \lambda l - C_4 \cos \lambda l = 0 \quad (\text{iv})$$

Eliminate C_1 and C_2 in Equation (iii) and Equation (iv) by substituting Equation (i) and Equation (ii). We obtain

$$[\cosh \lambda l + \cos \lambda l]C_3 + [\sinh \lambda l + \sin \lambda l]C_4 = 0 \quad (\text{v})$$

$$[\sinh \lambda l - \sin \lambda l]C_3 + [\cosh \lambda l + \cos \lambda l]C_4 = 0 \quad (\text{vi})$$

or, in the vector-matrix form

$$\begin{bmatrix} \cosh \lambda l + \cos \lambda l & \sinh \lambda l + \sin \lambda l \\ \sinh \lambda l - \sin \lambda l & \cosh \lambda l + \cos \lambda l \end{bmatrix} \begin{bmatrix} C_3 \\ C_4 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (4.179)$$

The trivial solution of Equation 4.179 is $C_3 = 0 = C_4$. Then, from Equation (i) and Equation (ii), we also have $C_1 = 0 = C_2$. This solution corresponds to $Y(x) = 0$ and is not acceptable in general for a vibrating system. Hence, the matrix in Equation 4.179 must be noninvertible (i.e., singular). Hence, the determinant of the matrix must vanish (see Appendix 3A); thus

$$(\cosh \lambda l + \cos \lambda l)^2 - (\sinh \lambda l + \sin \lambda l)(\sinh \lambda l - \sin \lambda l) = 0$$

or

$$\cosh^2 \lambda l + 2 \cosh \lambda l \cos \lambda l + \cos^2 \lambda l - \sinh^2 \lambda l + \sin^2 \lambda l = 0$$

However, it is well known that

$$\cosh^2 \lambda l - \sinh^2 \lambda l = 1 \quad \text{and} \quad \cos^2 \lambda l + \sin^2 \lambda l = 1$$

Hence,

$$\cos \lambda l \cosh \lambda l = -1 \quad (4.180)$$

This equation has an infinite number of solutions λ_i for $i = 1, 2, 3, \dots$ giving an infinite number of natural frequencies:

$$\omega_i = \lambda_i^2 \sqrt{\frac{EI}{\rho A}} \quad (4.181)$$

The corresponding mode shapes are given by Equation 4.134 subject to Equation (i), Equation (ii), and Equation (v) or Equation (vi). This gives $Y_i(x) = C_3(\cos \lambda_i x - \cosh \lambda_i x) + C_4(\sin \lambda_i x - \sinh \lambda_i x)$ with

$$C_3 = -\frac{[\sinh \lambda_i l + \sin \lambda_i l]}{[\cosh \lambda_i l + \cos \lambda_i l]} C_4$$

It follows that

$$Y_i(x) = C_4[\sin \lambda_i x - \sinh \lambda_i x] + C_4 \left[\frac{\sinh \lambda_i l + \sin \lambda_i l}{\cosh \lambda_i l + \cos \lambda_i l} \right] [-\cos \lambda_i x + \cosh \lambda_i x]$$

The unknown multiplier C_4 simply scales the mode shape and is absorbed into the generalized coordinate $q_i(t)$ as usual. In fact, this is a process of normalization of mode shapes, where $C_4 = 1$ is used. So, we have the normalized mode shapes:

$$Y_i(x) = a \sin \lambda_i x + b \sinh \lambda_i x + \alpha_i [c \cos \lambda_i x + d \cosh \lambda_i x] \quad (4.182)$$

with

$$a = 1, \quad b = -1, \quad c = -1, \quad d = 1 \quad \text{and} \quad \alpha_i = \frac{\sinh \lambda_i l + \sin \lambda_i l}{\cosh \lambda_i l + \cos \lambda_i l} \quad (4.183)$$

The first three roots of Equation 4.180 are

$$\lambda_1 l = 1.875104; \quad \lambda_2 l = 4.694091; \quad \lambda_3 l = 7.854757$$

FIGURE 4.15 First three modes of a cantilever (fixed–free beam) in transverse vibration.

The corresponding three mode shapes are sketched in Figure 4.15. Note, in particular, that the node points are not physically fixed but remain stationary during a modal motion. This completes the solution.

The modal information corresponds to the infinite set of natural frequencies that are obtained by solving Equation 4.180 subject to Equation 4.181, and the mode shapes are given by Equation 4.182 subject to Equation 4.183. Modal information corresponding to other common BCs may also be put in this form. Table 4.3 summarizes such data. Table 4.4 provides numerical values corresponding to this modal information for the first three modes.

4.5.7 Bending Vibration of Beams with Axial Loads

In practice, beam-type members that undergo flexural (transverse) vibrations may carry axial forces. Examples are structural members such as columns, struts, and towers. Generally, a tension will increase the natural frequencies of bending and compression will decrease them. Hence, one way to avoid the excitation of a particular natural frequency (and mode) of bending vibration is to use a suitable tension or compression in the axial direction.

The equation of motion for the transverse motion of a thin beam subjected to an axial tension P may be easily derived by following the procedure that led to Equation 4.122. For simplicity, assume a thin beam subjected to a constant tensile force P . A small element δx of the beam is shown in Figure 4.16. The vertical component (in the positive y direction) of the axial force is

$$-P \sin \theta + P \sin(\theta + \delta\theta) \cong -P\theta + P(\theta + \delta\theta) = P \delta\theta$$

because the slope $\theta = \partial v / \partial x$ is small. Also, the change in slope is

$$\delta\theta = \frac{\partial^2 v}{\partial x^2} \delta x$$

It is clear that the previous equation of transverse dynamics of element δx has to be modified simply by adding the term $P(\partial^2 v / \partial x^2) \delta x$ to the $f(x, t) \delta x$ side of the equation. Then, the resulting equation of transverse vibration will be

$$\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) - P \frac{\partial^2 v}{\partial x^2} = f(x, t) \quad (4.184)$$

FIGURE 4.16 Beam element in transverse vibration and subjected to axial tension.

For modal analysis of a uniform beam, then, we use the equation of free motion

$$\rho A \frac{\partial^2 v}{\partial t^2} + EI \frac{\partial^4 v}{\partial x^4} - P \frac{\partial^2 v}{\partial x^2} = 0 \quad (4.185)$$

With a separable (modal) solution of the form

$$v(x, t) = Y(x)q(t) \quad (4.186)$$

we have

$$\frac{\ddot{q}(t)}{q(t)} = - \frac{EI (d^4 Y/dx^4) - P (d^2 Y/dx^2)}{\rho A Y} = -\omega^2 \quad (4.187)$$

which gives, as before, the time response equation of the generalized coordinates

$$\ddot{q}(t) + \omega^2 q(t) = 0 \quad (4.188)$$

and the mode shape equation

$$EI \frac{d^4 Y}{dx^4} - P \frac{d^2 Y}{dx^2} - \rho A \omega^2 Y = 0 \quad (4.189)$$

Note that the mode shape equation is still fourth order, but is different. The analysis, however, may be done as before by using four BCs at the two ends of the beam to determine the natural frequencies (an infinite set) and the corresponding normalized mode shapes.

4.5.8 Bending Vibration of Thick Beams

In our derivation of the governing equation for the lateral vibration of thin beams (known as the Bernoulli–Euler beam equation), we neglected the following effects in particular:

1. Deformation and associated lateral motion due to shear stresses
2. Moment of inertia of beam elements in rotatory motion

Note, however, that we did use the fact that shear forces (Q) are present in a beam cross section, even though the resulting deformations were not taken into account. Also, in writing the equation for rotational motion of a beam element δx , we simply summed the moments to zero, without including the inertia moment. These assumptions are valid for a beam whose cross-sectional dimensions are small compared with its length. However, for a thick beam, the effect of shear deformation and rotatory inertia must be included in deriving the governing equation. The resulting equation is known as the *Timoshenko beam equation*. Important steps in the derivation of the equation of motion for the forced transverse vibration of beams, including the effects of shear deformation and rotatory inertia, are given now.

FIGURE 4.17 A Timoshenko beam element: (a) combined effect of bending and shear; (b) dynamic effects including rotatory inertia.

Consider a small element δx of a beam. Figure 4.17(a) illustrates the contribution of the bending of an element and the deformation due to transverse shear stresses towards the total slope of the beam neutral axis. Let

θ = angle of rotation of the beam element due to bending

ϕ = increase in slope of the element due to shear deformation in transverse shear (this is equal to shear strain)

Then, the total slope of the beam element is

$$\frac{\partial v}{\partial x} = \theta + \phi \quad (4.190)$$

Here, v and x take the usual meanings, as for a thin beam.

Figure 4.17(b) shows an element δx of the beam with the forces, moments, and the linear and angular accelerations marked. With the sign convention shown in Figure 4.17(b), the linear shear-stress–shear-strain relation can be stated as

$$Q = -kGA\phi \quad (4.191)$$

where the Timoshenko shear coefficient

$$k = \frac{\text{Average shear stress on beam cross section at } x}{\text{Shear stress at the neutral axis at } x}$$

and

$$G = \text{shear modulus}$$

The equation for translatory motion is

$$f(x, t)\delta x + Q - \left(Q + \frac{\partial Q}{\partial x}\delta x\right) = (\rho A \delta x) \frac{\partial^2 v}{\partial t^2}$$

Hence,

$$f(x, t) - \frac{\partial Q}{\partial x} = \rho A \frac{\partial^2 v}{\partial t^2} \quad (4.192)$$

The equation for the rotatory motion of the element, taking into account the rotatory inertia, is

$$M + \frac{\partial M}{\partial x} \delta x - M - Q \delta x = (I\rho \delta x) \frac{\partial^2 \theta}{\partial t^2}$$

which becomes

$$\frac{\partial M}{\partial x} - Q = I\rho \frac{\partial^2 \theta}{\partial t^2} \quad (4.193)$$

From the elementary theory of bending, as before

$$M = EI \frac{\partial \theta}{\partial x} \quad (4.194)$$

The relationship between the shear modulus and the modulus of elasticity is known to be

$$E = 2(1 + \nu)G \quad (4.195)$$

where ν = Poisson's ratio. This relation may be substituted if desired.

Manipulation of these equations yields

$$\begin{aligned} EI \frac{\partial^4 \nu}{\partial x^4} + \rho A \frac{\partial^2 \nu}{\partial t^2} - \rho I \left(1 + \frac{E}{kG} \right) \frac{\partial^4 \nu}{\partial x^2 \partial t^2} + \frac{\rho^2 I}{kG} \frac{\partial^4 \nu}{\partial t^4} \\ = f(x, t) - \frac{EI}{kGA} \frac{\partial^2 f(x, t)}{\partial x^2} + \frac{\rho I}{kGA} \frac{\partial^2 f(x, t)}{\partial t^2} \end{aligned} \quad (4.196)$$

This is the Timoshenko beam equation for forced transverse motion. Note that this equation is fourth order in time, whereas the thin beam equation is second order in time. The modal analysis may proceed as before, by using the free ($f = 0$) equation and a separable solution. However, the resulting differential equation for the generalized coordinates will be fourth order in time and, as a result, additional natural frequency bands will be created. The reason is the independent presence of shear and bending motions. The differential equation of mode shapes will be fourth order in x and the solution procedure will be as before, through the use of four BCs at the two ends of the beam.

4.5.9 Use of the Energy Approach

So far, we have used only the direct, Newtonian approach in deriving the governing equations for continuous members in vibration. Of course, the same results may be obtained by using the Lagrangian (energy) approach. The general approach here is to first express the Lagrangian L of the system as

$$L = T^* - V \quad (4.197)$$

where

T^* = total kinetic co-energy (equal to kinetic energy T for typical systems)

V = total potential energy

Then, for a virtual increment (variation) of the system through incrementing the system variable, the following condition will hold:

$$\int_{t_1}^{t_2} [\delta L + \delta W] dt = 0 \quad (4.198)$$

where δL is the increment in the Lagrangian and δW is the work done by the external forces on the system due to the increment. Finally, using the arbitrariness of the variation, the equation of motion, along with the BCs, can be obtained. This approach is illustrated now.

First, consider the free motion. We can easily extend the result to the case of forced motion. Kinetic energy is given by

$$T = \frac{1}{2} \int_0^l \rho A \, dx \left(\frac{\partial v}{\partial t} \right)^2 = \frac{1}{2} \int_0^l \rho A \left(\frac{\partial v}{\partial t} \right)^2 dx \quad (4.199)$$

Potential energy due to bending results from work needed to bend the beam (angle denoted by $\theta = \partial v / \partial x$ as usual) under bending moment M ; thus

$$V = \frac{1}{2} \int_{\text{End 1}}^{\text{End 2}} M \, d\phi = \frac{1}{2} \int_0^l EI \left(\frac{\partial^2 v}{\partial x^2} \right)^2 dx \quad (4.200)$$

Before proceeding further, note the following steps of variation and integration by parts with respect to t :

$$\delta \int_{t_1}^{t_2} \frac{1}{2} \left(\frac{\partial v}{\partial t} \right)^2 dt = \int_{t_1}^{t_2} \frac{\partial v}{\partial t} \delta \left(\frac{\partial v}{\partial t} \right) dt = \int_{t_1}^{t_2} \frac{\partial v}{\partial t} \frac{\partial \delta v}{\partial t} dt = \left[\frac{\partial v}{\partial t} \delta v \right]_{t_1}^{t_2} - \int_{t_1}^{t_2} \frac{\partial^2 v}{\partial t^2} \delta v \, dt \quad (4.201)$$

Note that we interchanged the operations δ and $\partial/\partial t$ prior to integrating by parts. Also, by convention, we assume that no variations are performed at the starting and ending times (t_1 and t_2) of integration. Hence,

$$\delta v(t_1) = 0 \quad \text{and} \quad \delta v(t_2) = 0 \quad (4.202)$$

Similarly, variation and integration by parts with respect to x are done as follows:

$$\begin{aligned} \delta \int_0^l \frac{1}{2} EI \left(\frac{\partial^2 v}{\partial x^2} \right)^2 dx &= \int_0^l EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial^2 v}{\partial x^2} \right) dx = \int_0^l EI \frac{\partial^2 v}{\partial x^2} \frac{\partial}{\partial x} \delta \left(\frac{\partial v}{\partial x} \right) dx \\ &= \left[EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial v}{\partial x} \right) \right]_0^l - \int_0^l \frac{\partial}{\partial x} EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial v}{\partial x} \right) dx = \left[EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial v}{\partial x} \right) \right]_0^l - \int_0^l \frac{\partial}{\partial x} EI \frac{\partial^2 v}{\partial x^2} \frac{\partial \delta v}{\partial x} dx \\ &= \left[EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial v}{\partial x} \right) \right]_0^l - \left[\frac{\partial}{\partial x} EI \frac{\partial^2 v}{\partial x^2} \delta v \right]_0^l + \int_0^l \frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} \delta v \, dx \end{aligned} \quad (4.201a)$$

Now, for the case of free vibration ($\delta W = 0$), substitute Equation 4.201 and Equation 4.201a in δT , and δV of Equation 4.199 and Equation 4.200, to obtain

$$\begin{aligned} \int_{t_1}^{t_2} \delta L \, dt = 0 &= - \int_{t_1}^{t_2} dt \int_0^l dx \left[\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} \right] \delta v + \int_0^l dx \rho A \left[\frac{\partial v}{\partial t} \delta v \right]_{t_1}^{t_2} \\ &\quad - \int_{t_1}^{t_2} dt \left[EI \frac{\partial^2 v}{\partial x^2} \delta \left(\frac{\partial v}{\partial x} \right) \right]_0^l + \int_{t_1}^{t_2} dt \left[\frac{\partial}{\partial x} EI \frac{\partial^2 v}{\partial x^2} \delta v \right]_0^l \end{aligned} \quad (4.203)$$

Since Equation 4.203 holds for all arbitrary variations $\delta v(t)$, its coefficient should vanish. Hence,

$$\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} = 0 \quad (4.204)$$

which is the same Bernoulli–Euler beam equation for free motion as we had derived before.

The second integral term on the RHS of Equation 4.203 has no consequence. We conventionally pick $\delta v(t_1) = 0$ and $\delta v(t_2) = 0$ at the time points t_1 and t_2 .

The third integral term on the RHS of Equation 4.203 gives some BCs. Specifically, if the slope BC $\partial v / \partial x$ is zero (i.e., fixed end), then the corresponding bending moment at the end is arbitrary, as expected. However, if the slope at the boundary is arbitrary, then the bending moment $EI(\partial^2 v / \partial x^2)$ at the end should be zero (i.e., pinned or free end).

The last integral term on the RHS of Equation 4.203 gives some other BCs. Specifically, if the displacement BC v is zero (i.e., pinned or fixed end) then the corresponding shear force at the

end is arbitrary. However, if the displacement at the boundary is arbitrary, then the shear force $(\partial/\partial x)EI(\partial^2 v/\partial x^2)$ at that end should be zero (i.e., free or sliding end).

Next, consider a forced beam with force per unit length given by $f(x, t)$. Then, the work done by $f(x, t)dx$ in a small element dx of the beam, when moved through a displacement of δv , is

$$f(x, t)dx \delta v \quad (4.205)$$

Then, by combining Equation 4.205 with Equation 4.203, for arbitrary variation δv , we obtain the forced vibration equation

$$\rho A \frac{\partial^2 v}{\partial t^2} + \frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} = f(x, t) \quad (4.206)$$

Note that external forces and moments applied at the ends of the beam can be incorporated into the BCs in the same manner.

4.5.10 Orthogonality with Inertial Boundary Conditions

It can be verified that the conventional orthogonality condition (Equation 4.163) holds for beams in transverse vibration, under common noninertial BCs. When an inertia element (rectilinear or rotatory) is present at an end of the beam, this condition is violated. A modified and more general orthogonality condition can be derived for application to beams with inertial boundary conditions.

To illustrate the procedure, consider a beam with a mass m attached at the end $x = l$, as shown in Figure 4.18(a). A free-body diagram giving the sign convention for shear force Q acting on m is shown in Figure 4.18(b).

The BCs at $x = l$ are:

1. Bending moment vanishes, because there is no rotatory inertia at the end that is free. Hence,

$$EI \frac{\partial^2 v(l, t)}{\partial x^2} = 0 \quad (4.207)$$

FIGURE 4.18 (a) A beam with an end mass in transverse vibration; (b) free-body diagram showing the shear force acting on the end mass.

2. Equation of rectilinear motion of the end mass

$$m \frac{\partial^2 v(l, t)}{\partial t^2} = \frac{\partial}{\partial x} EI \frac{\partial^2 v(l, t)}{\partial x^2} \quad (4.208)$$

In the usual manner, by substituting $v(x, t) = Y_i(x)q_i(t)$ for mode i , along with $\ddot{q}_i(t) = -\omega_i^2 q_i(t)$, into Equation 4.207 and Equation 4.208, with the understanding that the result should hold for any $q_i(t)$, we obtain the corresponding modal boundary conditions:

$$\frac{d^2 Y_i(l)}{dx^2} = 0 \quad (4.209)$$

$$\frac{d}{dx} EI \frac{d^2 Y_i(l)}{dx^2} + \omega_i^2 m Y_i(l) = 0 \quad (4.210)$$

for mode i .

Now, we return to Equation 4.162:

$$(\omega_i^2 - \omega_j^2) \int_0^l \rho A Y_i Y_j dx - \left[Y_j \frac{d}{dx} EI \frac{d^2 Y_i}{dx^2} - Y_i \frac{d}{dx} EI \frac{d^2 Y_j}{dx^2} \right]_0^l \left[\frac{dY_j}{dx} EI \frac{d^2 Y_i}{dx^2} - \frac{dY_i}{dx} EI \frac{d^2 Y_j}{dx^2} \right]_0^l = 0 \quad (4.162)$$

The second and the third terms of Equation 4.162 will vanish at $x = 0$ for noninertial BCs, as usual. At $x = l$, the third term will vanish in view of Equation 4.209. So, we are left with the second term at $x = l$. Substitute Equation 4.210:

$$\left(Y_j \frac{d}{dx} EI \frac{d^2 Y_i}{dx^2} - Y_i \frac{d}{dx} EI \frac{d^2 Y_j}{dx^2} \right)_l = -(\omega_i^2 - \omega_j^2) m Y_i(l) Y_j(l) \quad (4.211)$$

Substitute Equation 4.211 into Equation 4.162 and cancel $\omega_i^2 - \omega_j^2 \neq 0$ for $i \neq j$. We obtain

$$\int_0^l \rho A Y_i Y_j dx + m Y_i(l) Y_j(l) = \begin{cases} 0 & \text{for } i \neq j \\ \alpha_j & \text{for } i = j \end{cases} \quad (4.212)$$

This is the modified and more general orthogonality property. If the mass is at $x = 0$, the direction of Q that acts on m will reverse and, hence, the second term in Equation 4.212 will become $-m Y_i(0) Y_j(0)$.

4.5.10.1 Rotatory Inertia

If there is a free rotatory inertia at $x = l$, without an associated rectilinear inertia, then the shear force will vanish, giving

$$\frac{d}{dx} EI \frac{d^2 Y_i(l)}{dx^2} = 0 \quad (4.213)$$

The equation of rotational motion of J will give

$$EI \frac{d^2 Y_i(l)}{dx^2} - \omega_i^2 J \frac{dY_i(l)}{dx} = 0 \quad (4.214)$$

Here, the second term in Equation 4.162 will vanish in view of Equation 4.213. Then, by substituting Equation 4.214 into the third term of Equation 4.162, we obtain the modified orthogonality relation

$$\int_0^l \rho A Y_i Y_j dx + J \frac{dY_i(l)}{dx} \frac{dY_j(l)}{dx} = \begin{cases} 0 & \text{for } i \neq j \\ \alpha_j & \text{for } i = j \end{cases} \quad (4.215)$$

4.6 Damped Continuous Systems

All practical mechanical systems have some form of energy dissipation (damping). When the level of dissipation is small, damping is neglected, as we have done thus far in this chapter. Yet, some effects of damping (e.g., the fact that at steady state the natural [modal] vibration components decay to zero leaving only the steady forcing component) are tacitly assumed even in undamped analysis.

The natural behavior of a system is expected to change due to the presence of damping. In particular, the system's natural frequencies will decrease (and be called damped natural frequencies) as a result of damping. Furthermore, it is quite possible that a damped system would not possess "real" modes in which it could independently vibrate. Mathematically, in that case, the modes will become complex (as opposed to real) and, physically, all the points of the system will not move, maintaining a constant phase at a given damped natural frequency. In other words, a real solution that is separable in space (x) and time (t) may not be possible for the free vibration problem of a damped system. Also, node points of an undamped system may vary with time as a result of damping. With light damping, of course, such effects of damping will be negligible.

Since there are damped systems that do not possess real natural modes of vibration, care should be exercised when extending the results of modal analysis from an undamped system to a damped one. However, in some cases, the mode shapes will remain the same after including damping (even though the natural frequencies will change). This is analogous to the case of proportional damping, which was discussed in the section on lumped-parameter (multi-degree-of-freedom) vibrating systems. The modal analysis of a damped system will become significantly easier if we assume that the mode shapes will remain the same as those for the undamped system. Even when the actual type of damping in the system results in complex modes, for analytical convenience, an equivalent damping model that gives real modes is used in simplified analysis. This is analogous to the use of proportional damping in lumped-parameter systems.

4.6.1 Modal Analysis of Damped Beams

Consider the problem of free damped transverse vibration of a thin beam, given by

$$\frac{\partial^2}{\partial x^2} EI \frac{\partial^2 v}{\partial x^2} + L \left(\frac{\partial v}{\partial t} \right) + \rho A \frac{\partial^2 v}{\partial t^2} = 0 \quad (4.216)$$

where L is a spatial differential operator (in x). Consider the following two possible models of damping:

$$1. \quad L = \frac{\partial^2}{\partial x^2} E^* I \frac{\partial^2}{\partial x^2} \quad (4.217)$$

$$2. \quad L = c \quad (4.218)$$

Model 1 corresponds to the Kelvin–Voigt model of material (internal) damping given by the stress–strain relation

$$\sigma = E\varepsilon + E^* \frac{\partial \varepsilon}{\partial t} \quad (4.219)$$

where E^* is the damping parameter of the beam material. Hence, we obtain the damped beam equation simply by replacing E in the undamped beam equation by $E + E^* (\partial/\partial t)$. Also, E^* is independent of the frequency of vibration for the *viscoelastic damping* model, but will be frequency dependent for the *hysteretic damping* model. Modal analysis is done regardless of any frequency dependence of E^* and, in the final modal result for a particular modal frequency ω_i , the appropriate frequency function for $E^*(\omega)$ is used with $\omega = \omega_i$ if the damping is of the hysteretic type. It can be easily verified that the mode shapes of the damped system with model 4.217 are identical to those of the undamped system, regardless of whether the beam cross section is uniform or not.

In Model 2 (Equation 4.218), the operator is a constant c . This corresponds to external damping of the linear viscous type, distributed along the beam length. For example, imagine a beam resting on a

foundation of viscous damping material. For Model 2, it can be shown that the damped mode shapes are identical to the undamped ones, assuming that the beam cross section is uniform. If the beam is nonuniform, the damped and the undamped mode shapes are identical if we assume that the damping constant c varies along the beam in proportion to the area of cross section $A(x)$ of the beam. We shall show this in the example given below.

Example 4.8

Perform the modal analysis for transverse vibration of a thin nonuniform beam with linear viscous damping distributed along its length and satisfying the beam equation

$$\frac{\partial^2}{\partial x^2} EI(x) \frac{\partial^2 v}{\partial x^2} + \rho A(x) b \frac{\partial v}{\partial t} + \rho A(x) \frac{\partial^2 v}{\partial t^2} = 0 \quad (4.220)$$

Determine damped natural frequencies, modal damping ratios, and the response $v(x, t)$ as a modal series expansion, given $v(x, 0) = d(x)$ and $\dot{v}(x, 0) = s(x)$.

Solution

Substitute the separable solution

$$v(x, t) = Y(x)q(t) \quad (4.221)$$

into Equation 4.220. We obtain

$$\frac{d^2}{dx^2} EI \frac{d^2 Y(x)}{dx^2} q(t) + \rho A(x) b Y(x) \dot{q}(t) + \rho A(x) Y(x) \ddot{q}(t) = 0$$

Group the functions of x and t separately and equate to the same constant ω^2 , as usual:

$$\frac{\frac{d^2}{dx^2} EI \frac{d^2 Y(x)}{dx^2}}{\rho A(x) Y(x)} = - \frac{\ddot{q}(t) + b \dot{q}(t)}{q(t)} = \omega^2 \quad (4.222)$$

We have

$$\frac{d^2}{dx^2} EI \frac{d^2 Y(x)}{dx^2} - \omega^2 \rho A Y(x) = 0 \quad (4.223)$$

and

$$\ddot{q}(t) + b \dot{q}(t) + \omega^2 q(t) = 0 \quad (4.224)$$

Note that Equation 4.223 is identical to that for the undamped beam. Hence, with known BCs, we will obtain the same mode shapes $Y_i(x)$ and the same *undamped* natural frequencies ω_i in the usual manner. However, the equation of modal generalized coordinates $q(t)$ given by Equation 4.224 is different from that for the undamped case ($b = 0$). We write, for mode i

$$\ddot{q}_i(t) + 2\zeta_i \omega_i \dot{q}_i(t) + \omega_i^2 q_i(t) = 0 \quad (4.225)$$

where

$$\zeta_i = \frac{b}{2\omega_i} \quad (4.226a)$$

is the modal damping ratio for mode i . Damped natural frequencies are

$$\omega_{di} = \sqrt{1 - \zeta_i^2} \omega_i \quad (4.226b)$$

Equation 4.225 can be solved in the usual manner, with initial conditions $q_i(0)$ and $\dot{q}_i(0)$ determined *a priori*, using known $v(x, 0)$ and $\dot{v}(x, 0)$.

The modal series solution is

$$v(x, t) = \sum Y_i(x)q_i(t) \quad (4.227)$$

The initial conditions are

$$\sum Y_i(x)q_i(0) = d(x) \quad (4.228)$$

$$\sum Y_i(x)\dot{q}_i(0) = s(x) \quad (4.229)$$

Multiply Equation 4.228 and Equation 4.229 by $\rho A(x)Y_j(x)$ and integrate from $x = 0$ to l using the orthogonality condition

$$\int_0^l \rho A(x)Y_i(x)Y_j(x)dx = \begin{cases} 0 & \text{for } i \neq j \\ \alpha_j & \text{for } i = j \end{cases} \quad (4.230)$$

We obtain

$$q_j(0) = \frac{1}{\alpha_j} \int_0^l d(x)\rho A(x)dx \quad (4.231)$$

$$\dot{q}_j(0) = \frac{1}{\alpha_j} \int_0^l s(x)\rho A(x)dx \quad (4.232)$$

This completes the solution for the free damped beam. The forced damped case can be analyzed in the same manner as for the forced undamped case because the mode shapes are the same.

4.7 Vibration of Membranes and Plates

The cables, rods, shafts, and beams whose vibration we have studied thus far in this chapter are *one-dimensional members* or *line structures*. These continuous members need one spatial variable (x), in addition to the time variable (t), as an independent variable to represent their governing equation of motion. Membranes and plates are *two-dimensional members* or *planar structures*. They need two independent spatial variables (x and y) in addition to time (t), for representing their dynamics.

A membrane may be interpreted as a two-dimensional extension of a string or cable. In particular, it has to be in tension and cannot support any bending moment. A plate is a two-dimensional extension of a beam. It can support a bending moment. Their governing equations will, therefore, resemble two-dimensional versions of their respective one-dimensional counterparts. Modal analysis will also follow the familiar steps, after accounting for the extra dimension. In this section, we will give an introduction to the modal analysis of membranes and plates. For simplicity, only special cases of rectangular members with relatively simple BCs will be considered. Analysis of more complicated boundary geometries and conditions will follow analogous procedures, but requires a greater effort and produces more complicated results.

4.7.1 Transverse Vibration of Membranes

Consider a stretched membrane (in tension) that lies on the x - y plane, as shown in [Figure 4.19](#). Transverse vibration $v(x, y, t)$ in the z -direction is of interest. By following a procedure that is somewhat analogous to the derivation of the cable equation, we can obtain the governing equation as

$$\frac{\partial^2 v(x, y, t)}{\partial t^2} = c^2 \left[\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right] v(x, y, t) \quad (4.233)$$

FIGURE 4.19 A membrane or a plate in Cartesian coordinates.

with

$$c = \sqrt{\frac{T'}{m'}} \quad (4.234)$$

where

T' = tension per unit length of membrane section (assumed constant)

m' = mass per unit surface area of membrane

For modal analysis, we seek a separable solution of the form

$$v(x, y, t) = Y(x)Z(y)q(t) \quad (4.235)$$

Substitute Equation 4.235 into Equation 4.233. We obtain

$$Y(x)Z(y)\ddot{q}(t) = c^2 \left[\frac{1}{Y(x)} \frac{d^2 Y(x)}{dx^2} + \frac{1}{Z(y)} \frac{d^2 Z(y)}{dy^2} \right] \quad (4.236)$$

Since Equation 4.236 is true for all possible values of t , x , and y that are independent, the three function groups should separately equal the constants; thus

$$\frac{1}{Y(x)} \frac{d^2 Y}{dx^2} = -\alpha^2 \quad \text{or} \quad \frac{d^2 Y(x)}{dx^2} + \alpha^2 Y(x) = 0 \quad (4.237)$$

$$\frac{1}{Z(y)} \frac{d^2 Z(y)}{dy^2} = -\beta^2 \quad \text{or} \quad \frac{d^2 Z(y)}{dy^2} + \beta^2 Z(y) = 0 \quad (4.238)$$

$$\frac{\ddot{q}(t)}{q(t)} = -\omega^2 \quad \text{or} \quad \ddot{q}(t) + \omega^2 q(t) = 0 \quad (4.239)$$

with

$$\omega^2 = c^2(\alpha^2 + \beta^2) \quad (4.240)$$

The argument for using positive constants α^2 , β^2 , and ω^2 is similar to that we gave for the one-dimensional case. Next, Equation 4.237 and Equation 4.238 have to be solved using two end conditions for each direction, as usual. This will provide an infinite number of solutions α_i and β_j , and the corresponding natural frequencies

$$\omega_{ij}^2 = c(\alpha_i^2 + \beta_j^2)^{1/2} \quad \text{for } i = 1, 2, 3, \dots \text{ and } j = 1, 2, 3, \dots \quad (4.241)$$

along with the mode shape components $Y_i(x)$ and $Z_j(y)$ for the two dimensions.

4.7.2 Rectangular Membrane with Fixed Edges

Consider a rectangular membrane of length a and width b as shown in Figure 4.19 and with the four edges fixed. The BCs are

$$v(0, y, t) = 0; \quad v(a, y, t) = 0; \quad v(x, 0, t) = 0; \quad v(x, b, t) = 0$$

Using these in solving Equation 4.237 and Equation 4.238, as usual, we obtain

$$Y_i(x) = \sin \alpha_i x \quad \text{with } \alpha_i = \frac{i\pi}{a} \quad (4.242)$$

$$Z_j(y) = \sin \beta_j y \quad \text{with } \beta_j = \frac{j\pi}{b} \quad (4.243)$$

$$\omega_{ij} = c[\alpha_i^2 + \beta_j^2]^{1/2} = \pi c \left[\frac{i^2}{a^2} + \frac{j^2}{b^2} \right]^{1/2} \quad \text{for } i = 1, 2, 3, \dots \text{ and } j = 1, 2, 3 \quad (4.244)$$

Note that the spatial mode shapes are given by

$$Y_i(x)Z_j(y) = \sin \frac{i\pi x}{a} \sin \frac{j\pi y}{b} \quad (4.245)$$

4.7.3 Transverse Vibration of Thin Plates

Consider a thin plate of thickness h in a Cartesian coordinate system as shown in Figure 4.19. The usual assumptions as for the derivation of the Bernoulli–Euler beam equation are used. In particular, h is assumed small compared with the surface dimensions (a and b for a rectangular plate). Then, shear deformation and rotatory inertia can be neglected, and also normal stresses in the transverse direction (z) can be neglected. Furthermore, any end forces in the planar directions (x and y) are neglected. The governing equation is

$$\frac{\partial^2 v(x, y, t)}{\partial t^2} + c^2 \left[\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right] v(x, y, t) = 0 \quad (4.246)$$

with

$$c^2 = \frac{E'I'}{\rho A'} = \frac{Eh^2}{12(1 - \nu^2)\rho} \quad (4.247)$$

where

$$E' = \frac{E}{(1 - \nu^2)} \quad (4.248)$$

$$I' = \frac{h^3}{12} = \text{second moment of area per unit length of section} \quad (4.249)$$

$A' = h$ = area per unit length of section

ρ = mass density of material

E = Young's modulus of elasticity of the plate material

ν = Poisson's ratio of the plate material

If we attempt modal analysis by assuming a completely separable solution of the form $v(x, y, t) = Y(x)Z(y)q(t)$ in Equation 4.246, a separable grouping of functions of x and y will not be achieved in general. However, the space and the time will be separable in modal motions. Hence, we seek a solution of the form

$$v(x, y, t) = Y(x, y)q(t) \quad (4.250)$$

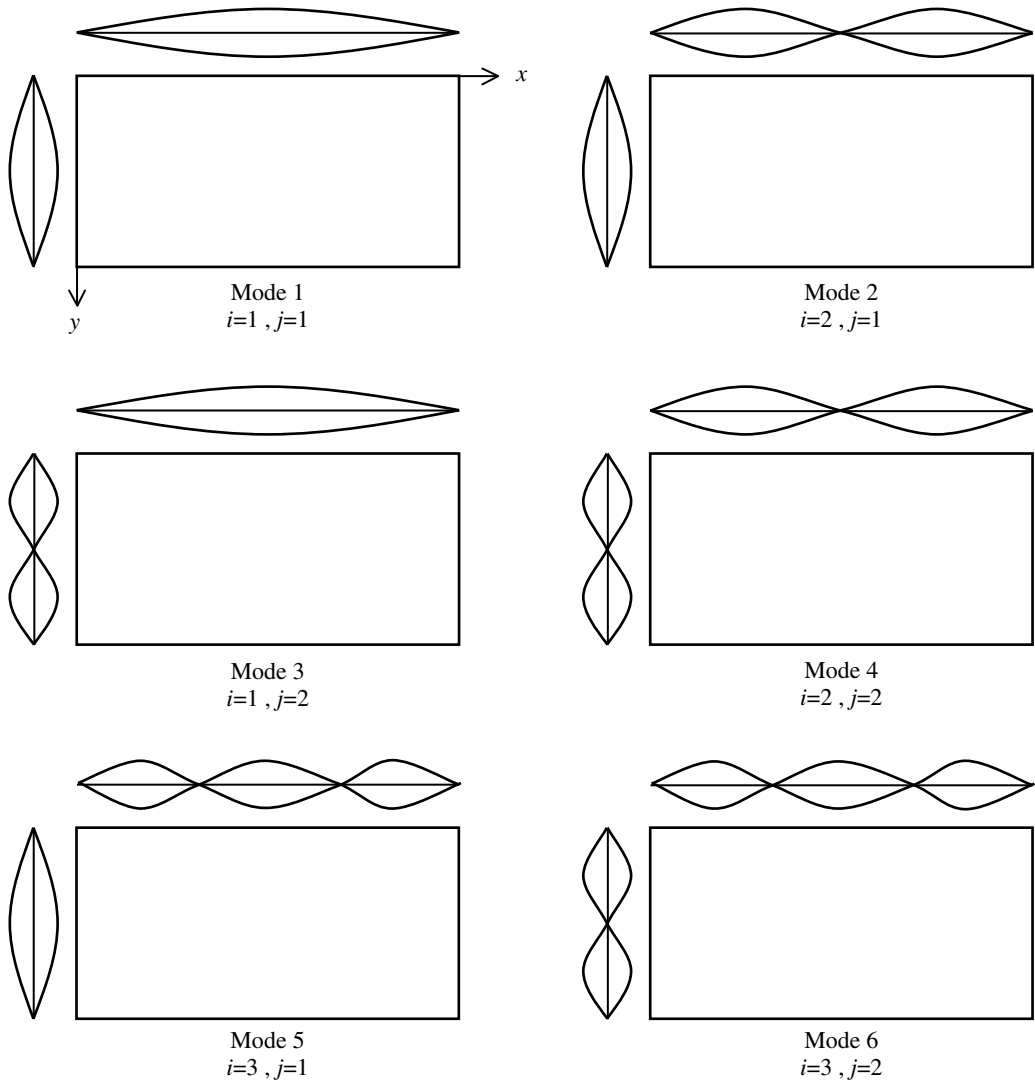

FIGURE 4.20 Mode shapes of transverse vibration of a simply supported rectangular plate.

We will obtain

$$\ddot{q}(t) + \omega^2 q(t) = 0 \quad (4.251)$$

and

$$\nabla^2 \nabla^2 Y(x, y) - \lambda^4 Y(x, y) = 0 \quad (4.252)$$

with the natural frequencies ω given by

$$\omega = \lambda^2 c \quad (4.253)$$

and ∇^2 is the Laplace operator given by

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \quad (4.254)$$

and, hence, $\nabla^2 \nabla^2$ is the biharmonic operation ∇^4 given by

$$\nabla^4 = \frac{\partial^4}{\partial x^4} + 2 \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4} \quad (4.255)$$

The solution of Equation 4.252 will require two sets of BCs for each edge of the plate (as for a beam), but will be mathematically involved. Instead of a direct solution, a logical trial solution that satisfies Equation 4.252 and the BCs is employed next for a simply supported rectangular plate. The solution tried is in fact the correct solution for the particular problem.

4.7.4 Rectangular Plate with Simply Supported Edges

As a special case, we now consider a thin rectangular plate of length a , width b , and thickness h , as shown in Figure 4.19, whose edges are simply supported. For each edge, the BCs are the displacement in zero and the bending moment about the edge zero. Specifically, we have

$$\begin{aligned} v(x, y, t) = 0 \text{ and } M_x = E'I' \left(\frac{\partial^2 v}{\partial x^2} + \nu \frac{\partial^2 v}{\partial y^2} \right) = 0 \text{ for } x = 0 \text{ and } a; 0 \leq y \leq b \\ v(x, y, t) = 0 \text{ and } M_y = E'I' \left(\frac{\partial^2 v}{\partial y^2} + \nu \frac{\partial^2 v}{\partial x^2} \right) = 0 \text{ for } y = 0 \text{ and } b; 0 \leq x \leq a \end{aligned} \quad (4.256)$$

where E' and I' are as given in Equation 4.248 and Equation 4.249. In this case, the mode shapes are found to be

$$Y_{ij}(x, y) = \sin \frac{i\pi x}{a} \sin \frac{j\pi y}{b} \quad \text{for } i = 1, 2, \dots \text{ and } j = 1, 2, \dots \quad (4.257)$$

which clearly satisfy the BCs (Equation 4.256) and the governing model equation 4.252, with an infinite set of solutions for λ given by

$$\lambda_{ij}^2 = \pi^2 \left(\frac{i^2}{a^2} + \frac{j^2}{b^2} \right) \quad (4.258)$$

Hence, from Equation 4.253, the natural frequencies are

$$\omega_{ij} = \pi^2 c \left(\frac{i^2}{a^2} + \frac{j^2}{b^2} \right) \quad (4.259)$$

where c is given by Equation 4.247. The overall response, then, is given by

$$v(x, y, t) = \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \left[A_{ij} \sin \omega_{ij} t + B_{ij} \cos \omega_{ij} t \right] \sin \frac{i\pi x}{a} \sin \frac{j\pi y}{b} \quad (4.260)$$

The unknown constants A_{ij} and B_{ij} are determined by the system initial conditions $v(x, y, 0)$ and $\dot{v}(x, y, 0)$. The first six mode shapes of transverse vibration of a rectangular plate are sketched in Figure 4.20.

Summary

This chapter summarizes the key ideas of linear random vibration. This discipline focuses on determining the response statistics of an oscillator or structure to input forces that are definable only in terms of their statistics. Typical problems include the following: (1) given the power spectrum of the force, find the power spectrum of the response; (2) given the mean value and variance of the force, find the mean value and variance of the response. The methodology is built upon the linear theory of vibration for discrete single- and multi-degree-of-freedom (DoF) systems, and continuous systems. The approaches are essentially the direct method and the modal analysis method. The direct method may also be called a transfer matrix method (see Chapter 2). Modal analysis (see Chapters 3 and 4) has the same benefit in random vibration as is done in deterministic vibration studies: it can be computationally more efficient. A number of examples are given, as are a list of representative references.

5.1 Random Vibration

The discipline of random vibration of structures was borne of the need to understand how structures respond to dynamic loads that are too complex to model deterministically. Examples include aerodynamic loading on aircraft and earthquake loading of structures. Essentially, the question that must be answered is: *given the statistics (read: uncertainties) of the loading, what are the statistics (read: most likely values with bounds) of the response?* Generally, for engineering applications the statistics of greatest concern are the mean, or average value, and the variance, or scatter. These concepts are discussed in detail subsequently.

Suppose that we are aircraft designers currently working on the analysis and design of a wing for a new airplane. As engineers, we are very familiar with the mechanics of solids and can size the wing for static loads. Also, we have vibration experience and can evaluate the response of the wing to a harmonic

or impulsive forcing. However, this wing provides lift to an airplane flying through a turbulent atmosphere. Even though we are not fluid dynamicists, we know that turbulence is a very complicated physical process. In fact, the fluid (air) motion is so complicated that probabilistic models are required to model the behavior. *Here, a plausibly deterministic but very complicated dynamic process is taken to be random for the purposes of modeling.* Wing design requires force data resulting from the interaction between fluid and structure. Such data can be shown as the time history in Figure 5.1.

FIGURE 5.1 Turbulent force history.

The challenge is to make sense of such intricate fluctuations. The analyst and designer must run scale model tests. A wing section is set up in the wind tunnel and representative aerodynamic forces are generated. Data on wind forces and structural response are gathered and analyzed. With additional data analysis, it is possible to estimate the force magnitudes. Estimates of the mean values of these forces can be calculated, as well as of the range of possible forces. With these estimates, it is possible to study the behavior of the wing under a variety of realistic loading scenarios using the tools of probability and statistics to model this complex physical problem. This text introduces the use of probabilistic information in mechanical systems, primarily structural and dynamic systems. These tools are applicable to all the sciences and engineering, even though this text focuses on the mechanical sciences and engineering.

5.2 Single Degree of Freedom: The Response to Random Loads

Consider the second-order differential equation¹ governing the linear motion of an oscillator

$$\ddot{X}(t) + 2\zeta\omega_n\dot{X}(t) + \omega_n^2X(t) = F(t) \quad (5.1)$$

where the input force per unit mass is given by stationary random process $F(t)$ and the output displacement by random process $X(t)$. Note that it is customary to use upper case letters $X(t)$ to represent random processes, and lower case letters $x(t)$ to represent the realizations of a random process. The notation here is standard: $2\zeta\omega_n = c/m$ where c = viscous damping and m = mass; and $\omega_n^2 = k/m$ where k = stiffness.

We assume that the reader understands the concepts of *impulse response* and *convolution*. We would also like to present *a priori* the results which are derived in the subsequent section; the mean value of the response μ_X and the spectral density of the output $S_{XX}(\omega)$:

$$\mu_X = H(0)\mu_F$$

$$S_{XX}(\omega) = |H(\omega)|^2 S_{FF}(\omega)$$

$$|H(\omega)|^2 = \left[\frac{1/\omega_n^2}{\sqrt{(1 - \omega^2/\omega_n^2)^2 + (2\zeta\omega/\omega_n)^2}} \right]^2$$

These equations tell us that the mean value of the response μ_x is proportional to the mean value of the force μ_F , and that the response spectral density $S_{XX}(\omega)$ is proportional to the force spectral density $S_{FF}(\omega)$. For both results, the proportionality constants depend on the structural or system parameters.

¹In this instance, the system parameters ζ and ω_n are deterministic and, therefore, so is the governing equation of motion. If ζ and ω_n are either random variables or processes then the governing equation is random. The case of random parameters is much more complicated because the system itself is random rather than just the forcing. We would have to solve the problem for the "many randomly prescribed systems" rather than for just one system with randomly prescribed forces.

By previewing the end results, the reader will hopefully be able to better follow the mathematical manipulations which follow.

5.2.1 Formulation

Consider the linear system defined by Equation 5.1 and assume random process input $F(t)$ to be stationary, with mean μ_F and power spectrum $S_{FF}(\omega)$. The stationarity assumption for the forcing means that transient dynamic behavior cannot be directly considered here.² Thus, the initial loading transients of an earthquake, a wind gust, or an extreme ocean wave cannot be considered as stationary. Assuming that the character of the loading does not change, steady-state behavior can be assumed to be statistically stationary.

5.2.2 Derivation of Equations

Begin with the convolution equation for the deterministic response of a linear oscillator

$$X(t) = \int_{-\infty}^{\infty} g(\tau)F(t - \tau)d\tau \quad (5.2)$$

where $g(t)$ is the impulse response given by

$$g(t) = \frac{1}{\omega_d} e^{-\zeta\omega_n t} \sin \omega_d t$$

and stationary random load per unit mass $F(t)$ is applied at $t = -\infty$, that is, long before the present time. This ensures that the impulse response is stationary. Beginning with Equation 5.2, take the expected value of both sides and use the linear property of mathematical expectation to interchange it with the integral:

$$\begin{aligned} E\{X(t)\} &= \int_{-\infty}^{\infty} g(\tau)E\{F(t - \tau)\}d\tau = E\{F(t)\} \int_{-\infty}^{\infty} g(\tau)d\tau \\ &= \mu_F \int_{-\infty}^{\infty} g(\tau)d\tau = \mu_F H(0) \end{aligned}$$

where the fact that $F(t)$ is stationary was utilized in the second and third equations,³ and $H(\omega)$ is the frequency response function; $H(0) = H(\omega)|_{\omega=0}$. Therefore, we arrive at the first important result

$$\mu_X = H(0)\mu_F = \frac{1}{\omega_n^2} \mu_F,$$

which shows us that since μ_F is time independent, then so must be $E\{x(t)\}$.

In order to derive the output spectral density, we must work through the intermediate results involving the correlation function.

5.2.3 Response Correlations

For a stationary process, the autocorrelation function is given by

$$R_{XX}(\tau) = \int_{-\infty}^{\infty} x(t)x(t + \tau)f_X(x)dx$$

where $f_X(x)$ is the probability density function of the process. We cannot take the Fourier transform of this equation to find the response spectral density because we do not know the response density

²There are, however, clever ways by which stationary solutions can be utilized in nonstationary cases. One possibility is to multiply the stationary process by a deterministic time function such that the product is an *evolutionary*, or nonstationary, process. For example, use $A(t)F(t)$ as the forcing function where $A(t)$ is a deterministic transient function and $F(t)$ is stationary.

³The force is stationary and has a constant mean value.

function $f_X(x)$. There are two other equivalent ways to proceed: (i) utilize the ergodic definition of the autocorrelation,⁴ or (ii) use Equation 5.2, utilizing available information on $F(t)$, as follows.

First, derive the cross-correlation between $F(t)$ and $X(t)$. Multiply both sides of Equation 5.2 by $F(t - \alpha_1)$ and take the expected values of both sides:

$$E\{X(t)F(t - \alpha_1)\} = \int_{-\infty}^{\infty} g(\tau_1)E\{F(t - \tau_1)F(t - \alpha_1)\}d\tau_1$$

where $E\{F(t - \tau_1)F(t - \alpha_1)\} = R_{FF}(\tau_1 - \alpha_1)$ and $E\{X(t)F(t - \alpha_1)\} = R_{XF}(\alpha_1)$, the cross-correlation between loading $F(t)$ and response $X(t)$. Thus,

$$R_{XF}(\alpha_1) = \int_{-\infty}^{\infty} g(\tau_1)R_{FF}(\tau_1 - \alpha_1)d\tau_1 \quad (5.3)$$

and R_{FF} is known from experimental data. Next, multiply both sides of Equation 5.2 by $X(t + \alpha_2)$ and take expected values of both sides:

$$\begin{aligned} E\{X(t + \alpha_2)X(t)\} &= \int_{-\infty}^{\infty} g(\tau_2)E\{X(t + \alpha_2)F(t - \tau_2)\}d\tau_2 \\ R_{XX}(\alpha_2) &= \int_{-\infty}^{\infty} g(\tau_2)R_{XF}(\tau_2 + \alpha_2)d\tau_2 \end{aligned} \quad (5.4)$$

Substitute Equation 5.3 into Equation 5.4 to find

$$R_{XX}(\tau) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(\alpha)g(\beta)R_{FF}(\tau + \beta - \alpha)d\alpha d\beta \quad (5.5)$$

which is a double convolution. To evaluate the variance, we use

$$\sigma_X^2 = E\{X(t)^2\} - E^2\{X(t)\} = R_{XX}(0) - [H(0)E\{F(t)\}]^2$$

While this information on the correlation is of interest, a more important result is the response spectral density that we derive in the next section.

5.2.4 Response Spectral Density

Begin with the Fourier transform relation between power spectrum and correlation function

$$S_{XX}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{XX}(\tau)e^{-i\omega\tau} d\tau,$$

and substitute Equation 5.5 for $R_{XX}(\tau)$, with $\lambda = \tau + \beta - \alpha$:

$$\begin{aligned} S_{XX}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega\tau} \left[\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(\alpha)g(\beta)R_{FF}(\lambda)d\alpha d\beta \right] d\tau \\ &= \int_{-\infty}^{\infty} g(\alpha)e^{-i\omega\alpha} d\alpha \int_{-\infty}^{\infty} g(\beta)e^{+i\omega\beta} d\beta \times \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{FF}(\lambda)e^{-i\omega\lambda} d\lambda \\ &= H(\omega)H^*(\omega)S_{FF}(\omega) \end{aligned}$$

by definition, where $*$ denotes complex conjugate and therefore

$$S_{XX}(\omega) = |H(\omega)|^2 S_{FF}(\omega) \quad (5.6)$$

This is the *fundamental* result for random vibration and linear systems theory that allows us to evaluate the output spectral density, given the input spectral density and the system frequency response.

⁴ $R_{xx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^{+T} x(t)x(t + \tau)dt.$

It is emphasized here that the derivation of Equation 5.6 made use of the convolution equation that is valid for linear systems and structures. Any generalization for nonlinear behavior requires problem-specific approaches.

Example 5.1 Oscillator Response to White Noise

Consider a simple application of the above ideas to an oscillator. What is the response of a damped oscillator to a force with white noise density?

Solution

The governing equation of motion is

$$\ddot{X}(t) + 2\zeta\omega_n\dot{X}(t) + \omega_n^2X(t) = F(t)$$

where $F(t)$ is the external force per unit mass, the system transfer function is given by

$$H(\omega) = \frac{1}{\omega_n^2 + i2\zeta\omega_n\omega + (i\omega)^2}$$

and the squared magnitude of $H(\omega)$ is given by

$$|H(\omega)|^2 = \frac{1}{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}$$

Therefore, given any input spectral density $S_{FF}(\omega)$, the response spectral density is

$$S_{XX}(\omega) = |H(\omega)|^2 S_{FF}(\omega) = \frac{S_{FF}(\omega)}{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}$$

Suppose, for mathematical simplicity, that the forcing is white noise, $S_{FF}(\omega) = S_0$. Then,

$$S_{XX}(\omega) = \frac{S_0}{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2} \quad (5.7)$$

and the mean-square response is given by

$$E\{X(t)^2\} = \int_{-\infty}^{\infty} S_{XX}(\omega) d\omega = \frac{\pi m^2 S_0}{kc} = \frac{\pi S_0}{2\omega_n^3 \zeta}$$

The mean-square response can also be written in terms of a one-sided spectrum

$$E\{X(t)^2\} = \frac{\pi m^2 S_0}{kc} = \frac{m^2 W_0}{4kc}$$

where the one-sided density W_0 is related to the two-sided density by $S_0 = \pi W_0/4$.

This integral is not standard, but can be found in texts on random vibration.⁵ Even though infinite mean-square energy is input to the system,⁶ it responds with finite mean-square energy. See Figure 5.2 for plots of the components of Equation 5.7. Only the positive frequency ranges are plotted as they are

⁵For example, the integral of this example problem is a specialized version of

$$\int_{-\infty}^{\infty} \left| \frac{B_0 + i\omega B_1}{A_0 + i\omega A_1 - \omega^2 A_2} \right|^2 d\omega = \frac{\pi(A_0 B_1^2 + A_2 B_0^2)}{A_0 A_1 A_2}$$

where

$$A_0 = \omega_n^2, \quad A_1 = 2\zeta\omega_n, \quad A_2 = 2, \quad B_0 = 1, \quad B_1 = 0.$$

⁶The energy input equals to the area under the spectral density, which for white noise is

$$\int_{-\infty}^{\infty} S_0 d\omega = \infty.$$

symmetric about the abscissae. White noise is useful and frequently used, even though it is nonphysical, because it leads to good approximate results.

Example 5.2 Response to Colored Noise

Suppose the same system as in the last example is subjected to more complex loading, where the spectral density of the forcing is not a constant, but a function of ω . How would the above analysis change?

Solution

The output spectral density becomes a more complex function of frequency, for example, if the loading density is similar to those found for wind loads. Then, the mean-square response must be evaluated numerically.

The applied problems are always solved numerically, although hopefully after some significant analytical exposition. There are numerical methods that are specifically geared to handling uncertainties. Of particular note is the group known as Monte Carlo methods. These methods utilize the massive computational power available today to account for uncertainties. This is accomplished by generating random numbers that are used to represent random parameters. For each of these generated random values, the program recalculates the problem. After running enough cycles to ensure the convergence of the statistics, these numerical realizations are averaged to find the mean value and variance of the relevant parameters.

We summarize the key results for the random vibration of a single-DoF linear oscillator in Table 5.1 to Table 5.3. Figure 5.3 shows some of the most important correlation and spectral density pairs.

$S_{FF}(\omega)$ is the input force power spectrum

FIGURE 5.3 Correlation functions and corresponding power spectral densities.

5.3 Response to Two Random Loads

Previously, the system responses were due to a single randomly varying force. In general, the situation is more complicated, because more than one load may act on a system and the resulting response depends not only on the properties of each force, but also on the correlation between the two forces.

Consider the response of the system to two random loadings, $P(t)$ and $Q(t)$, acting simultaneously but at different points on the system, as shown in Figure 5.4. We are interested in calculating the response statistics of the displacement $X(t)$ at an arbitrary point on the system. Assume that $E\{P(t)\} = 0$ and $E\{Q(t)\} = 0$. Also, by utilizing available data, we are able to estimate $R_{PP}(\tau)$ and $R_{QQ}(\tau)$. Our interest is in evaluating $R_{XX}(\tau)$ and its Fourier transform $S_{XX}(\omega)$. Using linear superposition and the convolution integral, the response due to both forces is given by

FIGURE 5.4 Response to two random loads.

$$X(t) = \int_{-\infty}^{\infty} [g_{XP}(\tau_1)P(t - \tau_1) + g_{XQ}(\tau_1)Q(t - \tau_1)]d\tau_1$$

Similarly, for $X(t + \tau)$:

$$X(t + \tau) = \int_{-\infty}^{\infty} [g_{XP}(\tau_2)P(t + \tau - \tau_2) + g_{XQ}(\tau_2)Q(t + \tau - \tau_2)]d\tau_2$$

where g_{XP} is the impulse response function at coordinate X due to force P and g_{XQ} is the impulse response function at X due to Q . Then,

$$R_{XX}(\tau) = E\{X(t)X(t + \tau)\} = E\left\{\int_{-\infty}^{\infty} [g_{XP}(\tau_1)P(t - \tau_1) + g_{XQ}(\tau_1)Q(t - \tau_1)]d\tau_1 \times \int_{-\infty}^{\infty} [g_{XP}(\tau_2)P(t + \tau - \tau_2) + g_{XQ}(\tau_2)Q(t + \tau - \tau_2)]d\tau_2\right\}$$

Now expand the product, and then move the expectation operator to the random processes, as follows:

$$\begin{aligned} R_{XX}(\tau) = & \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XP}(\tau_2) E\{P(t - \tau_1)P(t + \tau - \tau_2)\} d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XQ}(\tau_2) E\{P(t - \tau_1)Q(t + \tau - \tau_2)\} d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XQ}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XP}(\tau_2) E\{Q(t - \tau_1)P(t + \tau - \tau_2)\} d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XQ}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XQ}(\tau_2) E\{Q(t - \tau_1)Q(t + \tau - \tau_2)\} d\tau_2 \right] d\tau_1 \end{aligned}$$

In this expression

$$E\{P(t - \tau_1)P(t + \tau - \tau_2)\} = R_{PP}(\tau + \tau_1 - \tau_2)$$

$$E\{Q(t - \tau_1)Q(t + \tau - \tau_2)\} = R_{QQ}(\tau + \tau_1 - \tau_2)$$

The expectations in the second and third terms are cross-correlations of the form $R_{PQ}(\tau) = E\{P(t)Q(t + \tau)\}$. Therefore, the autocorrelation of the response becomes

$$\begin{aligned} R_{XX}(\tau) = & \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XP}(\tau_2) R_{PP}(\tau + \tau_1 - \tau_2) d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XQ}(\tau_2) R_{PQ}(\tau + \tau_1 - \tau_2) d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XQ}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XP}(\tau_2) R_{QP}(\tau + \tau_1 - \tau_2) d\tau_2 \right] d\tau_1 \\ & + \int_{-\infty}^{\infty} g_{XQ}(\tau_1) \left[\int_{-\infty}^{\infty} g_{XQ}(\tau_2) R_{QQ}(\tau + \tau_1 - \tau_2) d\tau_2 \right] d\tau_1 \end{aligned}$$

The importance of this result is primarily in the observation that we cannot derive $R_{XX}(\tau)$ unless the cross-correlations $R_{PQ}(\tau)$ and $R_{QP}(\tau)$ are also known. Using the Fourier transform relation between $R_{XX}(\tau)$ and $S_{XX}(\omega)$, that is

$$S_{XX}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{XX}(\tau) e^{-i\omega\tau} d\tau$$

we obtain

$$\begin{aligned} S_{XX}(\omega) = & H_{XP}^*(\omega)H_{XP}(\omega)S_{PP}(\omega) + H_{XP}^*(\omega)H_{XQ}(\omega)S_{PQ}(\omega) \\ & + H_{XQ}^*(\omega)H_{XP}(\omega)S_{QP}(\omega) + H_{XQ}^*(\omega)H_{XQ}(\omega)S_{QQ}(\omega) \end{aligned} \quad (5.8)$$

where

$$H_{XP}^*(\omega)H_{XP}(\omega) = |H_{XP}(\omega)|^2$$

$$H_{XQ}^*(\omega)H_{XQ}(\omega) = |H_{XQ}(\omega)|^2$$

and

$$S_{PQ}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{PQ}(\tau) e^{-i\omega\tau} d\tau$$

As expected, the evaluation of the output spectral density requires knowledge about the cross-spectra $S_{PQ}(\omega)$ and $S_{QP}(\omega)$. If there are more than two forces, then we will have additional cross-spectra between each pair of forces.

Examining Equation 5.8 closely, we find that we can write $S_{XX}(\omega)$ as

$$S_{XX}(\omega) = \begin{bmatrix} H_{XP}^*(\omega) & H_{XQ}^*(\omega) \end{bmatrix} \begin{bmatrix} S_{PP}(\omega) & S_{PQ}(\omega) \\ S_{QP}(\omega) & S_{QQ}(\omega) \end{bmatrix} \begin{bmatrix} H_{XP}(\omega) \\ H_{XQ}(\omega) \end{bmatrix} \quad (5.9)$$

Example 5.3 Conjugates of Cross Spectra

It was briefly mentioned that $R_{PQ}(\tau) = R_{QP}(-\tau)$. How are $S_{PQ}(\omega)$ and $S_{QP}(\omega)$ related?

Solution

By the definition of spectral density

$$S_{PQ}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{PQ}(\tau) \exp(-i\omega\tau) d\tau$$

Replacing $R_{PQ}(\tau)$ with $R_{QP}(-\tau)$

$$S_{PQ}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{QP}(-\tau) \exp(-i\omega\tau) d\tau$$

Letting $-\tau = t$

$$S_{PQ}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{QP}(t) \exp(i\omega t) dt$$

Then,

$$S_{PQ}(\omega) = S_{QP}(-\omega) = S_{QP}^*(\omega)$$

Example 5.4 Response Spectrum due to Two Random Loads

Consider a mass–spring–damper system in [Figure 5.5](#) subject to two random forces $P(t)$ and $Q(t)$. Find the response spectrum $S_{XX}(\omega)$ assuming that

$$S_{PP}(\omega) = S_P, \quad S_{PQ}(\omega) = 0, \quad S_{QQ}(\omega) = S_Q$$

Solution

The equation of motion for this system is given by

$$m\ddot{X} + c\dot{X} + kX = P(t) + Q(t)$$

First, assume that $Q(t) = 0$ in order to first obtain $H_{XP}(\omega)$. Taking the Fourier transform, the equation of motion is given by

$$(-m\omega^2 + ci\omega + k)X(\omega) = P(\omega)$$

Then, the frequency response function $H_{XP}(\omega)$ is

$$H_{XP}(\omega) = \frac{1}{(-m\omega^2 + ci\omega + k)}$$

or

$$H_{XP}(\omega) = \frac{1}{m(-\omega^2 + 2\omega_n \zeta i\omega + \omega_n^2)}$$

Similarly, $H_{XQ}(\omega)$ is obtained by setting $P(t) = 0$ and is also given by

$$H_{XQ}(\omega) = \frac{1}{m(-\omega^2 + 2\omega_n \zeta i\omega + \omega_n^2)}$$

Then, the spectral density of the response is given by

$$S_{XX}(\omega) = \begin{bmatrix} (m(\omega_n^2 - \omega^2 - 2\omega_n \zeta i\omega))^{-1} & (m(\omega_n^2 - \omega^2 - 2\omega_n \zeta i\omega))^{-1} \end{bmatrix} \begin{bmatrix} S_{PP}(\omega) & S_{PQ}(\omega) \\ S_{QP}(\omega) & S_{QQ}(\omega) \end{bmatrix} \\ \times \begin{bmatrix} (m(\omega_n^2 - \omega^2 + 2\omega_n \zeta i\omega))^{-1} \\ (m(\omega_n^2 - \omega^2 + 2\omega_n \zeta i\omega))^{-1} \end{bmatrix} = \frac{S_{PP}(\omega) + S_{PQ}(\omega) + S_{QP}(\omega) + S_{QQ}(\omega)}{m^2[(\omega_n^2 - \omega^2)^2 + (2\omega_n \zeta)^2]}$$

In our case, the spectral density is reduced to

$$S_{XX}(\omega) = \frac{S_P + S_Q}{m^2[(\omega_n^2 - \omega^2)^2 + (2\omega_n \zeta)^2]}$$

Spectral densities are rather complicated expressions to evaluate in general. A number of special cases will help better understand the effects of the cross-terms:

1. $P(t)$ and $Q(t)$ arise from independent sources and are, therefore, uncorrelated.⁷ Then, $R_{PQ}(\tau) = 0$, $R_{QP}(\tau) = 0$ and $S_{PQ}(\omega) = 0$, $S_{QP}(\omega) = 0$.
2. $P(t)$ and $Q(t)$ are directly correlated; that is, $Q(t) = kP(t)$ where k is a constant.
3. $P(t)$ and $Q(t)$ are exponentially correlated, $E\{P(t)Q(t + \tau)\} = k_{PQ} \exp\{-\alpha\tau\}$ where k_{PQ} is a constant.
4. $P(t)$ and $Q(t)$ are correlated in a “simplified” exponential; that is, with a triangular correlation defined by $E\{P(t)Q(t + \tau)\} = \bar{k}_{PQ}(1 - \tau/\tau_1)$, $-\tau_1 \leq \tau \leq \tau_1$.

FIGURE 5.5 Single-DoF system subjected to two random loads.

⁷Independence implies that

$$E\{P(t_1)Q(t_2)\} = E\{P(t_1)\}E\{Q(t_2)\}$$

They are uncorrelated if

$$\text{Cov}(P(t_1)Q(t_2)) = E\{P(t_1)Q(t_2)\} - E\{P(t_1)\}E\{Q(t_2)\} = 0$$

Independent processes are always uncorrelated whereas uncorrelated processes may not be independent.

We consider in more detail the first two cases listed above. Where the loads are independent, because the cross-correlations are identically zero, the output spectral density is just the sum of the two respective spectral densities obtained with the forces acting separately:

$$\begin{aligned} S_{XX}(\omega) &= H_{XP}(\omega)H_{XP}^*(\omega)S_{PP}(\omega) + H_{XQ}(\omega)H_{XQ}^*(\omega)S_{QQ}(\omega) \\ &= |H_{XP}(\omega)|^2 S_{PP}(\omega) + |H_{XQ}(\omega)|^2 S_{QQ}(\omega) \end{aligned} \quad (5.10)$$

We note that the output spectral density for a linear system follows a strict interpretation of the principle of linear superposition only when the forces are *uncorrelated*.

For the case where $Q(t) = kP(t)$, we have

$$\begin{aligned} R_{PQ}(\tau) &= E\{P(t)kP(t + \tau)\} = kR_{PP}(\tau) \\ R_{QP}(\tau) &= E\{kP(t)P(t + \tau)\} = kR_{PP}(\tau) \\ R_{QQ}(\tau) &= E\{kP(t)kP(t + \tau)\} = k^2 R_{PP}(\tau) \end{aligned}$$

Then, we can obtain the respective spectral densities

$$\begin{aligned} S_{PQ}(\omega) &= S_{QP}(\omega) = kS_{PP}(\omega) \\ S_{QQ}(\omega) &= k^2 S_{PP}(\omega) \end{aligned}$$

leading to the spectral density of the response

$$\begin{aligned} S_{XX}(\omega) &= H_{XP}^*(\omega)H_{XP}(\omega)S_{PP}(\omega) + H_{XP}^*(\omega)H_{XQ}(\omega)kS_{PP}(\omega) + H_{XQ}^*(\omega)H_{XQ}(\omega)kS_{PP}(\omega) \\ &\quad + H_{XQ}^*(\omega)H_{XQ}(\omega)k^2 S_{PP}(\omega) = (H_{XP} + kH_{XQ})(H_{XP}^* + kH_{XQ}^*)S_{PP}(\omega) \\ &= |H_{XP}(\omega) + kH_{XQ}(\omega)|^2 S_{PP}(\omega) \end{aligned} \quad (5.11)$$

This last expression is related to the relative phase between the two functions $H_{XP}(\omega)$ and $H_{XQ}(\omega)$. The addition of two frequency response functions $H_{XP} + kH_{XQ}$ is shown graphically in Figure 5.6.

Suppose $S_{PP}(\omega) = S_{QQ}(\omega) = S(\omega)$. Then, from Equation 5.10, for independent loadings

$$S_{XX}(\omega) = [|H_{XP}|^2 + |H_{XQ}|^2]S(\omega) \quad (5.12)$$

If the forces are directly correlated with parameter $k = 1$, Equation 5.11 yields

$$S_{XX}(\omega) = |H_{XP} + H_{XQ}|^2 S(\omega) = [|H_{XP}|^2 + |H_{XQ}|^2 + 2|H_{XP}||H_{XQ}|\cos \phi]S(\omega) \quad (5.13)$$

where ϕ is the phase difference between H_{XP} and H_{XQ} as shown in Figure 5.6. The law of cosines is used for the second relation. Therefore, a comparison of Equation 5.12 with Equation 5.13 shows that the results of an uncorrelated loading will be identical to those that are correlated where $\cos \phi = 0$, that is, $\phi = \pm \pi/2$. This is when the two vectors in Figure 5.6 are perpendicular to each other. For other values of ϕ , the spectral density in the correlated case may have any value in the range defined by $[|H_{XP}|^2 \pm |H_{XQ}|^2]S(\omega)$ depending on the value of ϕ .

If, at some frequency, $H_{XP} = -H_{XQ}$, the spectral density at that frequency for the correlated case with $k = 1$ will be zero. For any case where $H_{XP} = H_{XQ}$, the spectral density with correlation will be twice that obtained without correlation.

Another specialized result is where $Q(t)$ follows $P(t)$ after a lag of τ_0 so that $Q(t) = P(t + \tau_0)$.

FIGURE 5.6 Addition of frequency-response functions.

Then,

$$R_{PQ}(\tau) = E\{P(t)P(t + \tau_0 + \tau)\} = R_{PP}(\tau_0 + \tau)$$

with the respective spectral density

$$\begin{aligned} S_{PQ}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{PQ}(\tau) e^{-i\omega\tau} d\tau = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{PP}(\tau_0 + \tau) e^{-i\omega\tau} d\tau \\ &= \frac{1}{2\pi} e^{i\omega\tau_0} \int_{-\infty}^{\infty} R_{PP}(\tau_0 + \tau) e^{-i\omega(\tau_0 + \tau)} d(\tau_0 + \tau) = e^{i\omega\tau_0} S_{PP}(\omega) \end{aligned}$$

Since $S_{PQ}(\omega) = S_{QP}(\omega)$ are complex conjugates

$$S_{QP}(\omega) = e^{-i\omega\tau_0} S_{PP}(\omega)$$

Also, $S_{PP}(\omega) = S_{QQ}(\omega)$. Then,

$$S_{XX}(\omega) = [H_{XP}(\omega)H_{XP}^*(\omega) + e^{i\omega\tau_0}H_{XP}(\omega)H_{XQ}^*(\omega) + e^{-i\omega\tau_0}H_{XQ}(\omega)H_{XP}^*(\omega) + H_{XQ}(\omega)H_{XQ}^*(\omega)]S_{PP}(\omega)$$

5.4 Multi-Degree-of-Freedom Vibration

In this section, a review of deterministic vibration is provided. These results are used in the next section, where the forcing is taken to be a random process.

5.4.1 Deterministic Vibration

Consider a case where there is more than one DoF. The equations of motion can be written as

$$[m]\{\ddot{x}(t)\} + [c]\{\dot{x}(t)\} + [k]\{x(t)\} = \{F(t)\}$$

For an N -DoF system, the matrices $[m]$, $[c]$ and $[k]$ are of dimension $N \times N$, and the response $\{x(t)\}$ and force $\{F(t)\}$ vectors are of dimension $N \times 1$.

For purposes of demonstration and discussion, the necessary concepts will be introduced primarily by working through the solution of a two-DoF system. All these ideas transfer to larger systems, but with the two-DoF model we can demonstrate the key ideas without the complications of the major algebraic and numerical demands made by the larger systems.

For the system shown in Figure 5.7, we can derive the coupled equations of motion using either Newton's Second Law of motion applied to a free body diagram for each mass, as shown in Figure 5.8, or by Lagrange's equation. In either case, we find the governing equations to be

$$\begin{aligned} m_1\ddot{x}_1(t) + (c_1 + c_2)\dot{x}_1(t) + (k_1 + k_2)x_1(t) - c_2\dot{x}_2(t) - k_2x_2(t) &= F_1(t), \\ m_2\ddot{x}_2(t) + c_2\dot{x}_2(t) - c_2\dot{x}_1(t) - k_2x_1(t) + k_2x_2(t) &= F_2(t) \end{aligned}$$

or in matrix form

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1(t) \\ \ddot{x}_2(t) \end{Bmatrix} + \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \begin{Bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{Bmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} \begin{Bmatrix} x_1(t) \\ x_2(t) \end{Bmatrix} = \begin{Bmatrix} F_1(t) \\ F_2(t) \end{Bmatrix} \quad (5.14)$$

FIGURE 5.7 Two-DoF mass–spring–damper system.

FIGURE 5.8 Free body diagram of a two-DoF system.

In this case, the mass, damping, and stiffness matrices are given by

$$[m] = \begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix}, \quad [c] = \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix}, \quad [k] = \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix}$$

5.4.2 Solution by Frequency Response Function

Begin by taking the Fourier transform of the equations of motion, obtaining

$$(-\omega^2[m] + i\omega[c] + [k])\{X(\omega)\} = \{F(\omega)\}$$

where $\{X(\omega)\}$ and $\{F(\omega)\}$ are Fourier transforms of $\{x(t)\}$ and $\{F(t)\}$, respectively. The matrix $(-\omega^2[m] + i\omega[c] + [k])$ is denoted as $[Z(\omega)]$. Then,

$$\{X(\omega)\} = [Z(\omega)]^{-1}\{F(\omega)\}$$

The matrix $[Z(\omega)]^{-1}$ is identical to the frequency response matrix denoted as $[H(\omega)]$:

$$\{X(\omega)\} = [H(\omega)]\{F(\omega)\} \quad (5.15)$$

For the two-DoF system in Figure 5.7

$$[H(\omega)] = \frac{1}{\det[Z]} \begin{bmatrix} -m_2\omega^2 + i\omega c_2 + k_2 & i\omega c_2 + k_2 \\ i\omega c_2 + k_2 & -m_1\omega^2 + i\omega(c_1 + c_2) + (k_1 + k_2) \end{bmatrix}$$

$$\det[Z] = \omega^4 m_1 m_2 - i\omega^3 (m_1 c_2 + c_1 m_2 + c_2 m_2) + i\omega (c_1 k_2 + k_1 c_2)$$

$$- \omega^2 (m_1 k_2 + c_1 c_2 + k_1 m_2 + k_2 m_2) + k_1 k_2$$

Note that the frequency response function of a two-DoF system is given as a matrix with dimension of 2×2 . To clarify the meaning of each element, let us expand Equation 5.15:

$$X_1(\omega) = H_{11}(\omega)F_1(\omega) + H_{12}(\omega)F_2(\omega)$$

$$X_2(\omega) = H_{21}(\omega)F_1(\omega) + H_{22}(\omega)F_2(\omega)$$

Now, the meaning of each element is clear. Each element $H_{ij}(\omega)$ is the frequency response function for coordinate i due to a force at j . In general, $[H(\omega)]$ is a symmetric matrix since $[m]$, $[c]$ and $[k]$ are symmetric.

For a deterministic response, recall that the impulse response function is related to the frequency response function by

$$g_{ij}(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} H_{ij}(\omega) \exp(i\omega t) d\omega$$

which is written for each element in the matrix. For the two-DoF system

$$\begin{aligned} g_{11}(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{-m_2 \omega^2 + i\omega c_2 + k_2}{\det[Z]} \exp(i\omega t) d\omega \\ g_{12}(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{i\omega c_2 + k_2}{\det[Z]} \exp(i\omega t) d\omega \\ g_{21}(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{i\omega c_2 + k_2}{\det[Z]} \exp(i\omega t) d\omega = g_{12}(t) \\ g_{22}(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{-m_1 \omega^2 + i\omega(c_1 + c_2) + (k_1 + k_2)}{\det[Z]} \exp(i\omega t) d\omega \end{aligned}$$

Again, $[g(t)]$ is a symmetric matrix.

Using the convolution integral, the response $x_i(t)$ due to F_j is

$$x_i(t) = \int_{-\infty}^{\infty} g_{ij}(\tau) F_j(t - \tau) d\tau$$

The total response $x_i(t)$ of mass m_i is then equal to the sum of the individual responses to each of the forces. In our case, the responses are

$$\begin{aligned} x_1(t) &= \int_{-\infty}^{\infty} [g_{11}(\tau) F_1(t - \tau) + g_{12}(\tau) F_2(t - \tau)] d\tau \\ x_2(t) &= \int_{-\infty}^{\infty} [g_{21}(\tau) F_1(t - \tau) + g_{22}(\tau) F_2(t - \tau)] d\tau \end{aligned}$$

We can extend our analysis to a system with N DoF. The equations of motion are written in matrix form as

$$[m]\{\ddot{x}(t)\} + [c]\{\dot{x}(t)\} + [k]\{x(t)\} = \{F(t)\}$$

where $\{x(t)\}$ and $\{F(t)\}$ are response and force vectors and the frequency response matrix is given by

$$[H(\omega)] = (-\omega^2[m] + i\omega[c] + [k])^{-1}$$

The impulse response matrix $[g(t)]$ is given by

$$[g(t)] = \frac{1}{2\pi} \int_{-\infty}^{\infty} [H(\omega)] \exp(i\omega t) d\omega$$

and the response matrix is given by

$$\{x(t)\} = \int_{-\infty}^{\infty} [g(\tau)] \{F(t - \tau)\} d\tau$$

Note that the impulse response vector is not trivial to evaluate, much less the convolution integrals. More importantly, this method becomes much harder for each additional DoF. Therefore, this method is rarely used, and we often rely on *modal analysis*.

5.4.3 Modal Analysis

Let us first consider an undamped system in free vibration with equations of motion

$$[m]\{\ddot{x}(t)\} + [k]\{x(t)\} = 0$$

If we assume that $\{x(t)\}$ is harmonic with frequency ω ,

$$\{x(t)\} = A_0 \{u\} e^{i\omega t}$$

the equations of motion are reduced to the eigenvalue problem given by

$$(-\omega^2[m] + [k])\{u\} = \{0\} \quad (5.16)$$

The goal is to find the nonzero vector $\{u\}$. Therefore, equations must be linearly dependent,⁸ or there should be no inverse for $(-\omega^2[m] + [k])$. This can be satisfied if the determinant of $(-\omega^2[m] + [k])$ is zero:

$$|-\omega^2[m] + [k]| = 0$$

There are several values of ω^2 which can make the determinant equal zero, and these values of ω^2 are called *eigenvalues*. For each nonrepeating eigenvalue, there is a corresponding vector $\{u\}$ that satisfies Equation 5.16. This vector is called the *eigenvector*. Physically, the eigenvalues of this problem are the *natural frequencies* squared, and the eigenvectors are the *mode shapes*, since they represent the respective motion of each modal coordinate.

By solving this eigenvalue problem, we can obtain N sets of eigenvalues ω_i^2 with corresponding eigenvectors $\{u\}_i$ for an N -DoF system.⁹ It is customary that the eigenvalues are arranged in ascending order

$$\omega_1^2 < \omega_2^2 < \dots < \omega_N^2$$

The eigenvectors can be *normalized with respect to the mass matrix*,

$$\{u\}_i^T [m] \{u\}_i = 1, \quad i = 1, 2, \dots, N$$

where

$$\{u\}_i = \begin{Bmatrix} u_{1i} \\ \vdots \\ u_{Ni} \end{Bmatrix}$$

For the i th and j th set of eigenvalues and eigenvectors, we can write

$$-\omega_i^2 [m] \{u\}_i + [k] \{u\}_i = \{0\}$$

$$-\omega_j^2 [m] \{u\}_j + [k] \{u\}_j = \{0\}$$

Multiplying the first equation by $\{u\}_j^T$ and the second equation by $\{u\}_i^T$, we obtain

$$-\omega_i^2 \{u\}_j^T [m] \{u\}_i + \{u\}_j^T [k] \{u\}_i = \{0\} \quad (5.17)$$

$$-\omega_j^2 \{u\}_i^T [m] \{u\}_j + \{u\}_i^T [k] \{u\}_j = \{0\} \quad (5.18)$$

Take the transpose of Equation 5.18,

$$-\omega_j^2 \{u\}_j^T [m]^T \{u\}_i + \{u\}_j^T [k]^T \{u\}_i = \{0\}$$

Since $[m]$ and $[k]$ are symmetric, $[m] = [m]^T$ and $[k] = [k]^T$, and

$$-\omega_j^2 \{u\}_j^T [m] \{u\}_i + \{u\}_j^T [k] \{u\}_i = \{0\} \quad (5.19)$$

⁸An example of a linear dependent equation is

$$\begin{bmatrix} 1 & 2 \\ 2 & 4 \end{bmatrix} \begin{Bmatrix} u_1 \\ u_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix}$$

or

$$u_1 + 2u_2 = 0$$

$$2u_1 + 4u_2 = 0$$

In this case, u_1 and u_2 need not be zeros. Instead, the equations are satisfied as long as $u_1 = 2u_2$. Therefore, there is an infinite number of solutions.

⁹An eigenvalue problem will be demonstrated in the next example.

Subtracting Equation 5.19 from Equation 5.17, we obtain

$$(\omega_j^2 - \omega_i^2)\{u\}_j^T[m]\{u\}_i = 0$$

If the eigenvalues are unique ($\omega_j^2 \neq \omega_i^2$), then

$$\{u\}_j^T[m]\{u\}_i = 0, \quad i \neq j$$

From Equation 5.19, similarly

$$\{u\}_j^T[k]\{u\}_i = 0, \quad i \neq j$$

That is, the eigenvectors are *orthogonal (or normal) to each other with respect to the mass and the stiffness matrices*. If the eigenvectors are normalized with respect to the mass matrix, Equation 5.19 with $i = j$ can be written as

$$-\omega_i^2\{u\}_i^T[m]\{u\}_i + \{u\}_i^T[k]\{u\}_i = \{0\}$$

and therefore

$$\{u\}_i^T[k]\{u\}_i = \omega_i^2$$

In summary, we just found that the eigenvectors have the following properties:

$$\{u\}_i^T[m]\{u\}_j = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases}$$

and

$$\{u\}_i^T[k]\{u\}_j = \begin{cases} \omega_i^2, & i = j \\ 0, & i \neq j \end{cases}$$

If we construct a matrix composed of eigenvectors

$$[P] = [\{u\}_1 \quad \cdots \quad \{u\}_N] \quad (5.20)$$

we can write

$$[p]^T[m][p] = [I]$$

$$[p]^T[k][p] = \begin{bmatrix} \omega_1^2 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \omega_N^2 \end{bmatrix} = \text{diag}(\omega^2)$$

where $[I]$ is the identity matrix and $[P]$ is called the *modal matrix*.

Now, let us return to our original equations of motion given by

$$[m]\{\ddot{x}(t)\} + [c]\{\dot{x}(t)\} + [k]\{x(t)\} = \{F(t)\}$$

We restrict our problem to the proportional damping case, where $[c]$ is a linear combination of $[m]$ and $[k]$:

$$[c] = \alpha[m] + \beta[k]$$

with constant α and β .

Let us define a new set of coordinates $\{z(t)\}$, so that

$$\{x(t)\} = [P]\{z(t)\} \quad (5.21)$$

where $[p]$ is the modal matrix defined in Equation 5.20. The equations of motion then become

$$[m][P]\{\ddot{z}(t)\} + [c][P]\{\dot{z}(t)\} + [k][P]\{z(t)\} = \{F(t)\}$$

Multiplying by $[P]^T$,

$$[P]^T[m][P]\{\ddot{z}(t)\} + [P]^T[c][P]\{\dot{z}(t)\} + [P]^T[k][P]\{z(t)\} = [P]^T\{F(t)\}$$

which reduces to

$$\{\ddot{z}(t)\} + (\alpha[I] + \beta \times \text{diag}(\omega^2))\{\dot{z}(t)\} + \text{diag}(\omega^2)\{z(t)\} = [P]^T\{F(t)\}$$

or

$$\begin{aligned} \ddot{z}_1(t) + (\alpha + \beta\omega_1^2)\dot{z}_1(t) + \omega_1^2 z_1(t) &= \{u\}_1^T\{F(t)\} \\ &\vdots \\ \ddot{z}_N(t) + (\alpha + \beta\omega_N^2)\dot{z}_N(t) + \omega_N^2 z_N(t) &= \{u\}_N^T\{F(t)\} \end{aligned}$$

It is clear now why proportional damping is considered. The damping matrix $[c]$ becomes diagonalized so that the equations of motion are *decoupled*. The coordinates $z_i(t)$ are called the *modal coordinates*, and $\{u\}_i^T\{F(t)\}$ are called the *modal forces*. We often let

$$(\alpha + \beta\omega_i^2) = 2\omega_i\zeta_i$$

$$\{u\}_i^T\{F(t)\} = q_i(t)$$

to simplify the equations to

$$\begin{aligned} \ddot{z}_1(t) + 2\omega_1\zeta_1\dot{z}_1(t) + \omega_1^2 z_1(t) &= q_1(t) \\ &\vdots \\ \ddot{z}_N(t) + 2\omega_N\zeta_N\dot{z}_N(t) + \omega_N^2 z_N(t) &= q_N(t) \end{aligned} \tag{5.22}$$

The solution to these equations can be obtained using the impulse response function and the convolution integral for each coordinate

$$z_i(t) = \int_{-\infty}^{\infty} g_i(\tau)g_i(t - \tau)d\tau, \quad i = 1, 2, \dots, N$$

where

$$g_i(t) = \begin{cases} \frac{1}{\omega_{d_i}} e^{-\zeta_i\omega_i t} \sin \omega_{d_i} t, & t \geq 0 \\ 0, & t < 0 \end{cases}$$

and

$$\omega_{d_i} = \omega_i \sqrt{1 - \zeta_i^2}$$

Once we find all the $z_i(t)$, we recover the physical coordinates by using the transformation in Equation 5.21 or

$$\{x(t)\} = [P]\{z(t)\}$$

5.5 Multi-Degree-of-Freedom: The Response to Random Loads

From the analysis of the Single-DoF system, we know that knowledge of the frequency response function $H(\omega)$ is crucial in obtaining the response statistics to random loads. For a system with more than one DoF, there is more than one frequency response function $H(\omega)$. For an N -DoF system, the frequency response functions will be given as an $N \times N$ symmetric matrix $\mathbf{H}(\omega)$.

In the single-DoF system, the response statistics were given in terms of the mean response μ_X and the spectral density of the response $S_{XX}(\omega)$. We will find here that the response statistics of an N -DoF system are given in terms of the mean response for each DoF, $\mu_{X_1}, \dots, \mu_{X_N}$, and a matrix of spectral densities of the response $\mathbf{S}(\omega)$, which is also of dimension $N \times N$.

We present *a priori* the results which are derived in the subsequent section; the mean response vector μ_X and the matrix spectral density of the output $\mathbf{S}_{XX}(\omega)$:

$$\begin{aligned}\mu_X &= \mathbf{H}_{XX}(0)\mu_F \\ \mathbf{S}_{XX}(\omega) &= \mathbf{H}_{XX}^*(\omega)\mathbf{S}_{FF}(\omega)\mathbf{H}_{XX}^T(\omega)\end{aligned}$$

Here, we will first obtain the frequency response function of a typical two-DoF system. We will then consider a two-DoF system subjected to a single random load. Finally, we will expand our analysis to an N -DoF system subjected to N random loads.

5.5.1 Response due to a Single Random Force

When a body vibrates, points on the body move relative to each other. To describe this relative motion of two points on a body subjected to random loading, we must know both their cross-spectral densities and cross-correlations, and also the spectral densities and the autocorrelation function of the individual motions of each point. This requirement is true even though there is only one force acting on the system. This is similar to the problem of the single mass loaded by two random loads.

Consider a body excited by a single randomly varying force $P(t)$ with autocorrelation $R_{TT}(\tau)$ and spectral density $S_{PP}(\omega)$. Owing to this loading, two points on the body have displacements $X(t)$ and $Y(t)$ with means μ_X and μ_Y , autocorrelations $R_{XX}(\tau)$ and $R_{YY}(\tau)$, and spectral densities $S_{XX}(\omega)$ and $S_{YY}(\omega)$, respectively. Note again that upper case letters are used to signify random processes.

We know the following from our earlier studies

$$E\{X(t)\} = H_{XP}(0)\mu_P$$

$$E\{Y(t)\} = H_{YP}(0)\mu_P$$

and

$$S_{XX}(\omega) = |H_{XP}(\omega)|^2 S_{PP}(\omega) \quad (5.23)$$

$$S_{YY}(\omega) = |H_{YP}(\omega)|^2 S_{PP}(\omega) \quad (5.24)$$

where

$$H_{XP}(\omega) = \int_{-\infty}^{\infty} g_{XP}(\tau) e^{-i\omega\tau} d\tau$$

$$H_{YP}(\omega) = \int_{-\infty}^{\infty} g_{YP}(\tau) e^{-i\omega\tau} d\tau$$

and

$$X(t) = \int_{-\infty}^{\infty} g_{XP}(\tau) P(t - \tau) d\tau$$

$$Y(t) = \int_{-\infty}^{\infty} g_{YP}(\tau) P(t - \tau) d\tau$$

With these relations, we can now find the expressions for the cross-correlation $R_{XY}(\tau)$ and cross-spectral density $S_{XY}(\omega)$. Using the definition of a cross-correlation function, we obtain

$$\begin{aligned} R_{XY}(\tau) &= E\{X(t)Y(t+\tau)\} = E\left\{\int_{-\infty}^{\infty} g_{XP}(\tau_1)P(t-\tau_1)d\tau_1 \int_{-\infty}^{\infty} g_{YP}(\tau_2)P(t+\tau-\tau_2)d\tau_2\right\} \\ &= \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{YP}(\tau_2) E\{P(t-\tau_1)P(t+\tau-\tau_2)\} d\tau_2 \right] d\tau_1 \\ &= \int_{-\infty}^{\infty} g_{XP}(\tau_1) \left[\int_{-\infty}^{\infty} g_{YP}(\tau_2) R_{PP}(\tau+\tau_1-\tau_2) d\tau_2 \right] d\tau_1 \end{aligned}$$

Even though we have an explicit expression, it is generally not easy to interpret.

The cross-spectral density can be derived by using the Fourier transform relation between $R_{XY}(\tau)$ and $S_{XY}(\omega)$. Thus,

$$\begin{aligned} S_{XY}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{XY}(\tau) e^{-i\omega\tau} d\tau = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g_{XP}(\tau_1) \int_{-\infty}^{\infty} g_{YP}(\tau_2) R_{PP}(\tau+\tau_1-\tau_2) d\tau_2 d\tau_1 e^{-i\omega\tau} d\tau \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} g_{XP}(\tau_1) e^{+i\omega\tau_1} \int_{-\infty}^{\infty} g_{YP}(\tau_2) e^{-i\omega\tau_2} \int_{-\infty}^{\infty} R_{PP}(\tau+\tau_1-\tau_2) e^{-i\omega(\tau+\tau_1-\tau_2)} d\tau d\tau_2 d\tau_1 \end{aligned} \quad (5.25)$$

In order to integrate this last expression, it is easier to proceed by transforming the variables in the innermost integral according to

$$\lambda \equiv \tau + \tau_1 - \tau_2 \quad \text{and} \quad d\lambda = d\tau$$

where τ_1 and τ_2 are dummy variables. Then, Equation 5.25 becomes

$$\begin{aligned} S_{XY}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} g_{XP}(\tau_1) e^{+i\omega\tau_1} d\tau_1 \int_{-\infty}^{\infty} g_{YP}(\tau_2) e^{-i\omega\tau_2} d\tau_2 \int_{-\infty}^{\infty} R_{PP}(\lambda) e^{-i\omega\lambda} d\lambda \\ &= H_{XP}^*(\omega) H_{YP}(\omega) S_{PP}(\omega) \end{aligned} \quad (5.26)$$

Where points X and Y coincide, this result reduces to the classical fundamental relation $S_{XX}(\omega) = |H_{XP}|^2 S_{PP}(\omega)$.

Equation 5.23, Equation 5.24 and Equation 5.26 can be written in matrix form

$$\begin{bmatrix} S_{XX}(\omega) & S_{XY}(\omega) \\ S_{YX}(\omega) & S_{YY}(\omega) \end{bmatrix} = \begin{bmatrix} H_{XP}^*(\omega) \\ H_{YP}^*(\omega) \end{bmatrix} S_{PP}(\omega) \begin{bmatrix} H_{XP}(\omega) & H_{YP}(\omega) \end{bmatrix} \quad (5.27)$$

or

$$\begin{bmatrix} S_{XX}(\omega) & S_{XY}(\omega) \\ S_{YX}(\omega) & S_{YY}(\omega) \end{bmatrix} = \begin{bmatrix} H_{XP}^*(\omega) S_{XX}(\omega) H_{XP}(\omega) & H_{XP}^*(\omega) S_{XY}(\omega) H_{YP}(\omega) \\ H_{YP}^*(\omega) S_{YX}(\omega) H_{XP}(\omega) & H_{YP}^*(\omega) S_{YY}(\omega) H_{YP}(\omega) \end{bmatrix}$$

Example 5.5 Response Spectra for a Two-Degree-of-Freedom System Subjected to a Single Random Force

Consider the mass–spring–damper system shown in Figure 5.9. Assume that the random force $F_1(t)$ is a white noise random process with $S_{F_1 F_1}(\omega) = S_0$ and $F_2(t) = 0$. (i) Find the frequency response functions $H_{11}(\omega)$ and $H_{21}(\omega)$, and (ii) find the spectral densities $S_{X_1 X_1}(\omega)$, $S_{X_1 X_2}(\omega)$ and $S_{X_2 X_2}(\omega)$.

FIGURE 5.9 Two-DoF system excited by a single random force.

Solution

The equation of motion for this system has been obtained as Equation 5.14 with $F_2(t) = 0$. We found previously that the frequency response function for this system is given by

$$[H(\omega)] = \frac{1}{\det[Z]} \begin{bmatrix} -m_2\omega^2 + i\omega c_2 + k_2 & i\omega c_2 + k_2 \\ i\omega c_2 + k_2 & -m_1\omega^2 + i\omega(c_1 + c_2) + (k_1 + k_2) \end{bmatrix}$$

where

$$\det[Z] = \omega^4 m_1 m_2 - i\omega^3 (m_1 c_2 + c_1 m_2 + c_2 m_2) + i\omega (c_1 k_2 + k_1 c_2) - \omega^2 (m_1 k_2 + c_1 c_2 + k_1 m_2 + k_2 m_2) + k_1 k_2$$

Since $F_2 = 0$, the frequency response functions due to F_2 , $H_{12}(\omega)$ and $H_{22}(\omega)$, are zero. The frequency response functions due to F_1 are given by

$$H_{11}(\omega) = \frac{-m_2\omega^2 + i\omega c_2 + k_2}{\det[Z]}$$

$$H_{21}(\omega) = \frac{i\omega c_2 + k_2}{\det[Z]}$$

Using Equation 5.27, the response spectra are given by

$$S_{X_1 X_1}(\omega) = H_{11}^*(\omega) H_{11}(\omega) S_{F_1 F_1}(\omega) = S_0 \frac{(k_2 - m_2\omega^2)^2 + (\omega c_2)^2}{(\det[Z])^2}$$

$$S_{X_2 X_2}(\omega) = H_{22}^*(\omega) H_{22}(\omega) S_{F_1 F_1}(\omega) = S_0 \frac{k_2^2 + (\omega c_2)^2}{(\det[Z])^2}$$

$$S_{X_1 X_2}(\omega) = H_{11}^*(\omega) H_{21}(\omega) S_{F_1 F_1}(\omega) = S_0 \frac{(-m_2\omega^2 - i\omega c_2 + k_2)(i\omega c_2 + k_2)}{(\det[Z])^2}$$

$$S_{X_2 X_1}(\omega) = H_{21}^*(\omega) H_{11}(\omega) S_{F_1 F_1}(\omega) = S_0 \frac{(-m_2\omega^2 + i\omega c_2 + k_2)(-i\omega c_2 + k_2)}{(\det[Z])^2}$$

Note that $S_{X_2 X_1}(\omega) = S_{X_1 X_2}(-\omega) = S_{X_1 X_2}^*(\omega)$.

5.5.2 Response to Multiple Random Forces

Consider a multi-DoF system subjected to multiple random forces. The goal is to obtain the relation equivalent to Equation 5.27 for the general response for N DoF by first considering the response of a Single-DoF to N forces, and then generalizing to N DoF. This will be done in two ways. First, by extending the impulse-response method leading to the convolution integral, and then by utilizing the modal

analysis approach where the coupled physical equations of motion are decoupled in a new *modal* coordinate system.

5.5.3 Impulse-Response Approach

Let us start by expressing the response $X_k(t)$ using the impulse-response functions $g_{ki}(t)$. Recall that $g_{ki}(t)$ is the impulse response of mass m_k to force $F_i(t)$. By linear superposition, the total response $X_k(t)$ of mass m_k is equal to the sum of the individual responses to each of the N forces

$$X_k(t) = \sum_{i=1}^N X_{ki}(t) = \sum_{i=1}^N \int_{-\infty}^{\infty} g_{ki}(\tau) F_i(t - \tau) d\tau$$

Assuming that the forces are stationary with respective means μ_{F_i} and cross-correlations $R_{F_i F_j}(\tau)$, the mean and correlation of the response can be found as follows:

$$\begin{aligned} E\{X_k(t)\} &= \sum_{i=1}^N \int_{-\infty}^{\infty} g_{ki}(\tau) E\{F_i(t - \tau)\} d\tau \\ \mu_{X_k} &= \sum_{i=1}^N \mu_{F_i} \int_{-\infty}^{\infty} g_{ki}(\tau) d\tau = \sum_{i=1}^N \mu_{F_i} H_{ki}(0) \end{aligned}$$

In matrix form

$$\boldsymbol{\mu}_X = \mathbf{H}_{XX}(0) \boldsymbol{\mu}_F$$

This is a static response and, therefore, can be ignored here and added on at the end of the computations. We next evaluate the expressions for the response correlations and spectral densities, from which we can evaluate the mean-square response. By definition, the correlations are given by

$$\begin{aligned} R_{X_k X_j}(\tau) &= E\{X_k(t) X_j(t + \tau)\} = E\left\{ \sum_{m=1}^N X_{km}(t) \sum_{n=1}^N X_{jn}(t + \tau) \right\} \\ &= E\left\{ \sum_{m=1}^N \int_{-\infty}^{\infty} g_{km}(\zeta) F_m(t - \zeta) d\zeta \sum_{n=1}^N \int_{-\infty}^{\infty} g_{jn}(\xi) F_n(t + \tau - \xi) d\xi \right\} \\ &= \sum_{m=1}^N \sum_{n=1}^N \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g_{km}(\zeta) g_{jn}(\xi) E\{F_m(t - \zeta) F_n(t + \tau - \xi)\} d\zeta d\xi \\ &= \sum_{m=1}^N \sum_{n=1}^N \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g_{km}(\zeta) g_{jn}(\xi) R_{F_m F_n}(\tau - \xi + \zeta) d\zeta d\xi \end{aligned}$$

The response spectral density is by definition

$$S_{X_k X_j}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_k X_j}(\tau) \exp(-i\omega\tau) d\tau$$

Before substituting the correlation function into this equation, multiply it by $\exp(-i\omega[\zeta - \xi]) \times \exp(i\omega[\zeta - \xi])$. Also, define $\nu = \tau - \xi + \zeta$ with $d\nu = d\tau$. All of these manipulations allow us to put the spectral density in the following form:

$$\begin{aligned} S_{X_k X_j}(\omega) &= \sum_{m=1}^N \sum_{n=1}^N \int_{-\infty}^{\infty} g_{km}(\zeta) \exp(i\omega\zeta) d\zeta \int_{-\infty}^{\infty} g_{jn}(\xi) \exp(-i\omega\xi) d\xi \times \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{F_m F_n}(\nu) \exp(-i\omega\nu) d\nu \\ &= \sum_{m=1}^N \sum_{n=1}^N H_{km}^*(\omega) H_{jn}(\omega) S_{F_m F_n}(\omega) \end{aligned}$$

where the star denotes complex conjugate. In matrix form

$$S_{X_k X_j}(\omega) = \mathbf{H}_k^*(\omega) \mathbf{S}_{FF}(\omega) \mathbf{H}_j^T(\omega) \quad (5.28)$$

In this notation, $\mathbf{H}_k^*(\omega)$ is a row vector of dimension $1 \times N$

$$\mathbf{H}_k^*(\omega) = [H_{k1}^*(\omega) \quad \cdots \quad H_{kN}^*(\omega)]$$

$\mathbf{H}_j^T(\omega)$ is a column vector of dimension $N \times 1$

$$\mathbf{H}_j^T(\omega) = \begin{bmatrix} H_{j1}(\omega) \\ \vdots \\ H_{jN}(\omega) \end{bmatrix}$$

and $\mathbf{S}_{FF}(\omega)$ is a matrix of dimension $N \times N$

$$\mathbf{S}_{FF}(\omega) = \begin{bmatrix} S_{F_1 F_1}(\omega) & \cdots & S_{F_1 F_N}(\omega) \\ \vdots & \ddots & \vdots \\ S_{F_N F_1}(\omega) & \cdots & S_{F_N F_N}(\omega) \end{bmatrix}$$

Equation 5.28 can now be generalized for any X_k and X_j

$$\mathbf{S}_{XX}(\omega) = \mathbf{H}^*(\omega) \mathbf{S}_{FF}(\omega) \mathbf{H}^T(\omega) \quad (5.29)$$

where

$$\mathbf{H}(\omega) = \begin{bmatrix} H_{11}(\omega) & \cdots & H_{1N}(\omega) \\ \vdots & \ddots & \vdots \\ H_{N1}(\omega) & \cdots & H_{NN}(\omega) \end{bmatrix}$$

and

$$\mathbf{S}_{XX}(\omega) = \begin{bmatrix} S_{X_1 X_1}(\omega) & \cdots & S_{X_1 X_N}(\omega) \\ \vdots & \ddots & \vdots \\ S_{X_N X_1}(\omega) & \cdots & S_{X_N X_N}(\omega) \end{bmatrix}$$

Let us recall Equation 5.6, Equation 5.9, and Equation 5.27. Equation 5.6 is the response spectral density of a single-DoF system to a single random force, Equation 5.9 is the response spectral density of a single-DoF system to two random forces, and Equation 5.27 is the response spectral densities of a two-DoF system due to a single force. Comparing them with Equation 5.29, we realize that they are all special cases of this equation.

For a zero mean, the mean-square response of the j th coordinate is given by the relation

$$\sigma_{X_j}^2 = \int_{-\infty}^{\infty} S_{X_j X_j}(\omega) d\omega \quad (5.30)$$

Example 5.6 Spacecraft Design Problem (based on Wirsching et al., p. 228)

A rocket mounting is to be designed. The rocket of mass $m_1 = 181$ kg is mounted on a supporting structure of mass $m_2 = 362$ kg using structural brackets that can be modeled as springs of constant $k = 1.40$ MN/m. There is also damping with coefficient $c = 3.50$ kNsec/m. When the engine fires, the thrust can be interpreted as being composed of a mean value thrust and a random fluctuating thrust.

The random variations are due to factors such as fluctuations in fuel mix and eccentricities in thrust direction. The mean thrust is given by $\mu_T = 16$ kN and the random component is given by T , which is a random function of time. T is characterized as white noise of intensity $1980 \text{ N}^2/\text{Hz}$ over the frequency range 0–50 Hz. The mean thrust can be viewed as a static load while the random thrust as the dynamic load.

The design must consider that components in the supporting structure will be damaged if the acceleration is too large. Also, the structural brackets will fail if the relative displacement between the rocket and the supporting structure is too large. Both these design issues are difficult because the input is random. Therefore, there is a trade-off between the cost of making a component stronger and making it more reliable. The probabilistic framework allows the analyst to quantitatively understand the trade-off.

Solution

The goal of the analysis is to determine the acceleration of the supporting mass \ddot{X}_2 and the relative displacement $Z = X_2 - X_1$.

First we solve the mean value problem. The mean value acceleration is

$$a = \frac{F}{m_1 + m_2} = \frac{16,000}{181 + 362} = 29.46 \text{ m/sec}^2 = \frac{29.46}{9.81} = 3.00g$$

The mean force in the bracket is found by applying the equation of motion to m_2

$$\mu_{F_b} = m_2 a_2 = 362 \times 29.46 = 10665 \text{ N} = 10.66 \text{ kN}$$

The mean bracket deflection is

$$\mu_Z = \frac{\mu_{F_b}}{k} = \frac{10.66 \times 10^3}{1.40 \times 10^6} = 7.61 \times 10^{-3} \text{ m} = 7.61 \text{ mm}$$

While the mean value is the single most important descriptor of randomness, the variance is important because it is a measure of the scatter of possible results. In order to calculate the variance, we need to derive the response spectral density and the frequency response function (see Equation 5.30). This we compute next. The equations of motion are given by

$$\begin{aligned} m_1 \ddot{X}_1 - k(X_2 - X_1) - c(\dot{X}_2 - \dot{X}_1) &= F(t) \\ m_2 \ddot{X}_2 + k(X_2 - X_1) + c(\dot{X}_2 - \dot{X}_1) &= 0 \end{aligned}$$

Given the problem statement, the variables of interest are (Z, X_2) . Transform variables using $Z = X_2 - X_1$. The equations of motion become

$$\begin{aligned} m_1 \ddot{X}_2 - m_1 \ddot{Z} - kZ - c\dot{Z} &= F(t) \\ m_2 \ddot{X}_2 + kZ + c\dot{Z} &= 0 \end{aligned}$$

To derive the frequency response function, assume harmonic excitation

$$\mathbf{F}(t) = \begin{bmatrix} F_0 \\ 0 \end{bmatrix} e^{i\omega t}$$

and harmonic response of the form

$$\begin{bmatrix} Z(t) \\ \ddot{X}_2 \end{bmatrix} = \begin{bmatrix} Z_0 \\ \ddot{X}_0 \end{bmatrix} e^{i\omega t}$$

Substitute these equations into the matrix equation of motion to find

$$\begin{aligned} m_1 \ddot{X}_0 + m_1 \omega^2 Z_0 - kZ_0 - i c \omega Z_0 &= F_0 \\ m_2 \ddot{X}_0 + kZ_0 + i c \omega Z_0 &= 0 \end{aligned}$$

The frequency response function is then found to be

$$\mathbf{H}(\omega) = \frac{1}{\Delta(\omega)} \begin{bmatrix} m_2 & -m_1 \\ -k - i c \omega & m_1 \omega^2 - k - i c \omega \end{bmatrix}$$

$$\Delta(\omega) = m_1 m_2 \omega^2 - k(m_1 + m_2) - i c \omega(m_1 + m_2)$$

There is only one applied force, and the spectral density function matrix is

$$\mathbf{S}_F(\omega) = \begin{bmatrix} S_0 & 0 \\ 0 & 0 \end{bmatrix}$$

Apply Equation 5.29 to find

$$\mathbf{S}_{XX}(\omega) = \begin{bmatrix} S_{ZZ} & S_{Z\ddot{X}} \\ S_{\ddot{X}Z} & S_{\ddot{X}\ddot{X}} \end{bmatrix} = \frac{S_0}{|\Delta(\omega)|^2} \begin{bmatrix} m_2^2 & -k m_2 + i c m_2 \omega \\ -k m_2 + i c m_2 \omega & k^2 + (c \omega)^2 \end{bmatrix}$$

To determine the root mean square of relative displacement $Z(t)$, note that the spectral density function of $Z(t)$ is the top term on the diagonal of $S_{XX}(\omega)$:

$$S_{ZZ}(\omega) = S_0 \frac{m_2^2}{|\Delta(\omega)|^2}$$

The mean-square value of $Z(t)$ is then

$$\sigma_Z^2 = \int_{-\infty}^{\infty} S_{ZZ}(\omega) d\omega = \frac{\pi S_0 m_2^2}{c k (m_1 + m_2)^2}$$

The above are for a two-sided spectrum. The given spectrum is one-sided, therefore, $S_0 = W_0/4\pi$. Then, with appropriate substitutions, we find $\sigma_Z \approx 0.212$ mm. In summary, the relative displacement has mean and root mean-square

$$\mu_Z = 7.61 \text{ mm}, \quad \sigma_Z = 0.212 \text{ mm}$$

The force in the spring has mean and root mean-square

$$\mu_{F_b} = k \mu_Z = 1.40 \times 10^6 \times 7.61 = 10.65 \text{ kN}$$

$$\sigma_{F_b} = k \sigma_Z = 1.40 \times 10^6 \times 0.212 = 0.297 \text{ kN}$$

Finally, the spectral density of the acceleration is the second diagonal term of $S_X(\omega)$:

$$S_{\ddot{X}\ddot{X}} = S_0 \frac{k^2 + (c \omega)^2}{|\Delta(\omega)|^2}$$

$$\sigma_{\ddot{X}}^2 = \int_{-\infty}^{\infty} S_{\ddot{X}\ddot{X}}(\omega) d\omega$$

and

$$\sigma_{\ddot{X}}^2 = \pi S_0 \left[\frac{k}{c(m_1 + m_2)^2} + \frac{c}{(m_1 + m_2)m_1 m_2} \right]$$

Upon making the appropriate substitutions, we find

$$\sigma_{\ddot{X}} = 0.852 \text{ m/sec}^2 = 0.087g$$

In summary, the mean and standard deviation of \ddot{X}_2 are

$$\mu_{\ddot{X}_2} = 3g, \quad \sigma_{\ddot{X}_2} = 0.087g$$

See Example 5.1 for a discussion on the above nonstandard integrals.

A designer would now use these mean and standard deviation numbers to decide how reliable to make the components. For example, if we assume that F_b and \ddot{X}_2 are normal density, we can specify a design based

on $\mu \pm 3\sigma$, which tells us the probability of exceeding this 6σ range is less than 0.1%. If this design is too expensive, then the designer will try a design based on $\mu \pm 3\sigma$, one that will have a higher probability of failure. In this way, a trade-off study is performed weighing cost against probability of failure. Figure 5.10 demonstrates a design based on 5% failure probability.

FIGURE 5.10 Normal density with 5% failure probability.

5.5.4 Modal Analysis Approach

The response of a multi-DoF discrete system loaded by random forces is generally a very complicated problem to formulate and solve. Here, to demonstrate one possible approach, we study the modal analysis of such a structure and work through some of the intricacies.

We will start the analysis at the point where the modal equations of motion have been formulated and the assumption of proportional damping has been made. From Equation 5.22, for a random vibration, the modal equations in indicial notation are

$$\ddot{Z}_i + 2\zeta_i\omega_i\dot{Z}_i + \omega_i^2 Z_i = Q_i(t), \quad i = 1, 2, \dots, N \quad (5.31)$$

where the parameters are familiar. We further assume that the modal forces $Q_i(t)$ are *ergodic* random excitations. The transformation between physical and modal spaces is

$$X_j(t) = \sum_{i=1}^N u_{ji} Z_i(t)$$

and the transformation between physical and modal forces is

$$Q_j(t) = \sum_{i=1}^N u_{ji} F_i(t) = \mathbf{u}_j^T \mathbf{F} \quad (5.32)$$

where \mathbf{u}_i is the modal vector for the i th DoF and

$$\mathbf{u}_i = \begin{bmatrix} u_{1i} \\ \vdots \\ u_{Ni} \end{bmatrix}$$

In matrix form, we can write

$$\mathbf{X} = \mathbf{PZ}$$

$$\mathbf{Q} = \mathbf{P}^T \mathbf{F}$$

where \mathbf{P} is the modal matrix given by

$$\mathbf{P} = [\mathbf{u}_1 \quad \cdots \quad \mathbf{u}_N]$$

For a two-DoF system, we can be specific

$$\begin{aligned} X_j(t) &= \sum_{i=1}^2 u_{ji} Z_i(t) = u_{j1} Z_1(t) + u_{j2} Z_2(t), \quad j = 1, 2 \\ Q_j(t) &= \sum_{i=1}^2 u_{ji} F_i(t) = u_{j1} F_1(t) + u_{j2} F_2(t), \quad j = 1, 2 \end{aligned} \quad (5.33)$$

for each DoF j of a two-DoF structure. Our goal in this analysis is to evaluate the statistics of the response, that is, to find autocorrelations and cross-correlations, $R_{X_k X_j}(\tau)$, and its Fourier transform, the power spectrum, $S_{X_k X_j}(\omega)$.

Begin with the definition of the autocorrelation and substitute Equation 5.33 for $X_j(t)$:

$$R_{X_k X_j}(\tau) = E\{X_j(t)X_j(t + \tau)\} = E\left\{\sum_{l=1}^n \sum_{m=1}^n u_{kl}u_{jm}Z_l(t)Z_m(t + \tau)\right\} \quad (5.34)$$

where $Z_i(t)$ is the solution to Equation 5.31:

$$Z_i(t) = \int_0^t Q_i(\tau)g_i(t - \tau)d\tau \quad (5.35)$$

$$g_i(\tau) = \frac{1}{\omega_{d_i}} \exp(-\zeta_i \omega_i \tau) \sin \omega_{d_i} \tau \quad (5.36)$$

$$\omega_{d_i} = \omega_i(1 - \zeta_i^2)^{1/2} \quad (5.37)$$

Note that, since the impulse response function $g(t)$ is zero for $t < 0$, the lower limit on the integral defining $Z(t)$ can be made $-\infty$ without changing the value of the integral.

Substituting Equation 5.35 to Equation 5.37 into Equation 5.34 and letting the expectation operate only on the stochastic terms, we have

$$R_{X_k X_j}(\tau) = \sum_{l=1}^n \sum_{m=1}^n \int_{-\infty}^{t+\tau} \int_{-\infty}^t u_{kl}u_{jm}E\{Q_l(\theta_1)Q_m(\theta_2)\}g_l(t - \theta_1)g_m(t + \tau - \theta_2)d\theta_1 d\theta_2 \quad (5.38)$$

where θ_1 and θ_2 are dummy time variables, and

$$R_{Q_l Q_m}(\theta_2 - \theta_1) = E\{Q_l(\theta_1)Q_m(\theta_2)\}$$

owing to the assumed ergodicity (and thus stationarity) of the forcing. If the system is lightly damped and has well-separated modal frequencies, as is the case in many engineering structures, the response due to $Q_l(t)$ is almost statistically independent of the response due to $Q_m(t)$. The cross-correlation terms that arise in Equation 5.38 are then almost zero, with the only nonzero terms arising for $m = l$:

$$R_{Q_l Q_l}(\theta_2 - \theta_1) = E\{Q_l(\theta_1)Q_l(\theta_2)\}$$

Now that we have the correlation function for the response in terms of the correlation function for the random forcing, we can proceed to evaluate the response spectral density, from which we can evaluate probabilities of occurrence. To do this, the following transformation of variables is first necessary:

$$\begin{aligned} u_1 &\equiv t - \theta_1, & u_2 &\equiv t + \tau - \theta_2, \\ du_1 &= -d\theta_1, & du_2 &= -d\theta_2 \end{aligned}$$

resulting in the response correlation

$$R_{X_k X_j}(\tau) = \sum_{l=1}^n \sum_{m=1}^n \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} u_{kl}u_{jm}R_{Q_l Q_m}(u_1 - u_2 + \tau)g_l(u_1)g_m(u_2)du_1 du_2$$

The power spectral density for response $X(t)$ is equal to the Fourier transform of the correlation function

$$\begin{aligned} S_{X_k X_j}(\partial \varepsilon \omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_k X_j}(\tau) e^{-i\omega \tau} d\tau \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \left\{ \sum_{l=1}^n \sum_{m=1}^n \int_0^{\infty} \int_0^{\infty} u_{kl}u_{jm}R_{Q_l Q_m}(u_1 - u_2 + \tau)g_l(u_1)g_m(u_2)du_1 du_2 \right\} e^{-i\omega \tau} d\tau \end{aligned}$$

or, recalling and utilizing the assumption that the processes are ergodic, and, therefore, by averaging in time

$$S_{X_k X_j}(\omega) = \sum_{l=1}^n \sum_{m=1}^n u_{kl} u_{jm} \left\{ \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_l(u_1) du_1 \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_m(u_2) du_2 \right. \\ \left. \times \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T R_{Q_l Q_m}(u_1 - u_2 + \tau) e^{-i\omega\tau} d\tau \right\}$$

where the lower limits on the integrals were set to $-T$ since $g(t)$ is zero for $t < 0$, and thus the change in lower limit does not affect the values of the integrals. Using the change of variables

$$\gamma \equiv u_1 - u_2 + \tau, \quad d\gamma = d\tau$$

we obtain

$$S_{X_k X_j}(\omega) = \sum_{l=1}^n \sum_{m=1}^n u_{kl} u_{jm} \left\{ \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_l(u_1) \exp(i\omega u_1) du_1 \right. \\ \left. \times \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_m(u_2) \exp(-i\omega u_2) du_2 \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T-u_2+u_1}^{T-u_2+u_1} R_{Q_l Q_m}(\gamma) e^{-i\omega\gamma} d\gamma \right\}$$

In the last integral, we make the physical argument that $R_{Q_l Q_m}(\gamma) \rightarrow 0$ as $|\gamma|$ increases and, therefore, the limits can be replaced by $-T$ and T , respectively.¹⁰ Then,

$$H_l(-\omega) = \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_l(u_1) \exp(i\omega u_1) du_1 \\ H_m(\omega) = \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T}^T g_m(u_2) \exp(-i\omega u_2) du_2 \\ S_{Q_l Q_m}(\omega) = \lim_{T \rightarrow \infty} \frac{1}{2\pi} \int_{-T-u_2+u_1}^{T-u_2+u_1} R_{Q_l Q_m}(\gamma) e^{-i\omega\gamma} d\gamma$$

with the resulting response spectral density

$$S_{X_k X_j}(\omega) = \sum_{l=1}^n \sum_{m=1}^n u_{kl} u_{jm} H_l(-\omega) H_m(\omega) S_{Q_l Q_m}(\omega)$$

For a two-DoF system, we would have

$$S_{X_k X_j}(\omega) = \begin{bmatrix} u_{k1} & u_{k2} \end{bmatrix} \begin{bmatrix} H_1^*(\omega) & 0 \\ 0 & H_2^*(\omega) \end{bmatrix} \begin{bmatrix} S_{Q_1 Q_1}(\omega) & S_{Q_1 Q_2}(\omega) \\ S_{Q_2 Q_1}(\omega) & S_{Q_2 Q_2}(\omega) \end{bmatrix} \begin{bmatrix} H_1(\omega) & 0 \\ 0 & H_2(\omega) \end{bmatrix} \begin{bmatrix} u_{j1} \\ u_{j2} \end{bmatrix} \\ = u_{k1} u_{j1} H_1^*(\omega) H_1(\omega) S_{Q_1 Q_1}(\omega) + u_{k1} u_{j2} H_1^*(\omega) H_2(\omega) S_{Q_1 Q_2}(\omega) + u_{k2} u_{j1} H_2^*(\omega) H_1(\omega) S_{Q_2 Q_1}(\omega) \\ + u_{k2} u_{j2} H_2^*(\omega) H_2(\omega) S_{Q_2 Q_2}(\omega)$$

Suppose that we wish to find S_{XX} for a two-DoF system. Then

$$S_{XX} = \begin{bmatrix} u_{11} & u_{12} \\ u_{21} & u_{22} \end{bmatrix} \begin{bmatrix} H_1^*(\omega) & 0 \\ 0 & H_2^*(\omega) \end{bmatrix} \begin{bmatrix} S_{Q_1 Q_1}(\omega) & S_{Q_1 Q_2}(\omega) \\ S_{Q_2 Q_1}(\omega) & S_{Q_2 Q_2}(\omega) \end{bmatrix} \begin{bmatrix} H_1(\omega) & 0 \\ 0 & H_2(\omega) \end{bmatrix} \begin{bmatrix} u_{11} & u_{21} \\ u_{12} & u_{22} \end{bmatrix}$$

¹⁰Physically, we are stating that, as time difference (*trial mode*) increases, there will be an exponentially decaying correlation. This is borne out by experiments on physical systems.

In general, we can write

$$\mathbf{S}_{XX}(\omega) = \mathbf{P}\mathbf{H}^*(\omega)\mathbf{S}_{QQ}(\omega)\mathbf{H}(\omega)\mathbf{P}^T \quad (5.39)$$

where

$$\mathbf{H}(\omega) = \begin{bmatrix} H_1(\omega) & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & H_N(\omega) \end{bmatrix}$$

$$H_i(\omega) = \frac{1}{-\omega^2 + i2\zeta_i\omega_i\omega + \omega_i^2}$$

The spectral densities of the modal forces $S_{Q_lQ_m}(\omega)$ can be obtained from $S_{FF}(\omega)$ using Equation 5.32. The autocorrelation $R_{Q_lQ_m}(\tau)$ is defined as

$$R_{Q_lQ_m}(\tau) = E\{Q_l(t)Q_m(t + \tau)\} = E\left\{\sum_{i=1}^N u_{il}F_i(t) \sum_{j=1}^N u_{jm}F_j(t + \tau)\right\} = \sum_{i=1}^N \sum_{j=1}^N u_{il}u_{jm}E\{F_i(t)F_j(t + \tau)\}$$

$$= \sum_{i=1}^N \sum_{j=1}^N u_{il}u_{jm}R_{F_iF_j}(\tau)$$

Taking the Fourier transform

$$S_{Q_lQ_m}(\omega) = \sum_{i=1}^N \sum_{j=1}^N u_{il}u_{jm}S_{F_iF_j}(\omega)$$

or

$$S_{Q_lQ_m}(\omega) = \mathbf{u}_l^T \mathbf{S}_{FF} \mathbf{u}_m$$

or

$$\mathbf{S}_{QQ}(\omega) = \mathbf{P}^T \mathbf{S}_{FF} \mathbf{P} \quad (5.40)$$

Substituting Equation 5.40 into Equation 5.39, we obtain

$$\mathbf{S}_{XX}(\omega) = \mathbf{P}\mathbf{H}^*(\omega)\mathbf{P}^T \mathbf{S}_{FF}(\omega)\mathbf{P}\mathbf{H}(\omega)\mathbf{P}^T$$

Comparing this result with Equation 5.29, we find that

$$\mathbf{H}_{XX}^*(\omega) = \mathbf{P}\mathbf{H}^*(\omega)\mathbf{P}^T$$

$$\mathbf{H}_{XX}(\omega) = \mathbf{P}\mathbf{H}(\omega)\mathbf{P}^T$$

which is a fully populated transfer function matrix of $X(t)$.

For lightly damped systems with well-spaced modal frequencies, the cross-terms in the double summation, those where $l \neq m$, contribute very little to the mean-square response given by $\int_{-\infty}^{\infty} S_{X_iX_j}(\omega)d\omega$. In this case, we can use the approximation

$$S_{X_iX_j}(\omega) \approx \sum_{l=1}^n u_{ji}^2 |\mathbf{H}_l(\omega)|^2 S_{Q_lQ_l}(\omega)$$

where

$$|H_l(\omega)|^2 = \left[\frac{1/\omega_l^2}{\sqrt{(1 - \omega^2/\omega_l^2)^2 + (2\zeta_l\omega/\omega_l)^2}} \right]^2$$

Suppose that we only account for the first three modes out of 1000 DoF. Then, the spectral density \mathbf{S}_{XX} based on three modes can be obtained by

$$\mathbf{S}_{XX}(\omega) = \mathbf{P}|_{1000 \times 3} \mathbf{H}^*(\omega)|_{3 \times 3} \mathbf{P}^T|_{3 \times 1000} \mathbf{S}_{FF}|_{1000 \times 1000} \mathbf{P}|_{1000 \times 3} \mathbf{H}(\omega)|_{3 \times 3} \mathbf{P}^T|_{3 \times 1000}$$

where

$$\mathbf{P}|_{1000 \times 3} = [\mathbf{u}_1 \quad \mathbf{u}_2 \quad \mathbf{u}_3]$$

$$\mathbf{H}(\omega)|_{3 \times 3} = \begin{bmatrix} H_1(\omega) & 0 & 0 \\ 0 & H_2(\omega) & 0 \\ 0 & 0 & H_3(\omega) \end{bmatrix}$$

Thus, we can easily see that the modal approach allows the analyst and designer to retain only those modes that are key to the problem at hand. If, as above, a thousand-DoF system can be adequately modeled as a three-DoF system because that is where all the energy is located, then a great deal of unnecessary computation is avoided.

5.6 Continuous System Random Vibration

Continuous models of vibrating systems are viewed as more realistic because the structural properties are distributed rather than being concentrated at discrete points. The price to pay for increased realism is increased complexity. The governing equations of motion go from being ordinary differential equations for the discrete models, to partial differential equations for the continuous ones, since displacement is a function of both time and position. For our elementary applications, deriving and solving the partial differential equations does not pose a great challenge. But, when we need to model nonuniform structures with varying cross sections and material properties, approximate techniques will be needed. Here our introduction to continuous systems will focus on strings and vibrating beams. These are found in most structures and machines, and understanding how they behave is of great use to modeling more complex systems. We will approach these studies using the direct and modal solutions.

5.6.1 Transverse Vibration of Beams

Begin with the equation of motion of a damped, forced, simply-supported beam with uniform properties

$$EI \frac{\partial^4 y}{\partial x^4} + c \frac{\partial y}{\partial t} + m \frac{\partial^2 y}{\partial t^2} = p(x, t) \quad (5.41)$$

where it is assumed the natural frequencies and the mode shapes have already been evaluated. To solve this problem, we will use the normal mode method, which depends on the modal orthogonality properties. First, expand the applied force $p(x, t)$ in terms of the modes,¹¹ then do the

¹¹The modes $Y_j(x)$ are the eigenfunctions of the problem

$$EI \frac{\partial^4 y}{\partial x^4} + m \frac{\partial^2 y}{\partial t^2} = 0$$

That is, they satisfy

$$EI \frac{d^4 Y_j}{dx^4} - \omega^2 m Y_j = 0, \quad j = 1, 2, \dots$$

and the boundary conditions at hand.

same with the structural displacement

$$p(x, t) = \sum_{j=1}^{\infty} p_j(t) Y_j(x)$$

Multiply both sides of this equation by $mY_k(x)$ and then integrate over the beam span

$$\int_0^L mp(x, t) Y_k(x) dx = \sum_{j=1}^{\infty} p_j(x, t) \int_0^L mY_j(x) Y_k(x) dx$$

On the right-hand side of this equation, we note that, by the orthogonality properties of the modes, the integral equals zero for $k \neq j$, and otherwise is normalized to 1 for $k = j$. Therefore, we are left with

$$\int_0^L mp(x, t) Y_j(x) dx = p_j(t) \quad (5.42)$$

Apply the same procedure to the response

$$y(x, t) = \sum_{j=1}^{\infty} y_j(t) Y_j(x) \quad (5.43)$$

and multiply and integrate as above to find

$$\int_0^L my(x, t) Y_j(x) dx = y_j(t)$$

$y(x, t)$ can be differentiated with respect to x and t so that all the terms in the equation of motion (Equation 5.41) can be put into the modal expansion form

$$\sum_{j=1}^{\infty} \left[EI y_j(t) \frac{d^4 Y_j}{dx^4} + c \frac{dy_j}{dt} Y_j + m \frac{d^2 y_j}{dt^2} Y_j \right] = \sum_{j=1}^{\infty} p_j(t) Y_j(x) \quad (5.44)$$

We know that the modes are defined by and satisfy the equation $EI d^4 Y_j/dx^4 = \omega_j^2 m Y_j$. Substituting this relation into Equation 5.44 leads to

$$\sum_{j=1}^{\infty} [\omega_j^2 m y_j(t) + c \dot{y}_j(t) + m \ddot{y}_j(t) - p_j(t)] Y_j(x) = 0$$

Since the eigenfunctions $Y_j(x)$ are not zero except for unrestrained motion, the expression in the square brackets must vanish for every j ,

$$\ddot{y}_j(t) + \frac{c}{m} \dot{y}_j(t) + \omega_j^2 y_j(t) = \frac{1}{m} p_j(t), \quad j = 1, 2, \dots \quad (5.45)$$

As for single-DoF systems, let $c/m = 2\zeta_j \omega_j$, that is,

$$\zeta_j = \frac{c}{2m\omega_j}$$

Equation 5.52 is the damped, forced, harmonic oscillator, with the well-known convolution solution,

$$\eta_j(t) = \frac{1}{m} \int_0^t p_j(\tau) g_j(t - \tau) d\tau \quad (5.46)$$

where $g_j(t)$ is the impulse response function for a damped oscillator. Once solved, $y_j(t)$ is substituted into the expansion equation

$$y(x, t) = \sum_{j=1}^{\infty} y_j(t) Y_j(x) = \frac{1}{m} \sum_{j=1}^{\infty} Y_j(x) \int_0^t p_j(\tau) g_j(t - \tau) d\tau$$

and substituting Equation 5.42 for $p_j(t)$ results in

$$y(x, t) = \sum_{j=1}^{\infty} Y_j(x) \int_0^t \left[\int_0^L p(\xi, t - \tau) Y_j(\xi) d\xi \right] g_j(t - \tau) d\tau \quad (5.47)$$

This is the complete steady-state time-domain solution.

5.6.2 Random Transverse Vibration

Assume that the loading $P(x, t)$ is random and represents an ensemble of functions of space and time. We need only the first two statistics of the load to proceed with the analysis of the response. Its mean value is denoted

$$E\{P(x, t)\} = \mu_p(x, t)$$

with autocorrelation

$$E\{P(x_1, t_1)P(x_2, t_2)\} = R_{pp}(x_1, x_2; t_1, t_2)$$

These statistics are available through data-gathering experiments performed on the loading to be experienced by the structure. Our goal in this analysis is to derive the statistics for the response, μ_Y and R_{YY} , which are functions of the statistics of the loading and the structural parameters.

For steady-state vibration problems, we may reasonably assume that the statistics of the loading are stationary. Begin with Equation 5.47 but now, for random loading $P(x, t)$

$$y(x, t) = \sum_{j=1}^{\infty} Y_j(x) \int_0^t \left[\int_0^L P(\xi, t - \tau) Y_j(\xi) d\xi \right] g_j(\tau) d\tau$$

where the shift τ has been placed within $p(x, t)$ and take the expectation of both sides

$$E\{Y(x, t)\} = \sum_{j=1}^{\infty} Y_j(x) \int_0^t \left[\int_0^L E\{P(\xi, t - \tau)\} Y_j(\xi) d\xi \right] g_j(\tau) d\tau$$

The impulse response function is $g(t)$, and for stationary loading, the expected value is a constant, $E\{P(\xi, t - \tau)\} = \mu_p(\xi)$. In order to simplify the following analysis, we assume that the loading has zero mean. This does not overly simplify the problem since a nonzero mean can be introduced later by simply shifting the response by the (constant) mean value. For zero mean loading, $\mu_p(x) = 0$, and the response is also zero mean, $E\{Y(x, t)\} = \mu_Y = 0$.

We need to relate the autocorrelation of the response to that for the loading. Begin with Equation 5.42:

$$\begin{aligned} R_{p_j p_k}(t_1, t_2) &= E\{P_j(t_1)P_k(t_2)\} = m^2 \int_0^L \int_0^L E\{P(x_1, t_1)P(x_2, t_2)\} Y_j(x_1)Y_k(x_2) dx_1 dx_2 \\ &= m^2 \int_0^L \int_0^L R_{pp}(x_1, x_2; t_1, t_2) Y_j(x_1)Y_k(x_2) dx_1 dx_2 \end{aligned} \quad (5.48)$$

where, for a stationary loading, $R_{pp}(x_1, x_2; t_1, t_2) = R_{pp}(x_1, x_2; \tau)$, where $\tau = t_2 - t_1$ and therefore, $R_{p_j p_k}(t_1, t_2) = R_{p_j p_k}(\tau)$. Using Equation 5.43, the response autocorrelation is

$$\begin{aligned} R_{YY}(x_1, x_2; t_1, t_2) &= E\{Y(x_1, t_1)Y(x_2, t_2)\} = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} E\{Y_j(t_1)Y_k(t_2)\} Y_j(x_1)Y_k(x_2) \\ &= \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} R_{Y_j Y_k}(t_1, t_2) Y_j(x_1)Y_k(x_2) \end{aligned}$$

where, using Equation 5.46, with upper and lower limits extended to $\pm\infty$ without changing the final value of the integral due to the fact that the impulse response is zero outside the original limits

$$\begin{aligned} R_{Y_j Y_k}(t_1, t_2) &= \frac{1}{m^2} E \left\{ \int_{-\infty}^{\infty} P_j(t_1 - \theta) g_j(\theta) d\theta \int_{-\infty}^{\infty} P_k(t_2 - \kappa) g_k(\kappa) d\kappa \right\} \\ &= \frac{1}{m^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} E \{ P_j(t_1 - \theta) P_k(t_2 - \kappa) \} g_j(\theta) g_k(\kappa) d\theta d\kappa \\ &= \frac{1}{m^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{P_j P_k}(t_1 - \theta, t_2 - \kappa) g_j(\theta) g_k(\kappa) d\theta d\kappa \end{aligned}$$

Since $P(x, t)$ is stationary, $R_{P_j P_k}(t_1 - \theta, t_2 - \kappa) = R_{P_j P_k}(t_2 - t_1 + \theta - \kappa)$ and $R_{Y_j Y_k}(t_1, t_2) = R_{Y_j Y_k}(t_2 - t_1)$. Therefore,

$$R_{Y_j Y_k}(t_1, t_2) = \frac{1}{m^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{P_j P_k}(t_2 - t_1 + \theta - \kappa) g_j(\theta) g_k(\kappa) d\theta d\kappa \quad (5.49)$$

and

$$R_{YY}(x_1, x_2; t_2 - t_1) = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} R_{Y_j Y_k}(t_2 - t_1) Y_j(x_1) Y_k(x_2)$$

This last equation is a relation between the forcing and response autocorrelations. The spectral density of the response, $S_{YY}(\omega)$, is given by the Fourier transform of $R_{YY}(\tau)$

$$S_{YY}(\omega) = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \left[\int_{-\infty}^{\infty} R_{Y_j Y_k}(\tau) e^{-i\omega\tau} d\tau \right] Y_j(x_1) Y_k(x_2) \quad (5.50)$$

where $\tau = t_2 - t_1$, and the term in the square brackets equals $S_{Y_j Y_k}(\omega)$, which now needs to be evaluated in terms that have already been derived.

By definition, we know the Fourier transform relation

$$S_{Y_j Y_k}(\omega) = \int_{-\infty}^{\infty} R_{Y_j Y_k}(\tau) e^{-i\omega\tau} d\tau$$

We can evaluate $R_{Y_j Y_k}$ by beginning with Equation 5.49

$$R_{Y_j Y_k}(\tau) = \frac{1}{m^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{P_j P_k}(\tau + \theta - \kappa) g_j(\theta) g_k(\kappa) d\theta d\kappa$$

Take the Fourier transform of both sides, letting $\lambda = \tau + \theta - \kappa$, to find

$$S_{Y_j Y_k}(\omega) = \int_{-\infty}^{\infty} e^{-i\omega(\lambda - \theta + \kappa)} \frac{1}{m^2} \left[\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{P_j P_k}(\lambda) g_j(\theta) g_k(\kappa) d\theta d\kappa \right] d\lambda \quad (5.51)$$

where τ has been replaced by $\lambda - \theta + \kappa$ and $d\tau$ by $d\lambda$. Rewrite Equation 5.51 in a more useful form by separating the integrals according to dummy variables

$$S_{Y_j Y_k}(\omega) = \frac{1}{m^2} \int_{-\infty}^{\infty} g_j(\theta) e^{i\omega\theta} d\theta \int_{-\infty}^{\infty} g_k(\kappa) e^{-i\omega\kappa} d\kappa \int_{-\infty}^{\infty} R_{P_j P_k}(\lambda) e^{-i\omega\lambda} d\lambda \quad (5.52)$$

The Fourier transform of the impulse response function $g(t)$ is the frequency response function $H(\omega)$. Therefore, Equation 5.52 becomes

$$S_{Y_j Y_k}(\omega) = \frac{1}{m^2} H_j^*(\omega) H_k(\omega) S_{P_j P_k}(\omega) \quad (5.53)$$

where $H_j(\omega) = [\omega_j^2 - \omega^2 + 2\zeta_j\omega_j\omega]^{-1}$ and $S_{p_j p_k}(\omega)$, the spectral density of the modal force components, is derived assuming that the Fourier transform for $P_j(t)$ exists, as it does for most physical processes

$$P_j(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} P_j(\omega) e^{i\omega t} d\omega$$

Take the Fourier transform of Equation 5.48, to find

$$S_{p_j p_k}(\omega) = m^2 \int_0^L \int_0^L S_{pp}(\omega) Y_j(x_1) Y_k(x_2) dx_1 dx_2 \quad (5.54)$$

where $S_{pp}(\omega)$ is the spectral density of the loading, a quantity that is estimated from data. Substituting Equation 5.54 into Equation 5.53, we now have the expression for $S_{Y_j Y_k}(\omega)$, which can be substituted into Equation 5.50, resulting in

$$S_{YY}(x_1, x_2; \omega) = \frac{1}{m^2} \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} H_j^*(\omega) H_k(\omega) S_{p_j p_k}(\omega) Y_j(x_1) Y_k(x_2)$$

One value of having such an equation is that the mean-square displacement can be evaluated

$$Y_{MS}(x) = R_{YY}(x, x; 0) = \int_{-\infty}^{\infty} S_{YY}(x, x; \omega) d\omega$$

Recall that if $\mu_Y(x) = 0$ then $Y_{MS}(x) = \sigma_Y^2(x)$, the variance.

The derivations are now complete, but what do they mean and what do they do for us? One of the functions of a probabilistic analysis is to help us bound our uncertainties so that we can understand how randomness in the forcing results in a scatter of possible structural responses. Furthermore, this scatter is not haphazard, but is defined by a standard deviation and possibly a density function. It is the variance that is used to bound the mean-value response.

Nomenclature

Symbol	Quantity	Symbol	Quantity
$E\{\cdot\}$	mathematical expectation	$\{u\}_i$	structural mode
$H(\omega)$	frequency response function	W_0	one-sided spectral density
$R_{XX}(\tau)$	autocorrelation function	$z(t)$	modal coordinates
$R_{XY}(\tau)$	cross-correlation function	μ	mean value (first moment)
$S_{XX}(\omega)$	power spectral density	σ^2	variance (second moment)
$S_{XY}(\omega)$	power cross-spectral density		

Acknowledgments

I am pleased to acknowledge my collaboration over the past few years with Dr. Seon Mi Han of Wood-Hole Oceanographic Institute. Seon has had input to this document and has prepared the figures. It is also a great pleasure to acknowledge the support provided by the Office of Naval Research and by our program manager Dr. Thomas Swean under Grant No. N00014-97-10017. Finally, I appreciate the invitation by Professor Clarence W. de Silva to prepare this chapter.

Bibliography

The discipline of random vibration includes thousands of references. Applications include wind and earthquake engineering, aerospace engineering, and ocean engineering to name the broad areas.

More recently, applications in materials engineering and biomechanical engineering have also broadened to include random effects. Therefore, we provide here a brief list of references.

Summary

This chapter gives an overview of numerical techniques for vibration analysis. The centered difference approximation for the first, second, and fourth derivative are given. These form the basis for the finite difference approximation of both spring–mass systems and the continuous problem. The fourth-order Runge–Kutta method is presented. Both of these approaches are used to solve the single-degree-of-freedom (single-DoF) system. In order to demonstrate these techniques for the multiple-degree-of-freedom (multi-DoF) system a two-degree-of-freedom (two-DoF) system is explored. Finite element and finite difference methods are presented as solution techniques for the continuous problem (also see Chapter 9). The bar and beam are used for examples. The Rayleigh method and Dunkerley's formula are presented. These are methods for computing the fundamental frequency.

6.1 Introduction

This chapter presents numerical techniques for three classes of vibration problems; the single spring mass, the multiple spring mass, and the continuous model. The simplest oscillatory problem results when the problem can be modeled by the single spring–mass system. This system is modeled by a second-order constant coefficient differential equation, which can be solved analytically when either there is no forcing, or the forcing is harmonic. When the forcing is not harmonic, the finite difference method can be used to

solve this second-order equation or to solve the system of first-order equations, which is equivalent to the second-order equation. A larger computational problem arises when there are multiple springs and masses subjected to nonharmonic forcing. Again, the finite difference method can be used to compute the full solution. It is not always necessary to compute the full solution. Often, all that is needed is the fundamental frequency. This can be computed from the eigenvalues of a matrix problem. Both the numerical solution to the full problem and the matrix problem will be discussed. Finally, one may want to look at the vibration of a continuous element like a beam. Here, both the finite difference method and the finite element method will be discussed.

6.2 Single-Degree-of-Freedom System

The simple undamped spring–mass system oscillates with a frequency known as the natural frequency. The natural frequency is determined by the spring constant and the mass in the following way, $\omega = \sqrt{k/m}$. This relationship is derived by applying Newton's second law to the basic spring–mass system. The resulting equation is given by $m\ddot{x} = -kx$. The solution to this equation is harmonic with the frequency specified by the expression $\omega = \sqrt{k/m}$.

A more realistic vibration model of a simple oscillatory system includes a mass, a spring and a damper (see Figure 6.1). For simplicity, the mass is concentrated at the center of mass of the object, the spring is assumed to be of negligible mass, and, for the purposes of this discussion, the damping will be modeled by viscous damping. This is described by a force proportional to the velocity, denoted by \dot{x} . In the case of no external forcing, the system can be described by the following equation:

$$m\ddot{x} + c\dot{x} + kx = 0$$

where m , c , and k are constants and m is the mass, c is the damping coefficient, and k is the spring constant. This equation can be solved analytically by assuming a solution of the form

$$x = e^{st}$$

where s is a constant. Substitution into the differential equation yields the following quadratic equation:

$$(ms^2 + cs + k)e^{st} = 0$$

This equation is satisfied for all values of t when the following quadratic equation, known as the characteristic equation, is satisfied:

$$s^2 + \left(\frac{c}{m}\right)s + \frac{k}{m} = 0$$

The characteristic equation has two roots

$$s_1 = -\frac{c}{2m} + \sqrt{(c/2m)^2 - (k/m)}$$

and

$$s_2 = -\frac{c}{2m} - \sqrt{(c/2m)^2 - (k/m)}$$

The general solution is

$$x = A e^{s_1 t} + B e^{s_2 t}$$

The constants A and B are determined by the initial conditions $x(0)$ and $\dot{x}(0)$. The single spring–mass system exhibits three types of behavior, overdamped, underdamped and critically damped.

FIGURE 6.1 Single spring–mass system.

The overdamped state exists when k/m is larger than $(c/2m)^2$. No oscillations exist in this state. The underdamped case is oscillatory and results when $(c/2m)^2$ is larger than k/m . The limiting case between oscillatory and nonoscillatory motion occurs when $(c/2m)^2 = k/m$. When this condition is met, the system is said to be critically damped.

The next level of complexity results when the system is forced harmonically. The following equation serves as a model for this system:

$$m\ddot{x} + c\dot{x} + kx = F \sin \omega t$$

The solution of this equation is found by first computing the complementary function, which is the solution of the homogeneous equation discussed above, and then the particular solution. The details for computing a particular solution can be found in books on differential equations or mechanical vibrations (Thomson and Dahleh, 1998).

6.2.1 Forced Single-Degree-of-Freedom System

In general, when the oscillatory system is forced in a nonharmonic way, the resulting differential equation cannot be solved in closed form, and numerical methods must be employed to predict the behavior of the system. In this section, we consider two finite difference methods chosen for their simplicity. For a more detailed discussion of numerical methods for ordinary differential equations see Atkinson (1978) and Isaacson (1966).

The spring–mass system that is subjected to general forcing, $F(x, \dot{x}, t)$, can be modeled by the following differential equation:

$$m\ddot{x} + c\dot{x} + kx = f(x, \dot{x}, t)$$

$$x_0 = x(0)$$

$$\dot{x}_0 = \dot{x}(0)$$

where m , c , and k are constants and F is an arbitrary function. The two initial conditions, x_0 and \dot{x}_0 , are known.

In the first method, the second-order equation is integrated without change in form; in the second method, the second-order equation is rewritten as a system of two first-order equations and then the system of equations is integrated. Both methods approximate the first and second derivatives with the centered difference approximation for the derivatives. Finite difference methods are based on the Taylor expansion. The centered difference method for the first and second derivative results from a combination of the forward and backward Taylor expansion about the point x_i . To get the forward expansion, one writes the Taylor expansion for x_{i+1} . Similarly, the backward expression is obtained from the Taylor expansion about x_{i-1} . These are given by

$$x_{i+1} = x_i + h\dot{x}_i + \frac{h^2}{2}\ddot{x}_i + \frac{h^3}{6}\ddot{x}_i + \dots$$

$$x_{i-1} = x_i - h\dot{x}_i + \frac{h^2}{2}\ddot{x}_i - \frac{h^3}{6}\ddot{x}_i + \dots$$

where $h = \Delta t$. A second-order approximation is one which matches the Taylor expansion exactly up to and including terms of order h^2 ; that is, to determine a second-order expansion one neglects terms of order h^3 and higher. A second-order approximation for the first derivative is obtained by subtracting the backward difference from the forward difference. The resulting centered difference approximation is given by

$$\dot{x}_i = \frac{1}{2h}(x_{i+1} - x_{i-1}) - \frac{h^2}{6}\ddot{x}_i + \dots$$

Errors result when this expression is truncated after the first term. These errors depend on h^2 and the third derivative of x_i . If the error in the computed derivative is larger than order h^2 it may well arise from the neglected third derivative term.

The centered difference approximation for the second derivative is found by adding the forward and backward difference expansions and ignoring terms of order h^4 and higher. The resulting approximation is

$$\ddot{x}_i = \frac{1}{h^2}(x_{i-1} - 2x_i + x_{i+1}) + \frac{h^2}{12}x^{iv} + \dots$$

The truncation error that occurs for this expression depends on h^2 and the fourth derivative of x_i . Both the first and second derivative centered difference approximations are order h^2 . They can be used together to create a second-order approximation to a second-order ordinary differential equation such as that describing the spring–mass system.

6.2.1.1 Centered Difference Approximation

After substituting these two centered difference approximations into the differential equation and rearranging terms, one gets the following recurrence relation for the single spring–mass system:

$$x_{i+1} = h^2 f(x_i, t_i) - (fh^2 - 2m)x_i - (m - ch/2)x_{i-1}$$

with the initial conditions

$$x_0 = x(0)$$

$$\dot{x}_0 = \dot{x}(0)$$

The recurrence relation should be used to compute all values of x from the initial condition. By letting $i = 1$ in the recurrence relation, we get

$$x_2 = h^2 f(x_1, t_1) - (kh^2 - 2m)x_1 - (m - ch/2)x_0$$

In order to compute x_2 , both x_0 and x_1 are needed. The initial conditions provide x_0 . However, to start the calculation, we need an additional equation for x_1 . This equation is derived by substituting $i = 0$ into the Taylor expansion for x_{i+1} , using the initial conditions and ignoring terms of order h^2 and higher. Since the centered difference approximation is of order h^2 , it is consistent to compute x_1 with an error of order h^2 . For the point $i = 0$, the forward difference is given by

$$x_1 = x_0 + h\dot{x}_0$$

This equation allows one to find x_1 in terms of the two initial conditions, after which the recurrence relation can be used to find all subsequent discrete values of x .

6.2.1.2 Pseudocode for Centered Difference Approximation

The following is an example of the MATLAB[®] routine for the solution to the centered difference approximation of the general single-DoF spring–mass equations. The function f needs to be specified in a separate function file:

```
%initial conditions (index has to start at 1)
x(1) = x0
xd = x'0
%specify a time step
h = H
%specify the constants m, k, c.
m = M
k = K
c = C
%compute x(2) from the Taylor expansion
x(2) = x(1) + h * xd
%specify the total number of steps
TEND = tfinal
```

```

%compute the solution for all remaining times using the recurrence relation
t(1) = h
t(2) = 2 * h
for I = 3:TEND
Xi = h2 * f(xi-1, ti-1) - (k * h2 - 2 * m) * xi-1 - (m - c * h/2) * xi-2
T(i) = t(I - 1) + h
end

```

The method just presented has ignored terms of order h^2 and higher. This is known as the truncation error. The calculation will contain other errors such as round-off error due to the loss of significant figures. This loss is related to both the machine and the language used for the calculations. The round-off errors are also related to the time increment $h = \Delta t$ in a complicated way that is beyond the scope of this chapter. Better accuracy can be obtained by choosing a smaller Δt . However, the smaller the Δt , the larger the number of computations needed to reach the solution in a fixed time T . The increased number of computations affects both the total time of the calculation and the overall accuracy.

6.2.1.3 Runge–Kutta Methods

The centered difference approximation is not a self-starting method. In other words, the calculation that determines x_1 from the initial conditions does not come from the discretized equation, but rather from the Taylor expansion directly. An alternate way to solve this equation is to use what is known as a Runge–Kutta method. All of these methods approximate the differential equation with Taylor series expansions. The advantage of this class of methods is that they are self-starting. The disadvantage is that they only work on first-order equations (or systems of first-order equations). Before the Runge–Kutta method is discussed in detail, the second-order spring–mass equation has to be written as a system of two first-order equations. The equation for the single-DoF system, subjected to arbitrary forcing f is

$$m\ddot{x} + c\dot{x} + kx = f(x, \dot{x}, t)$$

It can be rewritten as the following system of first-order equations

$$\begin{aligned}\dot{x} &= u \\ \dot{u} &= \ddot{x} = \frac{1}{m}[f(x, u, t) - cu + kx]\end{aligned}$$

These equations are coupled and need to be solved together. Any Runge–Kutta method for the system of equations requires a Taylor series expansion of x and u about x_i and u_i . The Taylor expansion is given by

$$\begin{aligned}x_{i+1} &= x_i + \dot{x}_i h + \ddot{x}_i \frac{h^2}{2} + \cdots \\ u_{i+1} &= u_i + \dot{u}_i h + \ddot{u}_i \frac{h^2}{2} + \cdots\end{aligned}$$

As above, the time increment will be denoted by $h = \Delta t$. The first-order Runge–Kutta method (also known as Euler's method) is obtained by retaining terms of first-order and lower, i.e., the Euler approximation is given by

$$\begin{aligned}x_{i+1} &= x_i + \dot{x}_i h - o(h) \\ u_{i+1} &= u_i + \dot{u}_i h - o(h)\end{aligned}$$

The truncation error for Euler's method is order h . The error depends linearly on h .

Matching more terms in the Taylor expansion generates higher order Runge–Kutta methods. The most commonly used Runge–Kutta method is the fourth-order method that matches the Taylor expansion up to terms of order h^4 . This is a significant reduction in the error. For a derivation of this method see Cheney and Kincaid (1999).

TABLE 6.1 Fourth-Order Runge–Kutta Method for Spring–Mass Equation

t	x	$\dot{X} = u$	$\ddot{X} = G$
$T_1 = t_i$	$X_1 = x_i$	$U_1 = u_i$	$G_1 = G(T_1, X_1, U_1)$
$T_2 = t_i + h/2$	$X_2 = x_i + U_1 h/2$	$U_2 = u_i + G_1 h/2$	$G_2 = G(T_2, X_2, U_2)$
$T_3 = t_i + h/2$	$X_3 = x_i + U_2 h/2$	$U_3 = u_i + G_2 h/2$	$G_3 = G(T_3, X_3, U_3)$
$T_4 = t_i + h$	$X_4 = x_i + U_3 h$	$U_4 = u_i + G_3 h$	$G_4 = G(T_4, X_4, U_4)$

Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.

For the system of first-order equations given above, the fourth-order Runge–Kutta method requires four values of t , x , u , and, G where $G = 1/m[f(x, u, t) - cu + kx]$. It can be computed for each point i as follows in Table 6.1.

Combining these quantities in the following method gives the fourth-order Runge–Kutta method:

$$x_{i+1} = x_i + h/6(U_1 + 2U_2 + 2U_3 + U_4)$$
$$u_{i+1} = u_i + h/6(G_1 + 2G_2 + 2G_3 + G_4)$$

where it is recognized that the four values of U divided by six represent the average slope dx/dt and the four values of G divided by six result in an average of du/dt . A way to check the accuracy of a Runge–Kutta method is to Taylor expand G_1 , G_2 , G_3 , and G_4 and collect like terms. One will find that the above combination produces an expansion which is exact up to order h^4 .

6.2.1.4 Pseudocode for the Fourth-Order Runge–Kutta Method

For simplicity, the code is given for the single first-order equation

$\dot{x} = G(t, x)$ with the initial data $x(0) = x_0$.

The function G should be specified in a function file.

```
%initial conditions (index has to start at 1)
x(1) = x0;
%time step needs to be specified
h = H;
h2 = 2 * H;
%TEND is the total number of time steps
TEND = Tfinal;
T = h;
for I = 1:TEND
    G1 = H * G(t, x);
    G2 = H * G(t + h2, x = 0.5 * G1);
    G3 = H * G(t + h2, x = 0.5 * G2);
    G4 = h * G(t + h, x + G3);
    X = x + (G1 + 2 * G2 + 2 * G3 + G4)/6.0;
    t = (I + 1) * h;
end
```

6.2.1.5 Example

Solve numerically the differential equation

$$4\ddot{x} + 2000x = F(t)$$

with the initial conditions

$$x_0 = \dot{x}_0 = 0$$

The forcing is as shown in Figure 6.2.

FIGURE 6.2 The forcing function for Example 6.2.1.5. (Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.)

6.2.1.5.1 Centered Difference

Using the centered difference approximation for the second derivative, one gets the following discrete equation

$$x_{i+1} = h^2/4F(t) - 500h^2x_i - x_{i-1} + 2x_i$$

This equation is valid for $i \geq 1$. From the initial conditions $x_0 = \dot{x}_0 = 0$, x_1 is computed by the following $x_1 = x_0 + \dot{x}_0 = 0 + 0$. A time step of $h = 0.02$ sec has been used in the calculation. The numerical solution as compared with the exact solution is given in Table 6.2. Table 6.3 contains the absolute errors for the two discrete solutions.

6.2.1.5.2 Runge–Kutta

In order to use the Runge–Kutta method, the second-order equation needs to be written as a system of first-order equations.

Let $u = \dot{x}$; then

$$\dot{u} = G(x, t) = .25 * F(t) - 500x$$

where $x(0) = 0$ and $u(0) = 0$.

This is now in a form which can be directly input into a fourth-order Runge–Kutta solver.

The Runge–Kutta method is more accurate then the centered difference approximation. This can be seen in Table 6.3, which gives the absolute value of the difference between the exact solution and the computed solutions. This is known as the absolute error. Moreover, the Runge–Kutta method is self-starting and can be used for a single variable or a system of variables as in the above example. The price that is paid is that the fourth-order Runge–Kutta method requires four function evaluations for the first derivative for each time step. This is offset by the fact that this method has higher accuracy and has a large stability region so one can take larger time steps.

Stability is a measure of how quickly errors in the computed solution grow or decay. There are very few numerical methods that are stable for all choices of time step. For most methods, there is a range of time steps which produce a stable method. The fourth-order Runge–Kutta method is stable for larger values of the time step than are the lower-order Runge–Kutta methods. A numerical method will not converge to a solution if the time step does not produce a stable method. Often, the stability criterion places a stricter limitation on the time step than accuracy does. For a more complete discussion of stability, see Strang (1986). In Table 6.3, the absolute error for both methods grows but it does not grow exponentially. Controlled error growth is the signature of a stable time step.

6.2.2 Summary of Single-Degree-of-Freedom System

- Unforced equation of motion $m\ddot{x} + c\dot{x} + kx = 0$.
- Forced equation of motion $m\ddot{x} + c\dot{x} + kx = f(x, \dot{x}, t)$.
- Centered difference approximation for the first derivative $\dot{x}_i = \frac{1}{2h}(x_{i+1} - x_{i-1})$.
- Centered difference approximation for the second derivative $\ddot{x}_i = \frac{1}{h^2}(x_{i-1} - 2x_i + x_{i+1})$.
- Fourth-order Runge–Kutta method.

6.3 Systems with Two or More Degrees of Freedom

A system that requires more than one coordinate to describe its motion is a multi-DoF system. These systems differ from single-DoF systems in that n DoF are described by n simultaneous differential equations and have n natural frequencies. When these systems are written in matrix notation, they look

just like the single-DoF system. The equations of motion of a viscously damped multi-DoF system can be written as follows:

$$[M]\ddot{\mathbf{x}} + [C]\dot{\mathbf{x}} + [K]\mathbf{x} = \mathbf{f}$$

where $[M]$, $[C]$, and $[K]$ are the mass, damping, and stiffness matrices, respectively; \mathbf{x} is the displacement vector; and \mathbf{f} is the force vector. Both the central difference method and Runge–Kutta can be applied to the matrix equation. The method follows exactly that given above where the scalar quantities are replaced by the matrix quantities.

6.3.1 Example

As an example, consider the two-DoF system shown in Figure 6.3.

In this example, $k_1 = k_2 = 36 \text{ kN/m}$, $m_1 = 100 \text{ kg}$, $m_2 = 25 \text{ kg}$, and $f = 4000 \text{ N}$ for $t > 0$ and 0 for $t \leq 0$. The initial conditions are all zero, i.e., $x_1 = \dot{x}_1 = x_2 = \dot{x}_2 = 0$. The equation of motion for this system is

$$100\ddot{x}_1 + 36,000x_1 - 36,000(x_2 - x_1) = 0$$

$$25\ddot{x}_2 + 36,000(x_2 - x_1) = f$$

This can be written in matrix notation as

$$\begin{bmatrix} 100 & 0 \\ 0 & 25 \end{bmatrix} \ddot{\mathbf{x}} + 36,000 \begin{bmatrix} 2 & -1 \\ -1 & 1 \end{bmatrix} \mathbf{x} = \mathbf{f}$$

where $\mathbf{x} = (x_1, x_2)^t$ and $\mathbf{f} = (0, f)^t$.

FIGURE 6.3 Two-DoF system. (Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.)

6.3.1.1 Centered Difference

Using the centered difference approximation for the second derivatives, one obtains the following two recurrence relations

$$x_1^{i+1} = (-720x_1^i + 360x_2^i)\Delta t^2 + 2x_1^i - x_1^{i-1}$$

$$x_2^{i+1} = (1440(x_1^i - x_2^i) + 160)\Delta t^2 + 2x_2^i - x_2^{i-1}$$

These two equations are only valid for $i \geq 3$. From the single-DoF system, we know that this method is not self-starting. In order to compute x_1^2 and x_2^2 , one needs to use an additional equation, which one obtains from the Taylor expansion. First one needs to compute the initial acceleration for the system. This is obtained from the differential equation and the initial data. For this problem, the initial acceleration is given by $\ddot{x}_1 = 0$ and $\ddot{x}_2 = 160$. Next, values for x_1^{-1} and x_2^{-1} are computed from the Taylor expansion

$$x_1^{-1} = x_1^0 - \Delta t \dot{x}_1 + \frac{\Delta t^2}{2} \ddot{x}_1 = 0$$

$$x_2^{-1} = 80\Delta t^2$$

Now, the recurrence relations can be used to compute the rest of the terms. An example of the MATLAB code for this calculation is the following.

6.3.1.2 Pseudocode for Example 6.3.1

The following is a MATLAB m file for Example 6.3.1.

```
clear
deltat = 0.01;
deltsq = deltat*deltat;
x2(1) = 0;
x1(1) = 0;
x2(2) = 160/2*deltsq;
x1(2) = (60*x2(2)*deltsq)/(1 + 120*deltsq);
x2ddot(2) = 1440*(x1(2) - x2(2)) + 160;
x1ddot(2) = -720*x1(2) + 360*x2(2);
for i = 3:51
    x2(i) = x2ddot(i - 1)*deltsq + 2*x2(i - 1) - x2(i - 2);
    x1(i) = x1ddot(i - 1)*deltsq + 2*x1(i - 1) - x1(i - 2);
    x2ddot(i) = 1440*(x1(i) - x2(i)) + 160;
    x1ddot(i) = -720*x1(i) + 360*x2(i);
end
```

Figure 6.4 gives the displacement of x_1 and x_2 over time for Example 6.3.1.

6.3.1.3 Runge–Kutta

Alternately, the system of second-order equations can be integrated using the fourth-order Runge–Kutta method. In order to use Runge–Kutta, the second-order system has to be written as a system of first-order equations. The following second-order system

$$\ddot{x}_1 = -720x_1 + 360x_2$$

$$\ddot{x}_2 = 1440(x_1 - x_2) + 160$$

FIGURE 6.4 Displacement versus time. (Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.)

becomes the following first-order system

$$\begin{aligned}\dot{x}_1 &= x_3 \\ \dot{x}_2 &= x_4 \\ \dot{x}_3 &= -720x_1 + 360x_2 \\ \dot{x}_4 &= 1400(x_1 - x_2) + 160\end{aligned}$$

Two new variables have been introduced.

6.3.1.4 Integrating Ordinary Differential Equations Using MATLAB

There are several ODE solvers in MATLAB, especially in version six. The discussion here will be limited to the least complicated solvers. These are *ode23* and *ode45*, which are implementations of a second- and third-order, and a fourth- and fifth-order solver, respectively. Like all Runge–Kutta methods, these solvers work on first-order equations. If the equation is of higher order, it needs to be converted to a system of first-order equations. Then the equation should be written in vector form, i.e., $\mathbf{x}' = \mathbf{f}(\mathbf{x}, t)$. The user must write a MATLAB function routine which computes the values of $\mathbf{f} = (f_1, f_2, \dots, f_n)$ given the values of (\mathbf{x}, t) . Once this function file exists, it can be used as input in either *ode23* or *ode45*. The function call details are given in the on-line help facility in MATLAB. See the Appendix for an introduction to MATLAB.

6.3.2 Summary of Two-Degree-of-Freedom System

1. Equation of motion: $[\mathbf{M}]\ddot{\mathbf{x}} + [\mathbf{C}]\dot{\mathbf{x}} + [\mathbf{K}]\mathbf{x} = \mathbf{f}$.
2. Centered difference for systems of equations.
3. Runge–Kutta methods.
4. MATLAB commands for solution of ordinary differential equations — *ode23* and *ode45*.

6.4 Finite Difference Method for a Continuous System

6.4.1 Bar

A thin uniform rod is the first example of a continuous system that will be examined. The equation of motion for such a system is given by

$$\partial^2 u / \partial x^2 = 1/c^2 \partial^2 u / \partial t^2$$

where $c = \sqrt{E/\rho}$. E is the modulus of elasticity and ρ is the density of the rod. A complete derivation of this equation can be found in many books (see Thomson and Dahleh 1998). Separation of variables can be used to find a solution of the form $u(x, t) = U(x)G(t)$. This substitution gives the equation.

$$\frac{d^2 U}{dx^2} G(t) = \frac{1}{c^2} U(x) \frac{d^2 G(t)}{dt^2}$$

Upon rearrangement, this becomes

$$\frac{1}{U(x)} \frac{d^2 U}{dx^2} = \frac{1}{c^2 G(t)} \frac{d^2 G(t)}{dt^2}$$

The left-hand side of the equation is independent of t and the right-hand side is independent of x . Therefore, each side must equal a constant. Let this constant be denoted by α and $\alpha = -(\omega/c)^2$. There are now two differential equations, the displacement equation

$$d^2 U / dx^2 + \alpha^2 U = 0$$

U_{n+1} is the displacement of a point off the bar. We never compute U_{n+1} ; however, as one can see from a previous calculation, this value is used when the recurrence relationship is evaluated for $i = n$, $U_{n+1} - (2 - \lambda)U_n + U_{n-1} = 0$. Under the assumption that the stress is zero at the right-hand endpoint, the remaining constraint becomes

$$(2 - \lambda)U_n - 2U_{n-1} = 0$$

For a bar that has one fixed left-hand endpoint and a free right-hand end, the matrix problem is the following:

$$\begin{bmatrix} 2 - \lambda & -1 & 0 & 0 & \dots & 0 \\ -1 & 2 - \lambda & -1 & 0 & \dots & 0 \\ 0 & -1 & 2 - \lambda & -1 & \dots & 0 \\ & & & & & \\ 0 & & & -1 & 2 - \lambda & -1 \\ & & & & -2 & 2 - \lambda \end{bmatrix} \begin{bmatrix} U_2 \\ U_3 \\ U_4 \\ \\ U_{n-1} \\ U_n \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \\ 0 \\ 0 \end{bmatrix}$$

This matrix problem has a unique solution because there are $n - 1$ linearly independent equations and there are $n - 1$ unknowns.

6.4.1.1 Example

Consider a bar of unit length that is divided into four equal pieces. The left-hand end is fixed so that $U_1 = 0$, and the right-hand end is free. The eigenvalue problem for this system is the following:

$$\begin{bmatrix} 2 - \lambda & -1 & 0 & 0 \\ -1 & 2 - \lambda & -1 & 0 \\ 0 & -1 & 2 - \lambda & -1 \\ 0 & 0 & -2 & 2 - \lambda \end{bmatrix} \begin{bmatrix} U_2 \\ U_3 \\ U_4 \\ U_5 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

The eigenvalues, λ , are $\lambda = [0.1522, 1.2346, 2.7654, 3.8478]$. The natural frequencies can be recovered from the eigenvalues since $\lambda = h^2 \omega / c$ and $c = \sqrt{E/\rho}$ is determined by the material properties of the bar.

6.4.2 Beam

A second example of finite difference approximation is given by looking at a centered difference approximation to compute the transverse vibration of a uniform beam. We will consider a special case of the Euler equation for the beam. The following fourth-order equation results when the flexural rigidity, (EI) , is constant:

$$d^4 W / dx^4 - \beta^4 W = 0$$

where β contains all of the material properties of the beam (i.e., $\beta^4 = \rho A \omega^2 / EI$).

The centered difference formula for the fourth derivative is given by

$$f^{iv} = 1/h^4 (f_{i+2} - 4f_{i+1} + 6f_i - 4f_{i-1} + f_{i-2})$$

In order to see that this expansion is in fact second-order, combine the Taylor expansions for f_{i+2} , f_{i+1} , f_i , f_{i-1} , and f_{i-2} , and notice that you obtain an approximation for the fourth derivative which exactly matches the combined Taylor approximations up to order h^2 . Using this approximation, the transverse beam equation at the interior mesh point becomes

$$W_{i+2} - 4W_{i+1} + (6 - \lambda)W_i - 4W_{i-1} + W_{i-2} = 0$$

where $\lambda = h^4 \beta^4$. This equation is valid for $i = 3, n - 2$. As before, the boundary conditions have to be used in order to have sufficient conditions to determine all n values for the deflection, W . There will be two additional constraints placed at each end. In this case, all of the types of boundary condition require fictitious points. In other words, they require that the beam be extended beyond the physical boundaries to include W_{-1} , W_0 , W_{n+1} , and W_{n+2} . Let us consider three types of boundary conditions: fixed end, free end, and simply-supported end. For simplicity, we will derive all of the conditions for the right-hand endpoint $x = L$.

Fixed end: When the end of the beam is fixed, both the deflection $W = 0$ and $dW/dx = 0$. As above, the centered difference approximation for the first derivative requires the introduction of a fictitious point. These conditions translate into

$$W_n = 0 \text{ and } dW/dx|_n = 1/h^2(W_{n+1} - W_{n-1}) = 0$$

These constraints reduce to the following:

$$W_{n+1} = W_{n-1}$$

Free end: The bending moment and the shear force are zero at the free end. These are given by a second and third derivative, respectively. Assuming the free end is located at N , the two fictitious points introduced are at $n + 1$ and $n + 2$. The discrete version of the two constraints is:

$$d^2W/dx^2|_n = 1/h^2(W_{n-1} - 2W_n + W_{n+1}) = 0$$

$$d^3W/dx^3|_n = 1/(2h^3)(W_{n+2} - 2W_{n+1} + 2W_{n-1} - W_{n-2}) = 0$$

Simply-supported end: The boundary conditions of this type require that the deflection and the moment are zero. When these are applied to the right-hand endpoint

$$W_n = 0 \\ d^2W/dx^2 = 1/h^2(W_{n+1} - 2W_n + W_{n-1}) = 0$$

Combining these two equations, one sees that the value of W at the fictitious point is equal to the value on the beam, i.e., $W_{n+1} = W_{n-1}$.

All three of these boundary condition types allow one to replace the fictitious values in the recurrence relations with values on the beam. The procedures followed are very similar to those outlined for the longitudinal vibration of a beam.

6.4.3 Summary of Finite Difference Methods for a Continuous System

1. Equation of motion for the bar: $\partial^2 u / \partial x^2 = 1/c^2 \partial^2 u / \partial t^2$.
2. Displacement equation for the bar: $d^2 U / dx^2 + \alpha^2 U = 0$.
3. Finite difference approximation: $U_{i+1} - (2 - \lambda)U_i + U_{i-1} = 0$.
4. Equation of motion for the beam: $d^4 W / dx^4 - \beta^4 W = 0$.
5. Centered difference approximation for the fourth derivative: $f^{iv} = 1/h^4(f_{i+2} - 4f_{i+1} + 6f_i - 4f_{i-1} + f_{i-2})$.
6. Finite difference approximation for the beam equation: $W_{i+2} - 4W_{i+1} + (6 - \lambda)W_i - 4W_{i-1} + W_{i-2} = 0$.

6.5 Matrix Methods

In the preceding section, the equations of motion are solved for the system. Often, one is not interested in the complete solution. Rather, one is interested in the natural frequencies and the normal modes. When the number of DoF is very high, only the lowest natural frequency needs to be computed. Several methods to find some, but not all, of the eigenvalues of the system will be presented.

6.5.1 Example: Three-Degree-of-Freedom System

A three-DoF system will be used as an example. The larger DoF systems work exactly in the same manner but produce larger calculations.

Let us consider the following spring-mass system in Figure 6.6.

The equation of motion for this system is

$$M \begin{bmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \\ \ddot{x}_3 \end{bmatrix} + K \begin{bmatrix} 3 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

FIGURE 6.6 Three spring-mass system. (Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.)

Assuming a harmonic solution of the form $x = A \sin(\omega t)$ gives the following eigenvalue problem:

$$\left(-\lambda \begin{bmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + k \begin{bmatrix} 3 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{bmatrix} \right) \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

where $\lambda = \omega^2 m/k$. The eigenvalues are found by setting the characteristic equation of the determinant equal to zero. This gives the following polynomial:

$$\lambda^3 - 4.5\lambda^2 + 5\lambda - 1 = 0$$

It is a simple matter to graph this polynomial and see that there are three real roots to this equation.

6.5.2 Bisection Method

One method for calculating the roots of a nonlinear function is called the bisection method. This method finds the zeros of nonlinear functions by bracketing the zero in an interval $[a, b]$. The interval is chosen so that $f(a)$ and $f(b)$ are of opposite sign. If f is a continuous function and it is positive at one endpoint, say $f(a) > 0$, and it is negative at the other endpoint, $f(b) < 0$, then it has had to go through zero at some point in the interval. It is possible that it has gone through zero more than once in the interval. From Figure 6.7, one can see that one root is between $[0, 0.5]$; another is between $[1, 1.5]$; and a third root is in $[2.5, 3]$. In order to find all three roots, the bisection method has to be used three times; one for each interval. As an example, the MATLAB code for the first root is given below.

6.5.2.1 MATLAB Code for the Bisection Method

```
clear
%set an acceptable tolerance for the root
tol = 10e - 4
%endpoints of the interval
a = 0
b = 0.5
for i = 1:20
    c = 0.5*(a + b)
    if abs(f(c)) < tol, break, end
```

FIGURE 6.7 Graph of the cubic polynomial $\lambda^3 - 4.5\lambda^2 + 5\lambda - 1 = 0$. (Source: Thomson and Dahleh 1998. *Theory of Vibration Applications*, 5th ed. With permission.)

```

if f(a)*f(c) < 0
    b = c
else
    a = c
end
end
end

```

The root 0.2554 is found after ten iterations. As long as the initial interval is chosen so that the function has different signs at the endpoints, this method will always converge. There are nonlinear root finding methods, such as Newton's method, which when they converge do so more quickly. However, they may or may not converge.

6.5.2.2 MATLAB Function for Finding the Roots of a Polynomial

MATLAB has a built in root-finding method which requires the creation of a vector **c** that contains the coefficients of the polynomial in descending order. The MATLAB command *roots(c)*, produces the roots of the polynomial. For our example, **c** = [1, -4.5, 5, -1]. The roots of this equation are given by $\lambda = 2.8892, 1.3554, 0.2554$.

6.5.2.3 Mode Shapes

The mode shapes are determined by substituting each eigenvalue into the matrix problem and computing the corresponding eigenvector. As an example of how to compute the eigenvector for a given eigenvalue, we will compute the eigenvector associated with $\lambda = 2.8892$. The first step is to substitute this value of λ into the eigenvalue equation. This gives the following problem:

$$\begin{bmatrix} 2.489 & -1 & 0 \\ -1 & 1.745 & -1 \\ 0 & -1 & 0.744 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

The solution vector found by Gaussian elimination is given by

$$\mathbf{x} = (x_1, x_2, x_3)^t = (0.2992, 0.7446, 1.0)^t$$

6.5.3 Directly Calculating the Eigenvalues and Eigenvectors from the Matrix Equation

Ideally one would like to use a computer program such as MATLAB to compute both the eigenvalues and the eigenvectors directly from the matrix equation. In order to do this, the matrix equation needs to be rewritten slightly. In general, the matrix equation for the normal mode vibration is given by

$$[-\lambda \mathbf{M} + \mathbf{K}]x = 0$$

where \mathbf{M} and \mathbf{K} are the mass and stiffness matrices, respectively, both are square symmetric matrices, and λ is the eigenvalue related to the natural frequency by $\lambda = n\omega^2$. Premultiplying the preceding equation by \mathbf{M}^{-1} , we have another form of the equation:

$$[-\lambda \mathbf{I} + \mathbf{A}]x = 0$$

where $\mathbf{A} = \mathbf{M}^{-1}\mathbf{K}$ and \mathbf{A} is called the dynamic matrix. In general, \mathbf{A} is not symmetric. In order to use MATLAB to compute the eigenvectors and eigenvalues, the matrix must be symmetric. There is a standard transformation of coordinates that converts the matrix problem into a standard eigenvalue problem which can be solved by a computer. Assume that we have a transformation of coordinates which has the following form:

$$x = \mathbf{U}^{-1}y$$

When this transformation is substituted into the equation, we get

$$[-\lambda \mathbf{M}\mathbf{U}^{-1} + \mathbf{K}\mathbf{U}^{-1}]y = 0$$

Premultiplying the equation by \mathbf{U}^t gives

$$[-\lambda \mathbf{U}^t \mathbf{M} \mathbf{U}^{-1} + \mathbf{U}^t \mathbf{K} \mathbf{U}^{-1}]y = 0$$

From this equation, one can see that if either \mathbf{M} or \mathbf{K} equals $\mathbf{U}^t \mathbf{U}$, then the preceding equation is reduced to standard form, at which time it is possible to compute both the eigenvalues and eigenvectors directly. To see how this works, let us assume that $\mathbf{M} = \mathbf{U}^t \mathbf{U}$. The equation becomes

$$[-\lambda \mathbf{I} + \mathbf{U}^t \mathbf{K} \mathbf{U}^{-1}]y = 0$$

where $\lambda = \omega^2$. This equation is in standard form since $\mathbf{U}^t \mathbf{K} \mathbf{U}^{-1}$ is symmetric.

6.5.3.1 Example

To illustrate the use of the dynamic matrix and the standard computer form, we can use MATLAB to calculate the eigenvalues and eigenvectors for Example 6.5.1. The first step is to convert the problem into standard form. For this example, the dynamic matrix is given by

$$\mathbf{A} = \begin{bmatrix} 1.5 & -0.5 & 0 \\ -1.0 & 2.0 & -1.0 \\ 0 & -1.0 & 1.0 \end{bmatrix}$$

We can compute both the eigenvalues and the eigenvectors in MATLAB using the command $[U, D] = \text{eig}(A)$. The result of this command is two matrices, \mathbf{U} and \mathbf{D} . Matrix \mathbf{U} contains the eigenvectors as column vectors and \mathbf{D} is a diagonal matrix which has the eigenvalues on the diagonal. Continuing with our example, we get the following two matrices:

$$\mathbf{U} = \begin{bmatrix} 0.7569 & 0.3031 & 0.2333 \\ 0.2189 & -0.8422 & 0.5808 \\ -0.6158 & 0.4458 & 0.7799 \end{bmatrix}$$

and

$$\mathbf{D} = \begin{bmatrix} 1.3554 & 0 & 0 \\ 0 & 2.8892 & 0 \\ 0 & 0 & 0.2544 \end{bmatrix}$$

In order to use this transformation then, one has to be able to write \mathbf{M} or \mathbf{K} as $\mathbf{U}^t \mathbf{U}$. This is known as the Cholesky decomposition. In MATLAB, if one has a positive definite matrix \mathbf{M} , the matrix can be Cholesky-decomposed with the built in function *chol*. The command $U = chol(M)$ produces an upper triangular matrix \mathbf{U} such that $\mathbf{U}^t \mathbf{U} = \mathbf{M}$.

Cholesky decomposition is a special case of LU factorization where \mathbf{L} is a lower triangular matrix and \mathbf{U} is an upper triangular matrix. The computational procedure begins by writing the algebraic equations that result from the following calculation:

$$\begin{bmatrix} u_{11} & 0 & 0 \\ u_{12} & u_{22} & 0 \\ u_{13} & u_{23} & u_{33} \end{bmatrix} \begin{bmatrix} u_{11} & u_{12} & u_{13} \\ 0 & u_{22} & u_{23} \\ 0 & 0 & u_{33} \end{bmatrix} = \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \\ m_{31} & m_{32} & m_{33} \end{bmatrix}$$

If the matrix \mathbf{M} is positive definite, then the above matrix multiplication results in six linearly independent equations.

6.5.4 Summary of Matrix Methods

1. Bisection method for the roots of a polynomial.
2. MATLAB command *roots* for finding the roots of a polynomial.
3. Cholesky decomposition.

6.6 Approximation Methods for the Fundamental Frequency

The smallest natural frequency, known as the fundamental frequency, of a multi-DoF system is often of greater interest than the high natural frequencies because its forced response in many cases is the largest. One approach to this problem is to extend the Rayleigh method to matrix problems. We will see that the Rayleigh frequency approaches the fundamental frequency from the high side.

6.6.1 Rayleigh Method

Let \mathbf{M} and \mathbf{K} be the mass and stiffness matrices, respectively, and \mathbf{x} is the assumed displacement vector for the amplitude of vibration. For harmonic motion, the maximum kinetic energy is

$$T_{\max} = 1/2 \omega \mathbf{x}^t \mathbf{M} \mathbf{x}$$

and the maximum potential energy is

$$U_{\max} = 1/2 \mathbf{x}^t \mathbf{K} \mathbf{x}$$

Since the maximum kinetic energy equals the maximum potential energy, these two quantities are equal. Equating these two and solving for ω^2 gives the Rayleigh quotient:

$$\omega^2 = \frac{\mathbf{x}^t \mathbf{K} \mathbf{x}}{\mathbf{x}^t \mathbf{M} \mathbf{x}}$$

It can be shown (Thomson and Dahleh, 1998) that this quotient approaches the lowest natural frequency from above and it is somewhat insensitive to the choice of amplitudes.

6.6.2 Dunkerley's Formula

Dunkerley's formula produces a lower bound for the fundamental frequency and can be used in conjunction with the Rayleigh method to get a good approximation for the fundamental frequency. Dunkerley's formula is based on the characteristic equation for the flexibility coefficients. The flexibility influence coefficient, a_{ij} , is defined as the displacement at i due to a unit force applied at j with all other forces equal to zero. This concept is most easily understood through an example.

6.6.2.1 Computation of the Flexibility Matrix

The procedure for computing the flexibility matrix and in particular, the computation of the flexibility matrix for the three spring–mass matrix systems shown in [Figure 6.6](#), are discussed.

Example

First, one applies a unit force to mass 1 with no other forces present, i.e., $f_1 = 1$, $f_2 = f_3 = 0$. The displacements are located in the first column of the flexibility matrix.

This gives

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 1/k_1 & 0 & 0 \\ 1/k_1 & 0 & 0 \\ 1/k_1 & 0 & 0 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}$$

In this case, springs k_2 and k_3 are not stretched and are displaced equally with mass 1. Now, a unit force is applied to mass 2 and there are no other forces. This allows us to write the second column of the matrix to get

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 0 & 1/k_1 & 0 \\ 0 & 1/k_1 + 1/k_2 & 0 \\ 0 & 1/k_1 + 1/k_2 & 0 \end{bmatrix} \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$$

This time, the unit force is transmitted through k_1 and k_2 . The spring k_3 is not stretched. Finally, the force is applied to mass 3 and there are no other forces present. This gives the third column of the matrix:

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1/k_1 \\ 0 & 0 & 1/k_1 + 1/k_2 \\ 0 & 0 & 1/k_1 + 1/k_2 + 1/k_3 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}$$

Since the flexibility matrix is the sum of the three previous matrices, it is given by

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 1/k_1 & 1/k_1 & 1/k_1 \\ 1/k_1 & 1/k_1 + 1/k_2 & 1/k_1 + 1/k_2 \\ 1/k_1 & 1/k_1 + 1/k_2 & 1/k_1 + 1/k_2 + 1/k_3 \end{bmatrix} \begin{bmatrix} f_1 \\ f_2 \\ f_3 \end{bmatrix}$$

An interesting feature of the flexibility matrix is that it is symmetric about the diagonal. For simplicity of notation, let the ij element of the flexibility matrix be given by $a_{ij}m_j$. Dunkerley's formula is obtained from the characteristic equation of the flexibility matrix, which is obtained by computing the determinant of the following matrix:

$$\begin{vmatrix} a_{11}m_1 - 1/\omega^2 & a_{12} & a_{13} \\ a_{21} & a_{22}m_2 - 1/\omega^2 & a_{23} \\ a_{31} & a_{32} & a_{33}m_3 - 1/\omega^2 \end{vmatrix} = 0$$

A third-degree equation in $1/\omega^2$ is obtained by expanding the determinant. One obtains the following cubic equation:

$$(1/\omega^2)^3 - (a_{11}m_1 + a_{22}m_2 + a_{33}m_3)(1/\omega^2)^2 + \dots = 0$$

A cubic equation has three roots that are denoted by $(1/\omega_i^2)$ for $i = 1, 2, 3$. This allows the cubic equation to be factored:

$$(1/\omega^2 - 1/\omega_1^2)(1/\omega^2 - 1/\omega_2^2)(1/\omega^2 - 1/\omega_3^2) = 0$$

The highest two powers of this equation are given by

$$(1/\omega^2)^3 - (1/\omega_1^2 + 1/\omega_2^2 + 1/\omega_3^2)(1/\omega^2)^2 + \dots = 0$$

The coefficient of the second highest power is equal to the sum of the roots of the characteristic equation, which is also equal to the sum of the diagonal elements of the matrix \mathbf{A}^{-1} . This relationship is not just true for $n = 3$ but is more generally true for n greater than or equal to 3. For the general n -DoF system

$$1/\omega_1^2 + 1/\omega_2^2 + \dots + 1/\omega_n^2 = a_{11}m_1 + a_{22}m_2 + \dots + a_{nn}m_n$$

The fundamental frequency is the smallest natural frequency. Since $\omega_2, \omega_3, \dots$ are larger than ω_1 , the reciprocal of these frequencies is smaller than the reciprocal of the fundamental frequency. An estimate for the fundamental frequency is obtained by neglecting all of the higher modes in the left-hand side of the above equation. This estimate gives a value for ω_1 that is smaller than the true value of the fundamental frequency. Dunkerley's formula is a lower bound for the fundamental frequency and it is given by

$$1/\omega_1^2 < a_{11}m_1 + a_{22}m_2 + \dots + a_{nn}m_n$$

6.6.3 Summary of Approximations for the Fundamental Frequency

1. Rayleigh method

$$\omega^2 = \frac{\mathbf{x}^t \mathbf{K} \mathbf{x}}{\mathbf{x}^t \mathbf{M} \mathbf{x}}$$

2. Dunkerley's formula $1/\omega_1^2 < a_{11}m_1 + a_{22}m_2 + \dots + a_{nn}m_n$.

6.7 Finite Element Method

In the finite element method, complex structures are replaced by assemblages of simple structural elements known as finite elements. The elements are connected by joints or nodes. The force and moments at the ends of the elements are known from structural theory, the joints between the elements are matched for compatibility of displacement, and the force and moment at the joints are established by imposing the condition of equilibrium.

The accuracy obtainable from the finite element method depends on being able to duplicate the vibration mode shapes. Using only one finite element between structure joints or corners gives good results for the first lowest mode, because the static deflection curve is a good approximation to the lowest dynamic mode shape. For higher modes, several elements are necessary between structural joints. This leads to large matrices. The eigenvalues and eigenvectors need to be computed numerically.

This section introduces the basic idea of the finite element method as it applies to the simple vibration problem.

The basic idea behind the finite element method is to break up the structure into simple component structures. The structural elements for the bar and the beam are discussed here.

6.7.1 Bar Element

The force–displacement relationship for a uniform rod is

$$F = (EA/L)U$$

where E is the young's modulus, A is the cross sectional area, L is the length of the element and U is the displacement. Figure 6.8 shows this one-dimensional element. The two endpoints are the nodes.

For simplicity, assume the axial displacement at any point $s = x/L$ is linear:

$$U(x, t) = a(t) + b(t)x$$

and $U_1(t) = U(0, t)$, $U_2(t) = U(L, t)$. These two conditions uniquely determine the coefficients $a(t)$ and $b(t)$. They are given by the following:

$$a(t) = U_1(t)$$

and

$$b(t) = (U_2(t) - U_1(t))/L$$

Using the linear element, the displacement anywhere along the beam is given by

$$\begin{aligned} U(x, t) &= (1 - x/L)U_1(t) + x/LU_2(t) \\ &= \varphi_1 U_1(t) + \varphi_2 U_2(t) \end{aligned}$$

where

$$\varphi_1 = 1 - x/L \quad \text{and} \quad \varphi_2 = x/L$$

φ_1 and φ_2 are known as the mode shape, which can be seen in Figure 6.9.

These two mode shapes can be superimposed to create a linear function. An example of such a function is given in Figure 6.10.

The kinetic energy of the bar is given by

$$T = .5 \int_0^L \dot{u}^2 m dx = .5m \int_0^L ((1 - s)\dot{u}_1(t) + s\dot{u}_2(t))^2 ds = .5ml(1/3\dot{u}_1^2 + 1/3\dot{u}_1\dot{u}_2 + 1/3\dot{u}_2^2)$$

6.7.1.1 Mass Matrix

The generalized mass matrix is derived from the Lagrange equations using the following:

$$\frac{D}{Dt} \frac{\partial T}{\partial \dot{u}_1}$$

Given the kinetic energy for the bar, the Lagrange equations become

$$\begin{aligned} \frac{D}{Dt} \frac{\partial T}{\partial \dot{u}_1} &= mL(1/3\ddot{u}_1 + 1/6\ddot{u}_2) \\ \frac{D}{Dt} \frac{\partial T}{\partial \dot{u}_2} &= mL(1/3\ddot{u}_1 + 1/6\ddot{u}_2) \end{aligned}$$

FIGURE 6.8 One dimensional element.

FIGURE 6.9 Linear mode shapes.

FIGURE 6.10 Superposition of the linear mode shapes.

The mass matrix for an axial element with a uniform mass distribution per unit length is given by

$$\frac{mL}{6} \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$

6.7.1.2 Stiffness Matrix

The force–displacement relationship for a uniform bar is given by

$$\begin{bmatrix} F_1 \\ F_2 \end{bmatrix} = \frac{EA}{L} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

6.7.1.3 Variable Properties

A simple approach to problems with variable properties is to use a large number of elements of short length. The variation of mass or stiffness over each element is small and can be neglected. In this model, the mass and stiffness for each element is constant and can be placed outside the integral. If a large number of elements are needed to capture the behavior, this will lead to a large matrix problem.

Example

A tapered rod is modeled as two uniform sections where $EA_1 = 2EA_2$ and $m_1 = 2m_2$, $k_2 = 2EA_2/L$. The displacement equation for this system is given by

$$\frac{-\omega^2 m_2}{6} \begin{bmatrix} 2(2+1) & 1 \\ 1 & 2 \end{bmatrix} + \frac{2EA_2}{L} \begin{bmatrix} 2+1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

This can be written as a standard eigenvalue problem where $\lambda = \omega^2 m_2 L / 12EA_2$.

The eigenvalue problem is the following

$$\begin{vmatrix} 3 - 6\lambda & -(1 + \lambda) \\ -(1 + \lambda) & (1 - 2\lambda) \end{vmatrix} = 0$$

The solution of the determinant requires computing the roots of a quadratic equation. The two roots are $\lambda = [0.6140, 1.1088]$. The two natural frequencies can be computed from λ . They are

$$\omega_1 = 1.4029 \sqrt{((EA_2)/(M_2 L))}$$

$$\omega_2 = 3.6477 \sqrt{((EA_2)/(M_2 L))}$$

The modes shapes are calculated by solving the eigenvalue problem. The two eigenvectors are

$$\mathbf{x}_1 = [0.5773, 1]^t$$

and

$$\mathbf{x}_2 = [-5258, 1]^t$$

6.7.2 Beam

When the ends of the element are rigidly connected to the adjoining structure, the elements act like a beam with the moments and lateral forces acting at the joints. Generally, the axial displacement $u_2 - u_1$ is small compared to the lateral displacement V of the beam.

The local coordinates of the beam element are lateral displacements, V , and rotation, θ , at the two ends. This results in four coordinates $V_1, \theta_1, V_2, \theta_2$. Four constraints uniquely determine a cubic polynomial. Therefore, the lateral displacement of a beam is assumed to be described by a cubic

polynomial

$$V(x) = p_1 + p_2 s + p_3 s^2 + p_4 s^4$$

where $s = x/L$ and p_i , the coefficients of the polynomials, are related to the lateral displacement and the rotation. The lateral displacement at the left-hand side determines V_1 :

$$V(0, t) = V_1(t) = p_1$$

The rotation at the left-hand end determines the second coefficient, θ_1 :

$$\frac{\partial V}{\partial x}(0, t) = \theta_1 = p_2$$

The remaining two coefficients are combinations of the variables and they are given by the following two constraints:

$$V(L, t) = V_2(t) \quad \text{and} \quad \frac{\partial V}{\partial x}(L, t) = \theta_2$$

Applying these two conditions, one obtains

$$p_3 = 1/L^2(-3v_1(t) - 2\theta_1(t)L + 3v_2(t) - \theta_2(t)L)$$

$$p_4 = 1/L^3(2v_1(t) + \theta_1(t)L - 2v_2(t) + \theta_2(t)L)$$

These coefficients can be represented by the following matrix equation:

$$\begin{bmatrix} p_1 \\ p_2 \\ p_3 \\ p_4 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -3 & -2 & 3 & 1 \\ 2 & 1 & -2 & 1 \end{bmatrix} \begin{bmatrix} v_1 \\ L\theta_1 \\ v_2 \\ L\theta_2 \end{bmatrix}$$

The shape functions for the beam elements are determined by equating a single displacement to one, and all other displacement to zero. The first shape function is derived by letting $V_1 = 1$ and the remaining three variables zero; i.e., $V_2 = \theta_1 = \theta_2 = 0$. This gives

$$p_1 = 1 \quad p_2 = 0 \quad p_3 = -3 \quad p_4 = 2$$

The first shape function becomes

$$\varphi_1 = 1 - 3s^2 + 2s^3$$

A similar calculation for $\theta_1 = 1$ and $V_2 = V_1 = \theta_2 = 0$ yields

$$p_1 = 0 \quad p_2 = l \quad p_3 = -2l \quad p_4 = l$$

and the shape function becomes

$$\varphi_2 = ls - 2ls^2 + ls^3$$

The remaining two shape functions are determined similarly. The four shape functions for the beam are

$$\varphi_1 = 1 - 3s^2 + 2s^3$$

$$\varphi_2 = ls - 2ls^2 + ls^3$$

$$\varphi_3 = 3s^2 - 2s^3$$

$$\varphi_4 = -ls^2 + ls^3$$

6.7.2.1 Mass Matrix

Just as in the case of the bar, the generalized mass m_{ij} is given by

$$M_{ij} = \int_0^l \varphi_i \varphi_j m dx$$

Substitution of the above shape functions and integration yields the following mass matrix for the uniform beam element in terms of the end displacements:

$$\frac{mL}{420} \begin{bmatrix} 156 & 22L & 54 & -13L \\ 22L & 2L^2 & 13L & -3L^2 \\ 54 & 13L & 156 & -22L \\ -13L & -3L^2 & -22L & 4L^2 \end{bmatrix}$$

6.7.3 Summary of Finite Element Method

1. Linear finite element for a bar $\varphi_1 = 1 - x/L$ and $\varphi_2 = x/L$
2. Mass matrix for the bar

$$\frac{ML}{6} \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$

3. Stiffness matrix for the bar

$$\begin{bmatrix} F_1 \\ F_2 \end{bmatrix} = \frac{EA}{L} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

4. Cubic finite elements for the beam

$$\varphi_1 = 1 - 3\varsigma^2 + 2\varsigma^3$$

$$\varphi_2 = l\varsigma - 2l\varsigma^2 + l\varsigma^3$$

$$\varphi_3 = 3\varsigma^2 - 2\varsigma^3$$

$$\varphi_4 = -l\varsigma^2 + l\varsigma$$

Appendix 6A

Introduction to MATLAB®

MATLAB is a software package for numerical computation, visualization, and symbolic manipulation (also see Appendix 32A). It is an interactive environment with hundreds of built-in functions, which are in essence subroutines. These functions range from plotting commands, to those for finding the eigenvalues and eigenvectors of a matrix, to those for solving an ordinary differential equation, and much more. In addition to the built-in functions, MATLAB contains a programming language, which allows the user to write their own functions. The name MATLAB is an abbreviation of *matrix laboratory*. The original versions of MATLAB concentrated on numerical analysis of linear systems of equation. MATLAB is available from the Mathworks (www.mathworks.com).

The best way to learn MATLAB is by playing around with the different functions (Pratap, 2001). The first thing to note when you launch MATLAB is that it is a window-based environment. There are three windows: the command window, the graphics window, and the edit window. The command

window is the main window and it is the one in which you run all functions (built-in or user created). This is the window which appears when the program is launched, and it has the symbol \gg as a prompt. The graphics window is where all of the graphics are displayed, and the edit window is where users create and save all of their own programs, known as *m files*.

MATLAB provides routines for all of the basic areas of numerical analysis (numerical linear algebra, data analysis, Fourier transform, and interpolation), curve fitting, root-finding, numerical solution of ordinary differential equations, integration, and graphics. There are specialized tool boxes for signal processes and control systems to name two. With these hundreds of functions, it is imperative to have a good help facility. In the command window, the command *help functionname* provides online help. For example, type *help help* to get more information about help. There are three other commands for information: *lookfor*, *helpwin*, and *helpdesk*. *Lookfor* gives a list of functions with the keyword in their description. *Helpwin* gives a help window. *Helpdesk* is a web browser-based help.

Given the early history of MATLAB as a matrix laboratory, it should not be surprising that one of its strengths is its ability to manipulate vectors and matrices very well. A row vector is created by typing in the command window the following:

```
 $\gg x = [2, 3, 6, 4]$ 
```

This command will produce

```
 $x = \quad 2 \quad 3 \quad 6 \quad 4$ 
```

A common vector is created by entering the following

```
 $\gg x = [2; 1; 3; 4]$ 
```

This produces $x =$

```
2
1
3
4
```

The elements of a vector or matrix are separated by commas or by spaces, and the rows are separated by semicolons. Printing is suppressed by ending the line with a semicolon. The following command will produce a 2×2 matrix but it will not print it:

```
 $A = \begin{bmatrix} 2 & 4 \\ 1 & 5 \end{bmatrix}$ 
```

Providing that the operations make sense, it is easy to do operations on vectors and matrices in MATLAB. For example, if **A** and **B** are two matrices of the same size, the command $A + B$ adds the matrices.

There are several MATLAB commands given throughout the text of this chapter. Several books are available to get you started with MATLAB; for example, Hanselman and Littlefield (2001), Palm (2001), Pratap (2001), and Recktenwald (2000). The best way to learn more about these commands is to type help and the command name. This way, you get the most up-to-date information concerning the function.

Summary

In this chapter, several aspects of vibration modeling are addressed. They include the formulation of the equations of motion both in differential form and integral form, the Rayleigh–Ritz method and the finite element methods, and model reduction. Natural vibration analysis and response analysis are discussed in detail. Several commercial finite element analysis (FEA) software tools are listed and their capabilities for vibration analysis are introduced. The basic procedure in using the commercial FEA software packages for vibration analysis is outlined (also see Chapter 6 and Chapter 9). The vibration analysis of a gearbox housing is presented to illustrate the procedure.

7.1 Introduction

Vibration phenomenon, common in mechanical devices and structures [2,9], is undesirable in many cases, such as machine tools. But this phenomenon is not always unwanted; for example, vibration is needed in the operation of vibration screens. Thus, reducing or utilizing vibration is among the challenging tasks that mechanical or structural engineers have to face. Vibration modeling has been used extensively for a better understanding of vibration phenomena. The vibration modeling here implies a process of converting an engineering vibration problem into a mathematical model, whereby the major vibration characteristics of the original problem can be accurately predicted. The mathematical model of vibration in its general sense consists of four components: a mass (inertia) term; a stiffness term; an

excitation force term; and a boundary condition term. These four terms are represented in differential equations of motion for discrete (or, lumped-parameter) systems, or boundary value problems for continuous systems. A damping term is included if damping effects are of concern. Depending on the nature of the vibration problem, the complexity of the mathematical model varies from simple spring–mass systems (see Chapter 1) to multi-degree-of-freedom (DoF) systems (see Chapter 3); from a continuous system (see Chapter 4) for a single structural member (beam, rod, plate, or shell) to a combined system for a built-up structure; from a linear system to a nonlinear system. The success of the mathematical model heavily depends on whether or not the four terms mentioned before can represent the actual vibration problem. In addition, the mathematical model must be sufficiently simplified in order to produce an acceptable computational cost. The construction of such a representative and simple mathematical model requires an in-depth understanding of vibration principles and techniques, extensive experience in vibration modeling, and ingenuity in using vibration software tools. Furthermore, it also requires sufficient knowledge of the vibration problem itself in terms of working conditions and specifications.

Except for few special cases that promise exact and explicit analytical solutions, vibration models have to be studied by means of approximate numerical methods such as the finite element method. The finite element method has been very successfully used for vibration modeling for the past two decades. Its success is attributed to the development of sophisticated software packages and the rapid growth of computer technology.

In this chapter, several aspects of the construction of mathematical models of linear vibration problems without damping will be addressed. The capabilities of the available software packages for vibration analysis are listed and the basic procedure for vibration analysis is summarized. As an illustration, an engineering example is given.

7.2 Formulation

7.2.1 Differential Formulation

In a majority of engineering vibration problems, the amplitude of vibrations is very small, so that the following assumptions hold: (1) a linear form of strain–displacement relationships, and (2) a linear form of stress–strain relationships (Hooke's Law). If the energy losses are negligible, it is straightforward to apply Newton's (second) law and Hooke's Law to derive the equations of motion, which appear as differential equations. Consider a single-DoF spring–mass system, as shown in Figure 7.1. The two laws are given by

FIGURE 7.1 Single-DoF spring–mass system.

$$\begin{cases} m\ddot{u}(t) = -f, & \text{Newton's law} \\ f = ku(t), & \text{Hooke's Law} \end{cases} \quad (7.1)$$

The first equation describes the inertia force, and the second equation describes the elastic force. These two forces are essential for mechanical vibration to exist (see Chapter 1).

In a similar way, the differential equations are given directly when Newton's law plus Hooke's Law is applied to a multiple-DoF spring–mass system, shown in Figure 7.2

$$\begin{cases} \mathbf{M}\ddot{\mathbf{u}}(t) = -\mathbf{F}, & \text{Newton's law} \\ \mathbf{F} = \mathbf{K}\mathbf{u}(t), & \text{Hooke's Law} \end{cases} \quad (7.2)$$

where \mathbf{M} is the (diagonal) mass matrix, and \mathbf{K} is the stiffness matrix.

FIGURE 7.2 Multiple-DoF spring–mass system.

In the case of continua, the differential equations of motion can be derived by means of Newton's law and Hooke's Law in the same way as above. But in this case the boundary conditions have to be specified in order to make the problem statement complete (see Chapter 4). For example, as a direct consequence of Newton's law and Hooke's Law, the differential equation of bending vibration of a clamped–clamped Euler beam may be given as (Chapter 4)

$$\begin{cases} \rho \frac{\partial^2 u(x, t)}{\partial t^2} = -f, & \text{Newton's law} \\ f = EI \frac{\partial^4 u(x, t)}{\partial x^4}, & \text{Hooke's Law} \\ u(0, t) = u(l, t) = \frac{\partial u(0, t)}{\partial x} = \frac{\partial u(l, t)}{\partial x} = 0, & \text{Boundary conditions} \end{cases} \quad (7.3)$$

where ρ represents the mass per unit length, l the beam length, and EI the bending stiffness (flexural rigidity).

7.2.2 Integral Formulation and Rayleigh–Ritz Discretization

Besides the approach in which Newton's law and Hooke's Law are directly used to establish equations of motion, there are alternatives: Hamilton's principle, the minimum potential energy principle, and the virtual work principle; all of which appear in integral form. From a mathematical standpoint, the differential equations and the integral equations are equivalent in that one can be derived from another. However, they are very different in that the integral equations facilitate the application of the discretization schemes such as the finite element method, an element-wise application of Rayleigh–Ritz method. Therefore, Hamilton's principle, as one of the integral formulations, and its Rayleigh–Ritz discretization are briefly introduced here in order to provide a better understanding of the finite element method.

Denote T as the system kinetic energy, V the system potential energy, and δW the virtual work done by nonconservative forces. Hamilton's principle [11] states that the variation of the Lagrangian ($T - V$) Standard terminology plus the line integral of the virtual work done by the nonconservative forces during any time interval must be equal to zero. If the time interval is denoted by $[t_1, t_2]$, then Hamilton's principle can be expressed as

$$\delta \int_{t_1}^{t_2} (T - V) dt + \int_{t_1}^{t_2} \delta W dt = 0 \quad (7.4)$$

In the case of a continuum, we look for an approximate solution $u(x, y, z, t)$ in the form of

$$u(x, y, z, t) = \sum_{i=1}^n \varphi_i(x, y, z) q_i(t) \quad (7.5)$$

where $\varphi_i(x, y, z)$ is called a Rayleigh–Ritz shape function and $q_i(t)$ is called a generalized coordinate. In this way, the system kinetic energy and the system potential energy can be, respectively, expressed

as follows:

$$T = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n m_{ij} \dot{q}_i \dot{q}_j \equiv \frac{1}{2} \dot{\mathbf{u}}^T(t) \mathbf{M} \dot{\mathbf{u}}(t) \quad (7.6)$$

and

$$V = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n k_{ij} q_i q_j \equiv \frac{1}{2} \mathbf{u}^T(t) \mathbf{K} \mathbf{u}(t) \quad (7.7)$$

where $\mathbf{u}^T(t) \equiv [q_1, q_2, \dots, q_n]$, $\mathbf{M} \equiv [m_{ij}]$, $\mathbf{K} \equiv [k_{ij}]$.

The virtual work done by the generalized forces is

$$\delta W = \sum_{i=1}^n f_i(t) \delta q_i = \mathbf{F}^T \delta \mathbf{u}(t) \quad (7.8)$$

where $\mathbf{F}^T \equiv [f_1(t), f_2(t), \dots, f_n(t)]$ and $f_i(t)$ is the generalized force corresponding to the nonconservative force $f(x, y, z, t)$

$$f_i(t) = \int \varphi_i(x, y, z) f(x, y, z, t) dV \quad (7.9)$$

Substituting Equation 7.6, Equation 7.7 and Equation 7.8 into Hamilton's principle (Equation 7.4) and conducting a routine variation operation, one has

$$\int_{t_1}^{t_2} (\dot{\mathbf{u}}^T \mathbf{M} \delta \dot{\mathbf{u}} - \mathbf{u}^T \mathbf{K} \delta \mathbf{u} + \mathbf{F}^T \delta \mathbf{u}) dt = 0 \quad (7.10)$$

Applying the separation integration to the first term of the above equation and noting that the variations of the generalized coordinate $\delta \mathbf{u}$ at times t_1 and t_2 equal zero, Equation 7.10 is rewritten as

$$\int_{t_1}^{t_2} (-\mathbf{M} \ddot{\mathbf{u}}(t) - \mathbf{K} \mathbf{u}(t) + \mathbf{F}) \delta \mathbf{u} dt = 0 \quad (7.11)$$

Because $\delta \mathbf{u}$, the variation of the generalized coordinate vector, is arbitrary and independent, from the above equation one obtains

$$\mathbf{M} \ddot{\mathbf{u}}(t) + \mathbf{K} \mathbf{u} = \mathbf{F} \quad (7.12)$$

which is the vibration equation resulting from a Rayleigh–Ritz discretization.

7.2.3 Finite Element Method

In the finite element method (FEM) [7,10,12], a continuum is divided into a number of relatively small regions called elements that are interconnected at selected nodes. This procedure is called discretization. The deformation within each element is expressed by interpolating polynomials. The coefficients of these polynomials are defined in terms of the element nodal DoF that describe the displacements and slopes of selected nodes on the element. By using the connectivity between elements, the assumed displacement field can then be written in terms of the nodal DoF by means of the element shape function. Using the assumed displacement field, the kinetic energy and the strain energy of each element are expressed in the form of the element mass and stiffness matrices. The energy expressions for the entire continua can be obtained by adding the energy expressions of its elements. This leads to the assembled mass matrix and the assembled stiffness matrix, and finally to the finite element vibration equation.

The displacement in the interior of an element e is determined by a polynomial

$$u(x, y, z, t) = \mathbf{N} \mathbf{u}^e \quad (7.13)$$

where the matrix \mathbf{N} is called the shape function matrix of the element e , and \mathbf{u}^e the vector of the nodal DoF.

Based on the element displacement expression Equation 7.13, one can obtain the strain and the stress in the element e and finally the strain energy.

The strain and the stress in the element e are

$$\boldsymbol{\varepsilon} = \partial u(x, y, z, t) = \partial \mathbf{N} \mathbf{u}^e = \mathbf{B} \mathbf{u}^e \quad (7.14)$$

and

$$\boldsymbol{\sigma} = \mathbf{D} \boldsymbol{\varepsilon} = \mathbf{D} \mathbf{B} \mathbf{u}^e = \mathbf{S} \mathbf{u}^e \quad (7.15)$$

respectively, where ∂ is the differential operator matrix, $\mathbf{B} = \partial \mathbf{N}$ is the element strain matrix, \mathbf{D} is the elastic matrix, and $\mathbf{S} = \mathbf{D} \mathbf{B}$ is called the element stress matrix.

The strain energy in the element e is given by the element strain $\boldsymbol{\varepsilon}$ and stress $\boldsymbol{\sigma}$ as

$$V^e = \frac{1}{2} \int \boldsymbol{\varepsilon}^T \boldsymbol{\sigma} \, dV = \frac{1}{2} (\mathbf{u}^e)^T \mathbf{K}^e \mathbf{u}^e \quad (7.16)$$

where

$$\mathbf{K}^e = \int \mathbf{B}^T \mathbf{D} \mathbf{B} \, dV \quad (7.17)$$

is called the element stiffness matrix.

The velocity at a point (x, y, z) in the element e can be obtained from Equation 7.13 as

$$\dot{u}(x, y, z, t) = \mathbf{N} \dot{\mathbf{u}}^e \quad (7.18)$$

So the kinetic energy of the element e is

$$T^e = \frac{1}{2} \int \rho \dot{\mathbf{u}}^T \dot{\mathbf{u}} \, dV = \frac{1}{2} (\dot{\mathbf{u}}^e)^T \mathbf{M}^e \dot{\mathbf{u}}^e \quad (7.19)$$

where

$$\mathbf{M}^e = \int \rho \mathbf{N}^T \mathbf{N} \, dV \quad (7.20)$$

is called the element mass matrix.

The equivalent nodal force \mathbf{F}^e corresponding to the force \mathbf{f}^e applied onto the element e is determined by equaling the work done by \mathbf{F}^e to the work done by \mathbf{f}^e along any virtual displacement. This leads to the following:

$$(\delta \mathbf{u}^e)^T \mathbf{F}^e = \int \delta \mathbf{u}^T \mathbf{f}^e \, dV = (\delta \mathbf{u}^e)^T \left(\int \mathbf{N}^T \mathbf{f}^e \, dV \right) \quad (7.21)$$

Note that as the variation of the nodal displacement is arbitrary, one can obtain the expression of the equivalent nodal force \mathbf{F}^e from Equation 7.21 as

$$\mathbf{F}^e = \int \mathbf{N}^T \mathbf{f}^e \, dV \quad (7.22)$$

Now we have the kinetic energy, the strain energy, and the equivalent nodal force of the element e . But these quantities are expressed in the local coordinate system (X^e, Y^e, Z^e) of the element e , not in the global coordinate system (X, Y, Z) . In order to calculate the corresponding counterparts for the whole structure, it is necessary to transform the expressions of the kinetic energy, the strain energy, and the equivalent nodal force of the element e from the local coordinate system into the global one.

Let \mathbf{L} be the transformation matrix from the global coordinate system to the local coordinate system. Then the nodal displacement vector \mathbf{u}^e in the local coordinate system is related to the nodal displacement

vector $\bar{\mathbf{u}}^e$ in the global coordinate system by the following:

$$\mathbf{u}^e = \mathbf{L}\bar{\mathbf{u}}^e \quad (7.23)$$

Similarly, the equivalent nodal force vector \mathbf{F}^e in the local coordinate system is related to the equivalent nodal force vector $\bar{\mathbf{F}}^e$ in the global coordinate system by

$$\mathbf{F}^e = \mathbf{L}\bar{\mathbf{F}}^e \quad (7.24)$$

Substituting Equation 7.23 into Equation 7.16 and Equation 7.19, and noting that \mathbf{L} is a normal matrix ($\mathbf{L}^T = \mathbf{L}^{-1}$), the element stiffness and mass matrices in the global coordinate system can be, respectively, expressed as

$$\bar{\mathbf{K}}^e = \mathbf{L}^T \mathbf{K}^e \mathbf{L} \quad (7.25)$$

and

$$\bar{\mathbf{M}}^e = \mathbf{L}^T \mathbf{M}^e \mathbf{L} \quad (7.26)$$

The equivalent nodal force vector in the global coordinate system is solved from Equation 7.24

$$\bar{\mathbf{F}}^e = \mathbf{L}^T \mathbf{F}^e \quad (7.27)$$

In this way, we can obtain the total strain energy of the structure as

$$V = \sum_e \bar{V}^e = \frac{1}{2} \sum_e (\bar{\mathbf{u}}^e)^T \bar{\mathbf{K}}^e \bar{\mathbf{u}}^e = \frac{1}{2} \mathbf{u}^T \mathbf{K} \mathbf{u} \quad (7.28)$$

where the matrix

$$\mathbf{K} = \sum_e \bar{\mathbf{K}}^e \quad (7.29)$$

is called the global stiffness matrix of the structure. The vector \mathbf{u} is the global nodal displacement vector of the structure.

Similarly, the total kinetic energy of all of the elements can be written as

$$T = \sum_e \bar{T}^e = \frac{1}{2} \sum_e (\dot{\bar{\mathbf{u}}}^e)^T \bar{\mathbf{M}}^e \dot{\bar{\mathbf{u}}}^e = \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{M} \dot{\mathbf{u}} \quad (7.30)$$

where the matrix

$$\mathbf{M} = \sum_e \bar{\mathbf{M}}^e \quad (7.31)$$

is called the global mass matrix. The vector $\dot{\mathbf{u}}$ is the global nodal velocity vector.

The total virtual work done by the external forces is

$$\delta W = \sum_e \delta \bar{W}^e = \sum_e (\delta \bar{\mathbf{u}}^e)^T \bar{\mathbf{F}}^e = (\delta \mathbf{u})^T \mathbf{F} \quad (7.32)$$

where the vector

$$\mathbf{F} = \sum_e \bar{\mathbf{F}}^e \quad (7.33)$$

is a global generalized force vector.

Substituting Equation 7.28, Equation 7.30, and Equation 7.32 into Hamilton's principle (Equation 7.4) and conducting the routine variation operation, one has

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{F} \quad (7.34)$$

which is the vibration equation resulting from the finite element discretization.

7.2.4 Lumped Mass Matrix

The element mass matrix given by Equation 7.20 is normally a full symmetric matrix, because the element shape functions are not orthogonal with each other. It is desirable to reduce this full matrix into a diagonal matrix. In practice, this is achieved by lumping the element mass at its nodes. For example, the consistent element mass matrix of a beam element is

$$\mathbf{M}^e = \frac{\rho A l}{420} \begin{bmatrix} 156 & 22l & 54 & -13l \\ 22l & 4l^2 & 13l & -3l^2 \\ 54 & 13l & 156 & -22l \\ -13l & -3l^2 & -22l & 4l^2 \end{bmatrix} \quad (7.35)$$

When the inertia effect associated with the rotational DoF is negligible, the element lumped mass matrix can be obtained by lumping one half of the total beam element mass at each of the two nodes along the translation DoF:

$$\mathbf{M}^e = \frac{\rho A l}{2} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad (7.36)$$

When the inertia effect associated with the rotational DoF is not negligible, the mass moment of inertia of one half of the beam element about each node can be computed and included at the diagonal locations corresponding to the rotational DoF:

$$\mathbf{M}^e = \frac{\rho A l}{2} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & l^2/12 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & l^2/12 \end{bmatrix} \quad (7.37)$$

7.2.5 Model Reduction

The finite element discretization of an engineering vibration problem usually generates a very large number of DoF. In particular, when automatic meshing schemes are not properly applied, or three-dimensional elements must be used, the number of elements created could become too great to be cost-effectively handled with limited computer capabilities. To solve this problem, modelers have to pay close attention to how the meshing is done in commercial software packages. Very often, simplification and idealization based on the nature of the problem of concern can tremendously reduce the number

of elements. For example, there could be two ways of generating the finite elements of a clamped-free steel beam with a metal block attached to its free end. One way is to mesh both the beam and the block using three-dimensional elements; the other way is to mesh the beam with one-dimensional beam elements and treat the block as a lumped mass, zero-dimensional element. It is obvious that the first approach will result in many more elements than the second approach. However, both approaches will give very similar results for the first several natural frequencies and the associated mode shapes. Another technique for reducing the number of elements comes from deleting the detailed features. The detailed features here imply those geometrical details, such as fillets, chamfers, small holes, and so on, which do not have significant contributions to the vibration behavior of the entire structure, but increase the number of elements. Generally these detailed features can be deleted without any visible effect on the results, if the global behavior of the vibration problem is of concern. Note that such detailed features may have to be kept if the localized behavior such as fatigue (stress) induced by vibration is to be evaluated.

When further model reduction is necessary, Guyan reduction [3] is considered. It was proposed two decades ago when computer capabilities were much more limited than today. In fact, Guyan reduction is still in use today and has been cast into many commercial software packages. In Guyan reduction, the model scale is reduced by removing those DoF (called slave DoF) that can be approximately expressed by the rest of the DoF (called master DoF) through a static relation. The DoF associated with zero mass or relatively small mass are likely candidates for slave DoF.

By rearranging the DoF \mathbf{u} so that those to be removed, denoted by \mathbf{u}^2 , appear last in the vector, and partitioning the mass and the stiffness matrices accordingly, one obtains

$$\begin{bmatrix} \mathbf{M}_{11} & \mathbf{M}_{12} \\ \mathbf{M}_{21} & \mathbf{M}_{22} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{u}}^1 \\ \ddot{\mathbf{u}}^2 \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_{11} & \mathbf{K}_{12} \\ \mathbf{K}_{21} & \mathbf{K}_{22} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^1 \\ \mathbf{u}^2 \end{Bmatrix} = \begin{Bmatrix} \mathbf{F} \\ \mathbf{0} \end{Bmatrix} \quad (7.38)$$

If we assume $\mathbf{M}_{22} = \mathbf{0}$, and $\mathbf{M}_{21} = \mathbf{0}$, then the second equation in Equation 7.38 can be written as

$$\mathbf{u}^2 = -\mathbf{K}_{22}^{-1} \mathbf{K}_{21} \mathbf{u}^1 \quad (7.39)$$

Define the transformation

$$\mathbf{u} = \mathbf{Q} \mathbf{u}^1 \quad (7.40)$$

where the transformation matrix \mathbf{Q} is

$$\mathbf{Q} = \begin{bmatrix} \mathbf{I} \\ -\mathbf{K}_{22}^{-1} \mathbf{K}_{21} \end{bmatrix} \quad (7.41)$$

and \mathbf{I} is the unit (identity) matrix.

Substituting Equation 7.40 into Equation 7.38 and premultiplying the resulting equation by \mathbf{Q}^T , one obtains a new reduced-order model

$$\mathbf{Q}^T \mathbf{M} \mathbf{Q} \ddot{\mathbf{u}}^1 + \mathbf{Q}^T \mathbf{K} \mathbf{Q} \mathbf{u}^1 = \mathbf{F} \quad (7.42)$$

where

$$\mathbf{Q}^T \mathbf{M} \mathbf{Q} = \mathbf{M}_{11} - \mathbf{M}_{12} \mathbf{K}_{22}^{-1} \mathbf{K}_{21} + \mathbf{K}_{21}^T \mathbf{K}_{22}^{-1} \mathbf{M}_{22} \mathbf{K}_{22}^{-1} \mathbf{K}_{21} \quad (7.43)$$

and

$$\mathbf{Q}^T \mathbf{K} \mathbf{Q} = \mathbf{K}_{11} - \mathbf{K}_{12} \mathbf{K}_{22}^{-1} \mathbf{K}_{21} \quad (7.44)$$

Newton's law

$$\mathbf{M}\ddot{\mathbf{u}}(t) = -\mathbf{F}$$

Hooke's Law

$$\mathbf{F} = \mathbf{K}\mathbf{u}(t)$$

Hamilton's principle

$$\delta \int_{t_1}^{t_2} (T - V) dt + \int_{t_1}^{t_2} \delta W dt = 0$$

Finite element equation without damping

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{F}$$

$$\mathbf{M} = \sum_e \mathbf{L}^T \mathbf{M}^e \mathbf{L}, \quad \mathbf{K} = \sum_e \mathbf{L}^T \mathbf{K}^e \mathbf{L}, \quad \mathbf{F} = \sum_e \mathbf{L}^T \mathbf{F}^e$$

Guyan reduction scheme

$$\mathbf{Q}^T \mathbf{M} \mathbf{Q} \ddot{\mathbf{u}}^1 + \mathbf{Q}^T \mathbf{K} \mathbf{Q} \mathbf{u}^1 = \mathbf{F}$$

$$\mathbf{Q} = \begin{bmatrix} \mathbf{I} \\ -\mathbf{K}_{22}^{-1} \mathbf{K}_{21} \end{bmatrix}$$

7.3 Vibration Analysis

According to the vibration characteristics to be extracted, vibration analysis can be categorized into the following two types: natural vibration analysis, including modal analysis (see Chapter 1 and Chapter 3), and (forced) response analysis (see Chapter 2). Natural vibration analysis can extract natural vibration frequencies and the associated mode shapes, which is a matrix eigenvalue problem (see Chapter 3), and can result from a finite element discretization. The response analysis refers to the calculation of the response, which can be displacements, strain, or stress, when the system is subjected to time-varying excitation forces. The response analysis can be further divided into any one a combination of harmonic response analysis, transient response analysis, and response spectrum analysis, depending on the nature of excitation forces.

7.3.1 Natural Vibration

As noted in previous chapters, the natural vibration frequencies (or simply *natural frequencies*) and the associated mode shapes of a vibrating system are independent of excitation forces. In other words, they are intrinsic characteristics of the vibration problem. Therefore, they constitute an important part of vibration theory and vibration engineering. When vibration engineers specify design requirements in terms of vibration, they normally do so by restricting natural frequencies, and sometimes restricting mode shapes as well. For instance, in order to enhance the passenger comfort, vehicle designers have to ensure that the first few natural frequencies of the vehicle are not within a certain range; in order to avoid vibration resonance, the natural frequencies of a transmission shaft should be designed not to be identical or even close to the rotating speeds of the shaft; in order to effectively control vibration, vibration sensors and actuators have to be located at those places where the dominant mode shapes have large displacements.

From a mathematical standpoint, the natural vibration analysis of a multi-DoF system requires the solution of a matrix eigenvalue problem. According to the theory of second-order ordinary differential equations, the solution of Equation 7.34, when $\mathbf{F} = \mathbf{0}$, can be expressed as $\mathbf{u} = \mathbf{v} e^{i\omega t}$. By substituting $\mathbf{u} = \mathbf{v} e^{i\omega t}$ into Equation 7.34 and letting $\mathbf{F} = \mathbf{0}$, one can obtain

$$\omega^2 \mathbf{M} \mathbf{v} = \mathbf{K} \mathbf{v} \quad (7.45)$$

Equation 7.45 represents a generalized matrix eigenvalue problem. For an N -dimensional matrix pair (\mathbf{M}, \mathbf{K}) , there exist N pairs of solutions (ω_i, \mathbf{v}_i) , $\omega_i^2 \mathbf{M} \mathbf{v}_i = \mathbf{K} \mathbf{v}_i$ ($i = 1, 2, \dots, N$), where ω_i and \mathbf{v}_i are called the i th natural frequency and the associated i th mode shape, respectively.

The numerical methods for solving the matrix eigenvalue problem given by Equation 7.45 have been well developed with the symmetric and sparse features of (\mathbf{M}, \mathbf{K}) being fully considered. Those that have been used by commercial finite element software packages include the power method, the subspace iteration method, the LR method, the QR method, the Givens method, the Householder method, and the Lanczos method.

When conducting vibration modeling, modelers need to understand how idealization and simplification will affect the resulting natural frequencies and the associated mode shapes. Idealization and simplification cause a difference between the actual mass matrix \mathbf{M} and the resulting mass matrix \mathbf{M}_r ($\mathbf{M} = \mathbf{M}_r + \Delta \mathbf{M}$), and a difference between the actual stiffness matrix \mathbf{K} and the resulting stiffness matrix \mathbf{K}_r ($\mathbf{K} = \mathbf{K}_r + \Delta \mathbf{K}$). Rayleigh's quotient [9,11] can be used to determine the effect of $\Delta \mathbf{K}$ and $\Delta \mathbf{M}$ on a particular natural frequency. Rayleigh's quotient is defined as

$$R(\mathbf{x}) = \frac{\mathbf{x}^T \mathbf{K} \mathbf{x}}{\mathbf{x}^T \mathbf{M} \mathbf{x}} \quad (7.46)$$

Note that Rayleigh's quotient $R(\mathbf{x})$ becomes the square of the i th natural vibration frequency, $R(\mathbf{x}) = \omega_i^2$, when $\mathbf{x} = \mathbf{v}_i$. Thus, Rayleigh's quotient can be expressed as

$$\omega_i^2 + \Delta \omega_i^2 = \frac{(\mathbf{v}_i^T + \Delta \mathbf{v}_i^T)(\mathbf{K}_r + \Delta \mathbf{K})(\mathbf{v}_i + \Delta \mathbf{v}_i)}{(\mathbf{v}_i^T + \Delta \mathbf{v}_i^T)(\mathbf{M}_r + \Delta \mathbf{M})(\mathbf{v}_i + \Delta \mathbf{v}_i)} \quad (7.47)$$

where $\Delta \omega_i^2$ and $\Delta \mathbf{v}_i$ are the increase of the i th natural frequency and the variation of the i th mode shape, respectively, induced by $\Delta \mathbf{K}$ and $\Delta \mathbf{M}$. Because of the fact that $R(\mathbf{x})$ reaches the stationary value when \mathbf{x} is equal to the eigenvector \mathbf{v}_i , Equation 7.47 can be simplified as [1,4]

$$\Delta \omega_i^2 = \mathbf{v}_i^T (\Delta \mathbf{K} - \Delta \mathbf{M}) \mathbf{v}_i \quad (7.48)$$

Equation 7.48 indicates that an increase in stiffness leads to a rise in a natural frequency, but an increase in mass causes a decrease in a natural frequency, as is intuitively clear.

7.3.2 Harmonic Response

Harmonic response analysis determines the response of a vibration system (model) to harmonic excitation forces. A typical output is a plot showing response (usually displacement of a certain DoF) versus frequency. This plot indicates how the response at a certain DoF, as a function of excitation frequency, changes with excitation frequency. The harmonic response can also be used to calculate the response to a general periodic excitation force, if it can be satisfactorily approximated by a summation of its major harmonic components.

Consider a harmonic excitation force, $\mathbf{F}(t) = \mathbf{F}_0 e^{i\omega t}$. Substituting it into Equation 7.34, we have

$$\mathbf{M} \ddot{\mathbf{u}}(t) + \mathbf{K} \mathbf{u}(t) = e^{i\omega t} \mathbf{F}_0 \quad (7.49)$$

According to the theory of differential equations, its steady solution can be written as $\mathbf{u}(t) = e^{i\omega t} \mathbf{U}$. After substitution of $\mathbf{u}(t) = e^{i\omega t} \mathbf{U}$ into Equation 7.49, one obtains

$$(-\omega^2 \mathbf{M} + \mathbf{K}) \mathbf{U} = \mathbf{F}_0 \quad (7.50)$$

Harmonic response analysis will solve Equation 7.50 for \mathbf{U} against ω . There are many numerical methods available for solving Equation 7.50. The most efficient one is the modal superposition method.

In the modal superposition method, the response is expressed as a linear combination given by

$$\mathbf{u}(t) = \sum_{i=1}^j \mathbf{v}_i \hat{\mathbf{u}}_i(t) = \mathbf{\Phi} \hat{\mathbf{u}}(t) \quad (7.51)$$

where $\mathbf{\Phi} = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j]$ is a modal matrix that contains the dominant mode shapes, and $\hat{\mathbf{u}}^T(t) = [\hat{\mathbf{u}}_1(t), \hat{\mathbf{u}}_2(t), \dots, \hat{\mathbf{u}}_j(t)]$ are called modal coordinates. Substituting Equation 7.51 into Equation 7.49 and premultiplying the result by $\mathbf{\Phi}^T$, we obtain

$$\ddot{\hat{\mathbf{u}}}(t) + \mathbf{\Lambda} \hat{\mathbf{u}}(t) = \mathbf{\Phi}^T e^{i\omega t} \mathbf{F}_0 \quad (7.52)$$

Note that the modal matrix $\mathbf{\Phi}$ has already been normalized against the mass matrix ($\mathbf{\Phi}^T \mathbf{M} \mathbf{\Phi} = \mathbf{I}$), and that $\mathbf{\Lambda} = \text{diag}(\omega_1, \omega_2, \dots, \omega_j)$.

Equation 7.52 represents a set of decoupled modal equations with a much smaller dimension than Equation 7.49. After solving Equation 7.52 for $\hat{\mathbf{u}}(t)$ and transforming $\hat{\mathbf{u}}(t)$ back to $\mathbf{u}(t)$ through Equation 7.51, we obtain $\mathbf{u}(t)$.

7.3.3 Transient Response

Transient response analysis (sometimes called time-history analysis) determines the dynamic response of a structure under the action of time-varying excitation. Excitation forces are explicitly defined in the time domain. The computed response usually includes the time-varying displacements, accelerations, strains, and stresses. Consider Equation 7.34 in its general form

$$\begin{cases} \mathbf{M} \ddot{\mathbf{u}}(t) + \mathbf{K} \mathbf{u}(t) = \mathbf{F}(t) \\ \mathbf{u}(0) = \mathbf{u}_0; \quad \dot{\mathbf{u}}(0) = \dot{\mathbf{u}}_0 \end{cases} \quad (7.53)$$

where $\mathbf{F}(t)$ is the excitation force, \mathbf{u}_0 is the initial displacement, and $\dot{\mathbf{u}}_0$ is the initial velocity. As in the harmonic response analysis, Equation 7.53 can be solved by the modal superposition method.

Substituting Equation 7.51 into Equation 7.53, premultiplying the result of the first equation by $\mathbf{\Phi}^T$, and premultiplying the result of the initial condition by $\mathbf{\Phi}^T \mathbf{M}$, we obtain

$$\begin{cases} \ddot{\hat{\mathbf{u}}}(t) + \mathbf{\Lambda} \hat{\mathbf{u}}(t) = \mathbf{\Phi}^T \mathbf{F}(t) \\ \hat{\mathbf{u}}(0) = \mathbf{\Phi}^T \mathbf{M} \mathbf{u}_0; \quad \dot{\hat{\mathbf{u}}}(0) = \mathbf{\Phi}^T \mathbf{M} \dot{\mathbf{u}}_0 \end{cases} \quad (7.54)$$

Equation 7.54 represents a set of decoupled modal equations, which can be solved by means of numerical integration techniques. After solving Equation 7.54 for $\hat{\mathbf{u}}(t)$ and transforming $\hat{\mathbf{u}}(t)$ back to $\mathbf{u}(t)$ through Equation 7.51, we can obtain $\mathbf{u}(t)$.

To implement the numerical integration techniques, the overall time period being studied has to be divided into a number of smaller time steps. If the time step is too large, portions of the response (such as spikes) could be missed or truncated. On the other hand, if the time step is too small, the analysis will take an excessively long time or even a prohibitive amount of time.

7.3.4 Response Spectrum

The excitation forces, resulting from earthquakes, winds, ocean waves, jet engine thrust, uneven roads, and so on, do not have repeated patterns, for a variety of reasons, and thus it is difficult to describe them using a deterministic time history. Such excitations are normally treated as random excitations. The assumption that such excitation forces are random is recognition of our lack of knowledge of the detailed

characteristics of the excitation forces. Some excitation forces, like those resulting from an uneven road, could be measured to any desired accuracy, and thus they would become deterministic rather than random. But it is not cost-effective and not convenient to do so. Therefore, engineers prefer to characterize these excitation forces by a statistical description that can be easily measured on any particular representative length of time history. Of the statistical descriptions, the autocorrelation function and the power spectral density function are the most important. Denote $f(t)$ as a stationary random excitation force, and $R_f(\tau)$ as its autocorrelation function and $S_f(\omega)$ as its power spectral density function. Their relations [6] are

$$R_f(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T f(t)f(t + \tau)dt \quad (7.55)$$

$$S_f(\omega) = \int_{-\infty}^{\infty} R_f(\tau)e^{-i\omega\tau} d\tau \quad (7.56)$$

The response spectrum analysis here calculates the power spectral density function of the response of a vibration model to a random excitation force, described by its power spectral density function (see Chapter 5). For the single DoF system given in Figure 7.1

$$m\ddot{u}(t) + ku(t) = f(t) \quad (7.57)$$

The power spectral density function of the response $u(t)$ is given by

$$S_u(\omega) = |H(\omega)|^2 S_f(\omega) \quad (7.58)$$

where

$$H(\omega) = (-m\omega^2 + k)^{-1} \quad (7.59)$$

is the frequency response function representing the natural vibration characteristic of the system.

In the case of the multiple-DoF system given by Equation 7.34, the random excitation force $\mathbf{F}(t)$ is a column vector. For the sake of simplicity, we assume all of the components in the vector $\mathbf{F}(t)$ are stationary and statistically independent. Accordingly, all of the components in the vector of the response $\mathbf{u}(t)$ are stationary. Under this assumption, the power spectral density function of the response $\mathbf{u}(t)$ is determined by

$$\mathbf{S}_u(\omega) = \mathbf{H}(\omega)\mathbf{S}_f(\omega)\mathbf{H}^T(\omega) \quad (7.60)$$

where $\mathbf{S}_f(\omega)$ is a diagonal matrix with its i th element as the power spectral density function of the i th element in $\mathbf{F}(t)$, and $\mathbf{H}(\omega)$ is the frequency response function matrix defined by

$$\mathbf{H}(\omega) = (-\mathbf{M}\omega^2 + \mathbf{K})^{-1} \quad (7.61)$$

From Equation 7.60 and Equation 7.61 one can see that the power spectral density function matrix of the response is correlated to the power spectral density function matrix of the excitation force by means of the frequency response matrix of the system $\mathbf{H}(\omega)$. In commercial finite element software packages, $\mathbf{H}(\omega)$ is often calculated by the truncated modal method in which $\mathbf{H}(\omega)$ is approximately expressed by the dominant natural frequencies and the associated mode shapes, neglecting the contributions of the other mode shapes to $\mathbf{H}(\omega)$, as given below.

$$\mathbf{H}(\omega) \approx \sum_i \frac{\mathbf{v}_i \mathbf{v}_i^T}{\omega_i^2 - \omega^2} \quad (7.62)$$

Natural vibration analysis (generalized eigenvalue problem)

$$\omega^2 \mathbf{M} \mathbf{v} = \mathbf{K} \mathbf{v}$$

Rayleigh's quotient

$$R(\mathbf{x}) = \frac{\mathbf{x}^T \mathbf{K} \mathbf{x}}{\mathbf{x}^T \mathbf{M} \mathbf{x}}$$

Harmonic response

$$(-\omega^2 \mathbf{M} + \mathbf{K}) \mathbf{U} = \mathbf{F}_0$$

$$\mathbf{u}(t) = \sum_{i=1}^j \mathbf{v}_i \hat{\mathbf{u}}_i(t) = \Phi \hat{\mathbf{u}}(t)$$

$$\ddot{\hat{\mathbf{u}}}(t) + \Lambda \hat{\mathbf{u}}(t) = \Phi^T e^{i\omega t} \mathbf{F}_0$$

Transient response

$$\begin{cases} \mathbf{M} \ddot{\mathbf{u}}(t) + \mathbf{K} \mathbf{u}(t) = \mathbf{F}(t) \\ \mathbf{u}(0) = \mathbf{u}_0; \quad \dot{\mathbf{u}}(0) = \dot{\mathbf{u}}_0 \end{cases}$$

$$\begin{cases} \ddot{\hat{\mathbf{u}}}(t) + \Lambda \hat{\mathbf{u}}(t) = \Phi^T \mathbf{F}(t) \\ \hat{\mathbf{u}}(0) = \Phi^T \mathbf{M} \mathbf{u}_0; \quad \hat{\dot{\mathbf{u}}}(0) = \Phi^T \mathbf{M} \dot{\mathbf{u}}_0 \end{cases}$$

Response spectrum analysis

$$\mathbf{S}_u(\omega) = \mathbf{H}(\omega) \mathbf{S}_f(\omega) \mathbf{H}^T(\omega)$$

$$\mathbf{H}(\omega) = (-\mathbf{M}\omega^2 + \mathbf{K})^{-1}$$

7.4 Commercial Software Packages

There are many commercial finite element analysis (FEA) software packages available for vibration analysis, and they have been so well developed that they have an extensive range of vibration analysis capabilities. Some software packages are intended for generic engineering structures, for example, ABAQUS, ADINA, ALGOR, ANSYS, COSMOSWorks, MSC/NASTRAN, DYNA3D, and LS-DYNA. The others are designed for the vibration analysis of specific vibration problems. For example, the software package Bridge and the software package LUSAS Bridge are for the vibration analysis of bridges.

Normally, FEA modeling software has the following three major components: a preprocessor, a solver, and a postprocessor. The preprocessor is responsible for building up geometries, meshing, specification of element types, material properties, and boundary conditions; the solver solves the matrix equations; the postprocessor provides visualization of results and outputs the results in different formats. Because of the fact that those CAD/CAE systems such as CATIA, Unigraphics, Pro/E, and Solidworks have powerful capabilities for building up geometries, vibration modelers often import geometries from such systems rather than building them up using the FEA modeling software packages themselves.

In this section, we will select the software packages ABAQUS, ADINA, ALGOR, ANSYS, COSMOSWorks, MSC/NASTRAN, ABAQUS/Explicit, DYNA3D, and LS-DYNA, and will briefly introduce their major capabilities for vibration analysis. In fact, the vibration analysis capability is only a small portion of their total capabilities. All of these packages can perform basic vibration analysis

including: (1) determination of natural mode shapes and frequencies, (2) transient response, (3) steady-state response resulting from harmonic loading, and (4) response spectrum analysis. In addition, each of them has its own strengths in some specific areas. These special capabilities are listed below.

7.4.1 ABAQUS

The ABAQUS software is for linear and nonlinear engineering analyses. Due to its wide range of functionality, ABAQUS usage spans many industries, including automotive, aerospace and defense, consumer electronics, manufacturing, medical, and rubber sealing.

Some special capabilities include

- Analysis of the coupled phenomena: thermo-mechanical, thermo-electrical, piezoelectric, pore fluid flow-mechanical, stress–mass diffusion, and shock and acoustic-structural
- Substructures and submodeling
- Material removal and addition
- Fracture mechanics design evaluation
- Parameterization and parametric studies
- User subroutines

7.4.2 ADINA

The ADINA system offers comprehensive finite element analyses of structures, fluids, and fluid flows with structural interactions. It is widely used in many fields, including the automotive, aerospace, manufacturing, nuclear, and biomedical industries, and in civil engineering and research.

Some special dynamic capabilities include

- Contact problems in statics and dynamics
- Substructuring in statics and dynamics
- Wave propagation and shock wave analysis

7.4.3 ALGOR

ALGOR's Professional Multiphysics includes capabilities for static structural analysis and Mechanical Event Simulation with linear and nonlinear material models, steady state and transient thermal analysis, electrostatic analysis, linear dynamics, and steady and unsteady fluid flow analysis. It is used in aerospace and space exploration; the automotive, transportation, consumer products, electronics, entertainment, manufacturing, chemical processing and medical industries; in the defense, power, and utility sectors; in civil engineering and scientific research; and in recreation and sports.

Some special features include

- Rigid-body motion
- Hertzian contact
- Submodeling
- Earthquake simulation
- Fluid–solid interaction
- The EAGLE programming language

7.4.4 ANSYS

ANSYS Software Suite offers capabilities for determining the structural, thermal, acoustic, electrostatic, magnetostatic, electromagnetic, and fluid-flow behavior of three-dimensional product designs, including

the effects of multiphysics. The software simulates complex thermal/mechanical, fluid/structural and electrostatic/structural interactions. It is widely used in the aerospace, automotive, biomedical engineering, chemical engineering, civil engineering, communications, consumer products, defense, electronic packaging, industrial and scientific equipment production, and micro-electromechanical systems (MEMS) industries.

Some special dynamic capabilities include

- Modal analysis of prestressed structures
- Dynamic Topological design optimization
- Substructuring and submodeling
- Coupled field analysis of thermal-structural, fluid-structural, electrostatic-structural, magneto-structural, acoustic-structural, thermal-electric, thermal-electromagnetic, fluid-thermal, piezo-electric fields, and an electromechanical circuit simulator
- A parametric design language

7.4.5 COSMOSWorks

COSMOSWorks offers a wide spectrum of specialized analysis tools to virtually test and analyze complicated parts and assemblies, and is seamlessly integrated with Solidworks. COSMOSWorks is used for linear stress, strain, displacement, thermal analysis, design, optimization, and nonlinear analysis. Combined with ASTAR (Post Dynamics), COSMOSWorks is capable of more advanced dynamic analysis. It is used in a wide range of industries, including aerospace and defense, automotive and transportation, civil engineering, consumer products, electrical and electronics, heavy equipment, marine, medical and power.

The special dynamic features of the ASTAR module are

- Support of uniform and multi-base motion systems; the multi-base motion capability allows engineers to model structures with nonuniform support excitations.
- Support of the gap-friction element, which lets engineers model drop-test and other dynamic contact problems.
- The provision for several damper options such as Rayleigh damping, modal damping, concentrated damping, and composite modal damping.

7.4.6 MSC.Nastran

In 1965, MSC participated in a NASA-sponsored project to develop a unified approach to computerized structural analysis. The program became known as NASTRAN (NASA Structural Analysis Program); one of the first efforts to consolidate structural mechanics into a single computer program. The suite of MSC.Software is used in the space, aircraft, and automotive industries; in rail vehicle development; in general machinery; and in medical and electromechanical devices. Its capabilities include stress, vibration, heat transfer, acoustics, aeroelasticity, and coupled system analysis.

MSC.NASTRAN's special dynamic capabilities include

- Damping
- Direct matrix input
- Dynamic equations of motion
- Residual vector methods
- Enforced motion
- Complex eigenvalue analysis
- Normal mode of preloaded structures
- Dynamic design optimization
- Test-analysis correlation

7.4.7 ABAQUS/Explicit

ABAQUS/Explicit uses explicit time integration for time stepping and addresses the following special types of analysis:

- Explicit dynamic response with or without adiabatic heating effects
- Fully coupled transient dynamic temperature–displacement procedure; explicit algorithms are used for both the mechanical and thermal response
- Annealing for multistep forming simulations
- Acoustic and coupled acoustic-structural analysis
- Automatic adaptive meshing, which allows robust solutions of highly nonlinear problems

7.4.8 DYNA3D

DYNA3D is an explicit finite element program for structural and continuum mechanics problems. Due to its explicit nature, DYNA3D uses small time steps to integrate the equations of motion and is especially efficient at solving transient dynamic problems.

The specific analysis capabilities of DYNA3D include

- Static analysis using dynamic relaxation
- Dynamic analysis with static initialization from a NIKE3D implicit analysis
- Various contact slideline options for different contact situations between two bodies

7.4.9 LS-DYNA

LS-DYNA is a general-purpose transient dynamic finite element program, and is suited for complex dynamics, vibration, and wave propagation problems. Its explicit algorithm can be used for high-speed impact, shock, and vibration problems. Falling impact, rubber elasticity, and impact on sports goods (rackets, bats, and helmets) are typical examples of problems that can be handled by LS-DYNA. It is widely used in earthquake engineering; crashworthiness and occupant safety analysis; metal forming; biomedical engineering; train crashworthiness testing; sports, airbag, and seat-belt deployment; and in military, manufacturing, metal cutting, and bird strike applications.

The special capabilities of LS-DYNA include

- FEM-rigid multi-body dynamics coupling
- Underwater shock analysis
- Failure analysis
- Crack propagation analysis
- Real-time acoustics
- Design optimization
- Implicit springback analysis
- Multi-physics coupling
- Adaptive re-meshing
- Smooth particle hydrodynamics
- The element-free meshless method

7.5 The Basic Procedure of Vibration Analysis

In this section, a typical procedure in using commercial software packages to conduct vibration analysis is outlined.

7.5.1 Planning

This is a very important part of the entire analysis process, as it helps to ensure the success of the modeling. The quality of the results is strongly dependent on how accurately the model represents the actual problem being investigated. In order to generate a representative finite element model, all influencing factors must be scrutinized to determine whether their effects are considerable or negligible in the final result. The aspects listed below should be given consideration in the planning stage.

- *Modeling objectives.* Why is the vibration analysis required? What is the major concern of designers? What are the working conditions? Does the FEA model have to be used for static stress analysis as well as vibration analysis? These considerations affect how the FEA model is to be built up.
- *Modeling considerations.* Which type of analysis is required: natural vibration analysis or response analysis? What types of elements should be used? Where are loads and constraints applied? Can the model reduction/simplification resulting from symmetrical geometries and loading conditions be applied? There are no universal guidelines for these, but the aspects below can help you to make decision:
 - If the stress varies linearly through the thickness of thin-walled regions, shell elements can be used. If it varies parabolically, then at least three solid, second-order elements are required through the thickness in order to resolve a representative state of stress.
 - If a frequency or buckling analysis is being conducted, a full three-dimensional analysis may be needed to identify non-symmetric mode shapes.
 - If the region of interest is local, then a submodel may be appropriate, as it will save considerable time achieving a solution.
 - Large gradients in stress levels will require a high mesh density to capture the behavior appropriately.
 - The effects of simplifications on boundary conditions should be well predicted, for example: some over-constrained boundary conditions may result in higher natural frequencies of the finite element model.

The degree of accuracy of a model is very much dependant on the level of planning that has been carried out. Careful planning is the key to a successful analysis.

7.5.2 Preprocessing

The preprocessor stage in a general FEA package involves the following:

- *Defining the element type as planned before the analysis.* This may be one-, two-, or three-dimensional.
- *Creating the geometry.* The geometry is drawn in one-, two-, or three-dimensional space according to what kind of elements are going to be used. The model may be created in the preprocessor, or it can be imported from other CAD or CAE systems *via* a neutral file format (IGES, STEP, ACIS, Parasolid, DXF, etc.). The same units should be applied in all models, otherwise the results will be difficult to interpret or, in extreme cases, the results will not show up mistakes made during the loading and restraining of the model.
- *Applying a mesh.* Mesh generation is the process of dividing the continuum into a number of discrete parts or finite elements. The finer the mesh, the more accurate the result, but the longer the processing time. Therefore, a compromise between accuracy and solution speed is usually made. The mesh may be created manually or generated automatically, or, as in most cases, in a combined manner.

Manual meshing is a long and tedious process for models with a fair degree of geometric complication, but with useful tools emerging in preprocessors, the task is becoming easier. Automatic mesh generators are very useful and popular. The mesh is created automatically by a mesh engine; the only requirement is to define the mesh density along the model's edges.

Automatic meshing has limitations as regards mesh quality and solution accuracy. Automatic brick element meshers are limited in function, but are steadily improving. Any mesh is usually applied to the model by simply selecting the mesh command on the preprocessor list of the user interface.

Usually a complex geometry needs to be decomposed into many smaller components in order to use the automatic meshing tool.

- *Assigning properties.* Material properties (Young's modulus; Poisson's ratio; the density; and if applicable, the coefficients of expansion, friction, thermal conductivity, damping effect, specific heat, etc.) will have to be defined. In addition element properties may need to be set. If two-dimensional elements are being used, the thickness property is required. One-dimensional beam elements require area, I_{xx} , I_{yy} , I_{zz} , J , and the direction of the beam axis in three-dimensional space. Shell elements, which are two-dimensional elements in three-dimensional space, require orientation and neutral surface offset parameters to be defined. Special elements such as mass, contact, spring, gap, coupling, damper, and so on require properties (specific to the element type) to be defined for their use.
- *Applying loads.* In the case of transient response analysis, some type of load is usually applied to the analysis model. The loading may be in the form of a point force, a pressure or a displacement, or a temperature or heat flux in a thermal analysis. The loads may be applied to a point, an edge, a surface, or even a complete body. The loads should be in the same unit system as the model geometry and material properties specified. In the case of modal analyses, a load does not have to be specified for the analysis to run.
- *Applying boundary conditions.* Structural boundary conditions are usually in the form of zero displacements; thermal boundary conditions are usually specified temperatures. A boundary condition may be specified to act in all directions (x, y, z), or in certain directions only. Boundary conditions can be placed on nodes, key points, lines, or areas. The boundary conditions applied on lines or areas can be of a symmetric or antisymmetric type, one allowing inplane rotations and out of plane translations, the other allowing in plane translations and out of plane rotations for a given line or area. The application of correct boundary conditions is critical to the accurate solution of the design problem.

7.5.3 Solution

The FEA solver can be logically divided into three main parts: the presolver, the mathematical-engine, and the postsolver. The presolver reads in the model created by the preprocessor and formulates the mathematical representation of the model. All the parameters defined during the preprocessing stage are used to do this, so if something has been omitted the presolver is very likely to stop the call to the mathematical-engine. If the model is correct, the solver proceeds to form the element stiffness matrix and the element mass matrix for the problem and calls the mathematical-engine, which calculates the result. The results are returned to the solver and the postsolver is used to calculate strains, stresses, velocities, response, and so on for each node within the component or continuum. All these results are sent to a result file that may be read by the postprocessor.

7.5.4 Postprocessing

Here the results of the analysis are read and interpreted. They can be presented in the form of a table, a contour plot, a deformed shape of the component, or the mode shapes and natural frequencies if frequency analysis is involved. Most postprocessors provide animation tools.

Contour plots are usually the most effective way of viewing results for structural type problems. Slices can be made through three-dimensional models to facilitate the viewing of internal stress and deformation patterns.

All postprocessors now include the calculation of stresses and strains in any of the x , y , or z directions; or indeed in a direction at an angle to the coordinate axes. The principal stresses and strains may also be plotted, or if required, the yield stresses and strains according to the main theories of failure (Von Mises, St Venant, Tresca, etc.).

7.5.5 Engineering Judgment

For many reasons, the vibration analysis results may not represent the actual vibration problem very well. Software packages will not reveal anything about this, and so it is the responsibility of modelers to make judgments.

Sound judgment comes from a thorough understanding of the actual vibration problem; indepth knowledge of vibration theory, FEA, and the software package used; and also rich experience in modeling. When you are not confident of your vibration analysis results you should check the following:

1. What units have been used, SI units or Imperial units? Are the units used consistent and compatible with the software package you are using?
2. What are the material's properties?
3. Is the boundary free or partially constrained, or flexibly connected to other parts?
4. How are the interconnections between different parts modeled (e.g., the interconnection between a two-dimensional plate and a three-dimensional block)?

Sometimes, a judgment is made by comparing your model's results and the results of different models that are similar in some sense to the one of concern, but which have been validated. A judgment can also be made by vibration measurements or testing under laboratory conditions or in real-life situations (see [Chapter 17](#) and [Chapter 18](#)). By properly exploiting the combined test and analysis data, modelers can effectively and reliably identify otherwise only approximately known structural properties (e.g., joint stiffness), material properties, and loading; validate and refine the FEA model (simplification validation, model updating, etc.) by using test results as reference data; identify unknown or badly known physical properties; and better assess uncertainties in the FEA model.

7.6 An Engineering Case Study

In this section, we illustrate the procedure for the vibration analysis of a gearbox housing, shown in [Figure 7.3](#). The vibration analysis was performed using ANSYS [5].

7.6.1 Objectives

The chief aim of the vibration analysis is to ensure that the gearbox housing is not subject to a dangerous resonant condition during the full range of operation. Specifically, the natural vibration frequencies of the gearbox housing have to be widely separated from the rotating speeds of the shafts. Hence, natural vibration analysis is required for this purpose. Furthermore, there are concerns about the strength of the gearbox, and so a static stress analysis is also required.

7.6.2 Modeling Strategy

The gearbox housing shown in [Figure 7.3](#) contains the following three subparts: the vertical cylinder, the front housing, and the rear housing, which are welded together. Because the FEA model has to be built up with the considerations of both vibration analysis and static stress analysis, some detailed

FIGURE 7.3 Finite element model of the gearbox housing. (Courtesy of Pacific Rim Engineered Products, Surrey, British Columbia.)

geometries such as fillets are not deleted but modeled with fine meshes. In addition, a sufficient level of attention is paid to the interconnections between different sections. To achieve a balance between the accuracy of the results and the size of finite element model, quadratic elements (midsize nodes) are used for both shell elements and solid elements. These usually yield better results at less expense than linear elements.

Three types of finite elements are used to model the different parts:

1. The front cylinder plate, side plates and bottom plate: shell elements with variable thickness; 8 nodes, 6 DoF per node.
2. The ribs and fringes: solid elements; 20 nodes, 3 DoF per node.
3. The gears, shafts, clutch, and bearings: lumped mass elements; 1 node, 6 DoF per node.

Because of the discrepancy in the DoF between the shell elements and the solid elements, the nodal rotating freedoms around the edges that connect shell elements and solid elements together are not constrained, and consequently each rotating freedom needs to be constrained by two nodal translation freedoms on solid elements near the edge, but not on the edge.

The total numbers of nodes, shell elements, and solid elements are given in Table 7.1, and the complete finite element model is shown in Figure 7.3.

TABLE 7.1 Total Size of the Finite Element Model of the Gearbox Housing

Nodes	36,523
Shell elements	4,060
Solid elements	3,760

TABLE 7.2 Material Properties

Density	7800 kg/m ³
Young's modulus	2.1×10^{11} Pa
Poisson coefficient	0.29

TABLE 7.3 The First 10 Natural Frequencies

No.	Frequency (Hz)
1	46.46
2	67.73
3	81.57
4	105.5
5	166.2
6	204.6
7	205.1
8	212.0
9	213.4
10	222.8

7.6.3 Boundary Conditions

The four mountings on each side are constrained completely and the front edge of the cylinder is also completely constrained.

7.6.4 Material

The mechanical properties of the material are given in Table 7.2.

7.6.5 Results

The first 10 natural frequencies and the associated mode shapes are calculated with a Lanczos algorithm. They are listed in Table 7.3.

The first and the fifth mode shapes are shown in [Figure 7.4](#) and [Figure 7.5](#), respectively.

7.7 Comments

Vibration modeling using the finite element method is extremely powerful. However, with comforting contour plots, one can be easily deceived into thinking that a superior result has been achieved. Nevertheless, the quality of the result directly depends upon how accurately the model represents the actual physical problem being investigated. This involves three things: sufficient understanding of the actual vibration problem, sufficient knowledge of vibration theory including FEA, and hands-on experience in running an FEA software package. In particular, modelers have to understand the limitations of the theories applied and the numerical methods used. For example, the FEA can predict global characteristics such as natural frequencies of vibration and mode shapes more accurately than localized features such as stresses. This is an intrinsic nature of finite element methods. Without knowing this, modelers might incorrectly use an unnecessarily fine mesh for mode shape analysis while applying coarse meshes to evaluate stress.

Summary

This chapter presents the Euler–Newton formulation of oscillatory behavior of a multibody system interconnected by discrete stiffness elements. Bodies are interconnected by springs, and/or dashpots (dampers). Connections are described in terms of end coordinates of springs relative to the coordinate system of the body to which it is attached. Stiffness characteristics are described along the three principal axes of springs. Orientation of springs and masses are described by using appropriate Euler angles. The model developed is linear, and gyroscopic influences are ignored. The chapter gives a detailed treatment of rigid bodies in three dimensional space using vector-matrix formulation. Complete formulation and assembly issues relating to programming aspects are presented. A software suite called VIBRATIO, based on the present formulation, is described. The capabilities of VIBRATIO are indicated and illustrative examples are given in both frequency and time domains. A student version of VIBRATIO is available at no cost to the users of this handbook at www.signal-research.com.

8.1 Introduction

There are many commercial software packages for analysis of kinematics and dynamics of multibody linkage systems. There are fewer software tools for analysis of vibration of multiple rigid-body systems

in 3-D space, even though some finite element analysis (FEA) packages offer rigid-body capability. Common FEA software packages treat rigid bodies using point masses or point inertias. Although this is not a serious restriction, when it comes to attaching discrete stiffness elements to a body away from its center of gravity (COG), the attachment is achieved by introducing “lever arms” with a very high Young’s modulus. One may argue that the error introduced in doing so is acceptable but how true this argument is depends on the problem, and there is no escape from the fact that this approach can create ill-conditioned stiffness matrices. The correct way, however, is to incorporate the created kinematic constraints into rigid-body geometries. This is the approach presented in this chapter. A typical rigid multibody system supported or interconnected by discrete spring elements, as considered here, is shown in Figure 8.1. The chapter presents a complete formulation of a multibody system flexibly supported by linear mountings. The formulations and methods proposed in this chapter are used in the VIBRATIO suite of vibration analysis software.

FIGURE 8.1 Schematic representation of a multibody system.

8.2 Theory

8.2.1 Definitions and Assumptions

- Springs have zero length.
- The stiffness parameters of the springs in their principal axes of deflection remain uncoupled.
- The amplitude of oscillation is small. No geometrical nonlinearity is involved. In other words, the orientation of both mountings and bodies remains unaffected by oscillations.
- The time-dependent effects of polymeric material are excluded.
- Gyroscopic effects are negligible.

These assumptions are acceptable for most engineering vibration problems with small amplitude vibration.

8.2.2 Equations of Motion for the Linear Model

To set up equations of motion for a dynamic system, the following steps are required:

- (i) Generation of the equations of internal reactions and external forces. The internal reactions due to damping and stiffness elements have to be expressed in a unified and structured fashion for formulation of the stiffness matrix. (The damping matrix structure is identical to the stiffness matrix structure, except that stiffness coefficients need to be replaced by damping coefficients.)
- (ii) Generation of the equations of linear momentum (force–acceleration equations).
- (iii) Generation of the equations of angular momentum (turning moment equations).

8.2.3 Linear Momentum–Force Systems

8.2.3.1 Stiffness and Damping Systems

The formulations applied in this chapter to obtain the stiffness matrix apply equally to the damping matrix by replacing stiffness parameters with their corresponding damping parameters.

Let us assume that spring stiffness parameters are described in a local three-dimensional (3-D) Cartesian coordinate frame, the axes of which coincide with the principal axes of the springs. The force

vector \mathbf{f} acting on the springs may be expressed as

$$\mathbf{f} = \mathbf{k}\mathbf{x} \quad (8.1)$$

where \mathbf{k} is the stiffness matrix (diagonal with principal stiffness values) and \mathbf{x} is the displacement vector (expressing the spring extension).

In general, it is convenient to describe the behavior of a system in the global coordinate frame, OXYZ. This is not a prerequisite for the formulation. It is equally possible to obtain equations of motion for each body in its own frame. In this chapter, all spring stiffness matrices will be expressed in a common global coordinate frame. The individual spring matrices will be transformed accordingly. Since the principal axes of the springs and the global coordinates are all orthogonal, an orthogonal transformation exists between the two frames. A vector, \mathbf{x} , in the local coordinates could be expressed as a vector, \mathbf{X} , in the global coordinate system. Using, \mathbf{T} , a transformation matrix

$$\mathbf{X} = \mathbf{T}\mathbf{x} \quad (8.2)$$

If we premultiply Equation 8.1 by \mathbf{T} , then we have $\mathbf{T}\mathbf{f} = \mathbf{T}\mathbf{k}\mathbf{x}$. But $\mathbf{T}\mathbf{f} = \mathbf{F}$.

Therefore, force vector, \mathbf{F} , in the global coordinate frame, may be written as

$$\mathbf{F} = \mathbf{T}\mathbf{k}\mathbf{x} \quad (8.3)$$

For consistency, \mathbf{x} needs to be replaced by \mathbf{X} . To replace \mathbf{x} by \mathbf{X} , Equation 8.2 may be used, giving $\mathbf{x} = \mathbf{T}^T\mathbf{X}$. This is true since $\mathbf{T}^{-1} = \mathbf{T}^T$ for orthogonal transformation matrices. Therefore,

$$\mathbf{F} = \mathbf{T}\mathbf{k}\mathbf{T}^T\mathbf{X} \quad (8.4)$$

Then introduce a new matrix \mathbf{K} , where

$$\mathbf{K} = \mathbf{T}\mathbf{k}\mathbf{T}^T$$

Now $\mathbf{T}\mathbf{k}\mathbf{T}^T$ is the stiffness matrix of the spring in the global coordinate system. The transformation matrix \mathbf{T} may be described in three Euler angles of rotation.

8.2.3.2 Generalization of the Equation of Linear Momentum

If the mass/inertia matrix in the Euler–Newton formulation is obtained relative to the axes passing through the center of mass, then the submatrix of the mass matrix corresponding to linear momentum is a diagonal matrix containing the mass elements; thus,

$$\mathbf{h}_i = \mathbf{m}_i\mathbf{v} \quad (8.5)$$

Here, \mathbf{h}_i is linear momentum, \mathbf{m}_i is a diagonal matrix, and \mathbf{v} is the velocity vector of the center of mass (casually known as COG) of the body.

The usual transformation to the global coordinate frame, $\mathbf{H}_i = \mathbf{T}\mathbf{m}_i\mathbf{T}^T\mathbf{v}$, leaves the mass matrix, \mathbf{m} , unchanged. Therefore, the force acting on a body, i (i.e., the rate of change of linear momentum), may be expressed simply as

$$\text{Force} = \dot{\mathbf{H}}_i = \frac{\partial \mathbf{H}_i}{\partial t} = \mathbf{m}\mathbf{a} \quad (8.6)$$

where \mathbf{a} is the acceleration vector of the COG.

8.2.4 Generalization of the Equations of Moment of Momentum

The equations of moment of momentum may be expressed as

$$\mathbf{h}_a = \mathbf{j}\boldsymbol{\omega} \quad (8.7)$$

where \mathbf{h}_a is the angular momentum vector, \mathbf{j} is the moments of inertia matrix and $\boldsymbol{\omega}$ is the angular velocity of the coordinate frame. (In this case, the frame is attached to the body.)

Here, \mathbf{j} may or may not be a diagonal matrix. However, it is always symmetric. Equation 8.7 is described in the local coordinate system of the rigid body and it has to be expressed in the global coordinate system for the final matrix assembly. As presented for the stiffness elements, transformation follows exactly the same steps as before. In this case, \mathbf{T} refers to the transformation matrix of mass relative to the global coordinate system. Transforming Equation 8.7 to the global coordinates, we get

$$\mathbf{H}_a = \mathbf{T}\mathbf{j}\mathbf{T}^T\Omega \quad (8.8)$$

Introduce a new matrix notation

$$\mathbf{J} = \mathbf{T}\mathbf{j}\mathbf{T}^T \quad (8.9)$$

The vector differentiation of \mathbf{H}_a gives the moment vector in the global coordinates

$$\mathbf{M} = \dot{\mathbf{H}}_a = \frac{\partial \mathbf{H}_a}{\partial t} + \boldsymbol{\omega} \times \mathbf{H}_a \quad (8.10)$$

where $\boldsymbol{\omega}$ is the angular velocity of the body (or the coordinate frame, as the body is fixed to the frame).

Note that $\boldsymbol{\omega} \times \mathbf{H}_a$ contains the product of angular velocity terms and this, for small and geometrically linear vibration problems, is small and may be ignored.

8.2.5 Assembly of Equations

To assemble the equations of motion, the internal forces acting on individual bodies due to their motion relative to each other are required. In Figure 8.2, two bodies (i and j) in motion are shown, connected by spring \mathbf{K}_p .

Motion of the origin of vector \mathbf{i} (which coincides with the COG of body i) is given by $\mathbf{x}_i = (x_i, y_i, z_i)$, and the angular rotation of the coordinates is given by $\boldsymbol{\alpha}_i = (\alpha_i, \beta_i, \gamma_i)$. Similarly, the motion of body j is described by $\mathbf{x}_j = (x_j, y_j, z_j)$ and $\boldsymbol{\alpha}_j = (\alpha_j, \beta_j, \gamma_j)$.

For small motions, displacements of the end points of the springs on each body, described in the *coordinate frame* of each body, are given by

$$\mathbf{d}_i = \mathbf{x}_i + \boldsymbol{\alpha}_i \times \mathbf{r}_{pi} \quad (8.11)$$

$$\mathbf{d}_j = \mathbf{x}_j + \boldsymbol{\alpha}_j \times \mathbf{r}_{pj} \quad (8.12)$$

FIGURE 8.2 Two bodies connected by springs.

where \mathbf{r}_{pi} and \mathbf{r}_{pj} are the coordinates of the spring attachment relative to the bodies i and j in their respective coordinate frames, given as $\mathbf{r}_{pi} = (x_{pi}, y_{pi}, z_{pi})$ and $\mathbf{r}_{pj} = (x_{pj}, y_{pj}, z_{pj})$.

Cross-product terms in Equation 8.11 and Equation 8.12 can be converted into matrix form as

$$\boldsymbol{\alpha}_i \times \mathbf{r}_{pi} = \begin{bmatrix} 0 & z_{pi} & -y_{pi} \\ -z_{pi} & 0 & x_{pi} \\ y_{pi} & -x_{pi} & 0 \end{bmatrix} \begin{Bmatrix} \alpha_i \\ \beta_i \\ \gamma_i \end{Bmatrix} \quad (8.13)$$

and

$$\boldsymbol{\alpha}_j \times \mathbf{r}_{pj} = \begin{bmatrix} 0 & z_{pj} & -y_{pj} \\ -z_{pj} & 0 & x_{pj} \\ y_{pj} & -x_{pj} & 0 \end{bmatrix} \begin{Bmatrix} \alpha_j \\ \beta_j \\ \gamma_j \end{Bmatrix} \quad (8.14)$$

Let us choose the matrix notation \mathbf{R}_{pi} as

$$\mathbf{R}_{pi} = \begin{bmatrix} 0 & z_{pi} & -y_{pi} \\ -z_{pi} & 0 & x_{pi} \\ y_{pi} & -x_{pi} & 0 \end{bmatrix} \quad (8.15)$$

and \mathbf{R}_{pj} as

$$\mathbf{R}_{pj} = \begin{bmatrix} 0 & z_{pj} & -y_{pj} \\ -z_{pj} & 0 & x_{pj} \\ y_{pj} & -x_{pj} & 0 \end{bmatrix} \quad (8.16)$$

Therefore,

$$\mathbf{d}_i = \mathbf{x}_i + \boldsymbol{\alpha}_i \times \mathbf{r}_{pi}$$

which is

$$= \begin{Bmatrix} x_i \\ y_i \\ x_i \end{Bmatrix} + \begin{bmatrix} 0 & z_{pi} & -y_{pi} \\ -z_{pi} & 0 & x_{pi} \\ y_{pi} & -x_{pi} & 0 \end{bmatrix} \begin{Bmatrix} \alpha_i \\ \beta_i \\ \gamma_i \end{Bmatrix} \quad (8.17)$$

Using the new notation, we have

$$\mathbf{d}_i = \mathbf{x}_i + \mathbf{R}_{pi} \boldsymbol{\alpha}_i \quad (8.18)$$

Now \mathbf{d}_j is given by

$$\mathbf{d}_j = \mathbf{x}_j + \boldsymbol{\alpha}_j \times \mathbf{r}_{pj} \quad (8.19)$$

and can be written as

$$\mathbf{d}_j = \begin{Bmatrix} x_j \\ y_j \\ x_j \end{Bmatrix} + \begin{bmatrix} 0 & z_{pj} & -y_{pj} \\ -z_{pj} & 0 & x_{pj} \\ y_{pj} & -x_{pj} & 0 \end{bmatrix} \begin{Bmatrix} \alpha_j \\ \beta_j \\ \gamma_j \end{Bmatrix}$$

and therefore in matrix notation, we have

$$\mathbf{d}_j = \mathbf{x}_j + \mathbf{R}_{pj} \boldsymbol{\alpha}_j \quad (8.20)$$

To calculate the reactions acting on each body, the relative displacements between the connecting points (stretch) should be calculated.

The relative displacements are given by

$$\mathbf{d} = \mathbf{d}_j - \mathbf{d}_i \quad (8.21)$$

The reaction forces due to the relative displacements on each body are given by

$$\mathbf{F}_s = \mathbf{K}_p \mathbf{d} \quad (8.22)$$

For equal but opposite directions, we have

$$\mathbf{F}_s = -\mathbf{K}_p \mathbf{d} \quad (8.23)$$

Moments for spring forces acting at points \mathbf{r}_i and \mathbf{r}_j on bodies i and j , respectively, are given by

$$\mathbf{M}_i = \mathbf{r}_i \times \mathbf{F}\mathbf{s}_i \quad (8.24)$$

On body j , we have

$$\mathbf{M}_j = \mathbf{r}_j \times \mathbf{F}\mathbf{s}_j \quad (8.25)$$

The cross-products may be expressed in matrix form as

$$\mathbf{M}_i = \mathbf{r}_i \times \mathbf{F}\mathbf{s}_i = \begin{bmatrix} 0 & -z_{pi} & y_{pi} \\ z_{pi} & 0 & -x_{pi} \\ -y_{pi} & x_{pi} & 0 \end{bmatrix} \begin{Bmatrix} \mathbf{F}s_{xi} \\ \mathbf{F}s_{yi} \\ \mathbf{F}s_{zi} \end{Bmatrix} \quad (8.26)$$

$$\mathbf{M}_j = \mathbf{r}_j \times \mathbf{F}\mathbf{s}_j = \begin{bmatrix} 0 & -z_{pj} & y_{pj} \\ z_{pj} & 0 & -x_{pj} \\ -y_{pj} & x_{pj} & 0 \end{bmatrix} \begin{Bmatrix} \mathbf{F}s_{xj} \\ \mathbf{F}s_{yj} \\ \mathbf{F}s_{zj} \end{Bmatrix} \quad (8.27)$$

Note that the matrices in Equation 8.26 and Equation 8.27 are transposed forms of the matrices in Equation 8.15 and Equation 8.16

$$\mathbf{R}_{pi}^T = \begin{bmatrix} 0 & -z_{pi} & y_{pi} \\ z_{pi} & 0 & -x_{pi} \\ -y_{pi} & x_{pi} & 0 \end{bmatrix} \quad (8.28)$$

$$\mathbf{R}_{pj}^T = \begin{bmatrix} 0 & -z_{pj} & y_{pj} \\ z_{pj} & 0 & -x_{pj} \\ -y_{pj} & x_{pj} & 0 \end{bmatrix} \quad (8.29)$$

Now the equations of motion can be compiled for the translation of body i

$$\mathbf{m}_i \ddot{\mathbf{x}}_i + \mathbf{K}_p \mathbf{d}_i - \mathbf{K}_p \mathbf{d}_j = \mathbf{F}_i \quad (8.30)$$

In this case, \mathbf{F}_i is the vector of external forces acting on body i . Substituting \mathbf{d}_i and \mathbf{d}_j into Equation 8.30, from Equation 8.18 and Equation 8.20 we have

$$\mathbf{m}_i \ddot{\mathbf{x}}_i + \mathbf{K}_p(\mathbf{x}_i + \mathbf{R}_{pi}\boldsymbol{\alpha}_i) - \mathbf{K}_p(\mathbf{x}_j + \mathbf{R}_{pj}\boldsymbol{\alpha}_j) = \mathbf{F}_i \quad (8.31)$$

Expanding this, we get

$$\mathbf{m}_i \ddot{\mathbf{x}}_i + \mathbf{K}_p \mathbf{x}_i + \mathbf{K}_p \mathbf{R}_{pi} \boldsymbol{\alpha}_i - \mathbf{K}_p \mathbf{x}_j - \mathbf{K}_p \mathbf{R}_{pj} \boldsymbol{\alpha}_j = \mathbf{F}_i \quad (8.32)$$

Similarly, for body j , substituting the expressions for \mathbf{d}_i and \mathbf{d}_j , we get

$$\mathbf{m}_j \ddot{\mathbf{x}}_j + \mathbf{K}_p \mathbf{d}_i - \mathbf{K}_p \mathbf{d}_j = \mathbf{F}_j \quad (8.33)$$

Again, \mathbf{F}_j in this case is the vector of external forces acting on body j .

$$\mathbf{m}_j \ddot{\mathbf{x}}_j + \mathbf{K}_p(\mathbf{x}_i + \mathbf{R}_{pi}\boldsymbol{\alpha}_i) - \mathbf{K}_p(\mathbf{x}_j + \mathbf{R}_{pj}\boldsymbol{\alpha}_j) = \mathbf{F}_j \quad (8.34)$$

$$\mathbf{m}_j \ddot{\mathbf{x}}_j + \mathbf{K}_p \mathbf{x}_i + \mathbf{K}_p \mathbf{R}_{pi} \boldsymbol{\alpha}_i - \mathbf{K}_p \mathbf{x}_j - \mathbf{K}_p \mathbf{R}_{pj} \boldsymbol{\alpha}_j = \mathbf{F}_j \quad (8.35)$$

With Equation 8.32 and Equation 8.35, the force–acceleration equations are complete.

Moment Equations

The moment equation may be written for body i as shown in Equation 8.36, where \mathbf{M}_i is the external moment acting on body i .

$$\mathbf{J}_i \ddot{\boldsymbol{\alpha}}_i + \mathbf{r}_i \times (\mathbf{K}_p \mathbf{d}_i - \mathbf{K}_p \mathbf{d}_j) = \mathbf{M}_i \quad (8.36)$$

Substituting expressions for \mathbf{d}_i and \mathbf{d}_j and converting the cross-product to the matrix form, we get

$$\mathbf{J}_i \ddot{\alpha}_i + \mathbf{R}_{pi}^T (\mathbf{K}_p (\mathbf{x}_i + \mathbf{R}_{pi} \alpha_i) - \mathbf{K}_p (\mathbf{x}_j + \mathbf{R}_{pj} \alpha_j)) = \mathbf{M}_i \quad (8.37)$$

Expanding this, we get

$$\mathbf{J}_i \ddot{\alpha}_i + \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{x}_i + \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pi} \alpha_i - \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{x}_j - \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{M}_i \quad (8.38)$$

The moment equation may be written for body j as given in Equation 8.39, where \mathbf{M}_j is the external moment acting on body j . Thus,

$$\mathbf{J}_j \ddot{\alpha}_j - \mathbf{r}_j \times (\mathbf{K}_p \mathbf{d}_i - \mathbf{K}_p \mathbf{d}_j) = \mathbf{M}_j \quad (8.39)$$

Substituting \mathbf{d}_i and \mathbf{d}_j and converting the cross-product to the matrix form, we get

$$\mathbf{J}_j \ddot{\alpha}_j - \mathbf{R}_{pj}^T (\mathbf{K}_p (\mathbf{x}_i + \mathbf{R}_{pi} \alpha_i) - \mathbf{K}_p (\mathbf{x}_j + \mathbf{R}_{pj} \alpha_j)) = \mathbf{M}_j \quad (8.40)$$

Expanding this, we get

$$\mathbf{J}_j \ddot{\alpha}_j - \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{x}_i - \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pi} \alpha_i + \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{x}_j + \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{M}_j \quad (8.41)$$

If we then collect Equation 8.32 and Equation 8.38 for body i , then Equation 8.32 becomes

$$\mathbf{m}_i \ddot{\mathbf{x}}_i + \mathbf{K}_p \mathbf{x}_i + \mathbf{K}_p \mathbf{R}_{pi} \alpha_i - \mathbf{K}_p \mathbf{x}_j - \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{F}_i \quad (8.42)$$

and Equation 8.38 becomes

$$\mathbf{J}_i \ddot{\alpha}_i + \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{x}_i + \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pi} \alpha_i - \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{x}_j - \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{M}_i \quad (8.43)$$

Expressing Equation 8.42 and Equation 8.43 in matrix form, we have

$$\begin{bmatrix} \mathbf{m}_i & 0 \\ 0 & \mathbf{J}_i \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{x}}_i \\ \ddot{\alpha}_i \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pi} \\ \mathbf{R}_{pi}^T \mathbf{K}_p & \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pi} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_i \\ \alpha_i \end{Bmatrix} - \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pj} \\ \mathbf{R}_{pi}^T \mathbf{K}_p & \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pj} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_j \\ \alpha_j \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_i \\ \mathbf{M}_i \end{Bmatrix} \quad (8.44)$$

Similarly, if we collect Equation 8.34 and Equation 8.41 for body j , then Equation 8.34 becomes

$$\mathbf{m}_j \ddot{\mathbf{x}}_j - \mathbf{K}_p \mathbf{x}_i - \mathbf{K}_p \mathbf{R}_{pi} \alpha_i + \mathbf{K}_p \mathbf{x}_j + \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{F}_j \quad (8.45)$$

and Equation 8.41 becomes

$$\mathbf{J}_j \ddot{\alpha}_j - \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{x}_i - \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pi} \alpha_i + \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{x}_j + \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pj} \alpha_j = \mathbf{M}_j \quad (8.46)$$

Expressing Equation 8.45 and Equation 8.46 in the matrix form, we have

$$\begin{bmatrix} \mathbf{m}_j & 0 \\ 0 & \mathbf{J}_j \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{x}}_j \\ \ddot{\alpha}_j \end{Bmatrix} - \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pi} \\ \mathbf{R}_{pj}^T \mathbf{K}_p & \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pi} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_i \\ \alpha_i \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pj} \\ \mathbf{R}_{pj}^T \mathbf{K}_p & \mathbf{R}_{pj}^T \mathbf{K}_p \mathbf{R}_{pj} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_j \\ \alpha_j \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_j \\ \mathbf{M}_j \end{Bmatrix} \quad (8.47)$$

Overall, the equations of motion are now complete. Equation 8.44 and Equation 8.47 provide all that is needed to complete the final equations of motion. It is worth restating that the stiffness and damping matrices are identical in their structure. To obtain a damping matrix, all one needs to do is to replace the stiffness coefficients with the corresponding damping coefficients.

8.3 A Numerical Example

In order to illustrate the use of the equations given before, let us consider a rigid body flexibly supported by a number of springs. For this, the simplest starting point would be Equation 8.44

$$\begin{bmatrix} \mathbf{m}_i & 0 \\ 0 & \mathbf{J}_i \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{x}}_i \\ \ddot{\alpha}_i \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pi} \\ \mathbf{R}_{pi}^T \mathbf{K}_p & \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pi} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_i \\ \alpha_i \end{Bmatrix} - \begin{bmatrix} \mathbf{K}_p & \mathbf{K}_p \mathbf{R}_{pj} \\ \mathbf{R}_{pi}^T \mathbf{K}_p & \mathbf{R}_{pi}^T \mathbf{K}_p \mathbf{R}_{pj} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_j \\ \alpha_j \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_i \\ \mathbf{M}_i \end{Bmatrix} \quad (8.48)$$

Since body j does not exist, all the terms relevant to body j will disappear. Furthermore, since we are dealing with a single mass, the suffix i is not needed either. However, for n number of springs, the stiffness matrices need to be summed-up. Summation has to be carried out for each stiffness p attached at a position on the body. We then have

$$\begin{bmatrix} \mathbf{m} & \mathbf{0} \\ \mathbf{0} & \mathbf{J} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{x}} \\ \ddot{\boldsymbol{\alpha}} \end{Bmatrix} + \begin{bmatrix} \sum_{p=1}^n \mathbf{K}_p & \sum_{p=1}^n \mathbf{K}_p \mathbf{R}_p \\ \sum_{p=1}^n \mathbf{R}_p^T \mathbf{K}_p & \sum_{p=1}^n \mathbf{R}_p^T \mathbf{K}_p \mathbf{R}_p \end{bmatrix} \begin{Bmatrix} \mathbf{x} \\ \boldsymbol{\alpha} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F} \\ \mathbf{M} \end{Bmatrix} \quad (8.49)$$

For a situation where the axes of the springs are parallel to the global coordinate system, no transformation of the stiffness matrix is needed. Hence, $\mathbf{k}_p = \mathbf{K}_p$. To obtain the submatrices of the stiffness matrix given in Equation 8.49, start with the stiffness matrix for spring p . Specifically,

$$\mathbf{K}_p = \begin{bmatrix} k_{px} & 0 & 0 \\ 0 & k_{py} & 0 \\ 0 & 0 & k_{pz} \end{bmatrix} \quad (8.50)$$

Now, $\mathbf{K}_p \mathbf{R}_p$ is given by

$$\mathbf{K}_p \mathbf{R}_p = \begin{bmatrix} k_{px} & 0 & 0 \\ 0 & k_{py} & 0 \\ 0 & 0 & k_{pz} \end{bmatrix} \begin{bmatrix} 0 & z_p & -y_p \\ -z_p & 0 & x_p \\ y_p & -x_p & 0 \end{bmatrix} \quad (8.51)$$

Expanding this, we get

$$\mathbf{K}_p \mathbf{R}_p = \begin{bmatrix} 0 & k_{px} z_p & -k_{px} y_p \\ -k_{py} z_p & 0 & k_{py} x_p \\ k_{pz} y_p & -k_{pz} x_p & 0 \end{bmatrix} \quad (8.52)$$

For $\mathbf{R}_p^T \mathbf{K}_p$, we have

$$\mathbf{R}_p^T \mathbf{K}_p = \begin{bmatrix} 0 & -z_p & y_p \\ z_p & 0 & -x_p \\ -y_p & x_p & 0 \end{bmatrix} \begin{bmatrix} k_{px} & 0 & 0 \\ 0 & k_{py} & 0 \\ 0 & 0 & k_{pz} \end{bmatrix} \quad (8.53)$$

Expanding this, we get

$$\mathbf{R}_p^T \mathbf{K}_p = \begin{bmatrix} 0 & -k_{py} z_p & k_{pz} y_p \\ k_{px} z_p & 0 & -k_{pz} x_p \\ -k_{px} y_p & k_{py} x_p & 0 \end{bmatrix} \quad (8.54)$$

Finally, $\mathbf{R}_p^T \mathbf{K}_p \mathbf{R}_p$ is given by

$$\mathbf{R}_p^T \mathbf{K}_p \mathbf{R}_p = \begin{bmatrix} 0 & -k_{py} z_p & k_{pz} y_p \\ k_{px} z_p & 0 & -k_{pz} x_p \\ -k_{px} y_p & k_{py} x_p & 0 \end{bmatrix} \begin{bmatrix} 0 & z_p & -y_p \\ -z_p & 0 & x_p \\ y_p & -x_p & 0 \end{bmatrix} \quad (8.55)$$

$$\mathbf{R}_p^T \mathbf{K}_p \mathbf{R}_p = \begin{bmatrix} k_{pz}y_p^2 + k_{py}z_p^2 & -k_{pz}x_p y_p & -k_y x_p z_p \\ -k_{pz}x_p y_p & k_{pz}x_p^2 + k_{px}z_p^2 & -k_{px}y_p z_p \\ -k_{py}x_p z_p & -k_{px}y_p z_p & k_{py}x_p^2 + k_{px}y_p^2 \end{bmatrix} \quad (8.56)$$

The overall stiffness matrix from Equation (8.48) for a single spring is given by

$$\begin{bmatrix} k_{px} & 0 & 0 & 0 & k_{px}z_p & -k_{px}y_p \\ 0 & k_{py} & 0 & -k_{py}z_p & 0 & k_{py}x_p \\ 0 & 0 & k_{pz} & k_{pz}y_p & -k_{pz}x_p & 0 \\ 0 & -k_{py}z_p & k_{pz}y_p & k_{pz}y_p^2 + k_{py}z_p^2 & -k_{pz}x_p y_p & -k_{py}x_p z_p \\ k_{px}z_p & 0 & -k_{pz}x_p & -k_{pz}x_p y_p & k_{pz}x_p^2 + k_{px}z_p^2 & -k_{px}y_p z_p \\ -k_{px}y_p & k_{py}x_p & 0 & -k_{py}x_p z_p & -k_{px}y_p z_p & k_{py}x_p^2 + k_{px}y_p^2 \end{bmatrix} \quad (8.57)$$

The mass matrix is diagonal and, for the inertia matrix, it is assumed that the principal axes of the body coincide with the global coordinate system. Specifically,

$$\mathbf{m} = \begin{bmatrix} m & 0 & 0 \\ 0 & m & 0 \\ 0 & 0 & m \end{bmatrix} \quad (8.58)$$

$$\mathbf{J} = \begin{bmatrix} I_{xx} & 0 & 0 \\ 0 & I_{yy} & 0 \\ 0 & 0 & I_{zz} \end{bmatrix} \quad (8.59)$$

Now, the overall equations of motion may be assembled for n springs.

$$\begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 & 0 \\ 0 & 0 & 0 & I_{xx} & 0 & 0 \\ 0 & 0 & 0 & 0 & I_{yy} & 0 \\ 0 & 0 & 0 & 0 & 0 & I_{zz} \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{y} \\ \ddot{z} \\ \ddot{\alpha} \\ \ddot{\beta} \\ \ddot{\gamma} \end{Bmatrix} + \sum_{p=1}^n \begin{bmatrix} k_{px} & 0 & 0 & 0 & k_{px}z_p & -k_{px}y_p \\ 0 & k_{py} & 0 & -k_{py}z_p & 0 & k_{py}x_p \\ 0 & 0 & k_{pz} & k_{pz}y_p & -k_{pz}x_p & 0 \\ 0 & -k_{py}z_p & k_{pz}y_p & k_{pz}y_p^2 + k_{py}z_p^2 & -k_{pz}x_p y_p & -k_{py}x_p z_p \\ k_{px}z_p & 0 & -k_{pz}x_p & -k_{pz}x_p y_p & k_{pz}x_p^2 + k_{px}z_p^2 & -k_{px}y_p z_p \\ -k_{px}y_p & k_{py}x_p & 0 & -k_{py}x_p z_p & -k_{px}y_p z_p & k_{py}x_p^2 + k_{px}y_p^2 \end{bmatrix} \begin{Bmatrix} x \\ y \\ z \\ \alpha \\ \beta \\ \gamma \end{Bmatrix} = \begin{Bmatrix} F_x \\ F_y \\ F_z \\ M_x \\ M_y \\ M_z \end{Bmatrix} \quad (8.60)$$

8.3.1 A Uniform Rectangular Prism

A rectangular prism is supported by four springs as shown in Figure 8.3. Springs have stiffness values in all three directions (k_{px} , k_{py} , k_{pz} , where p is the spring number). The axes of each spring in which the stiffness values are measured are parallel to the principal axes of the springs, which in turn are parallel to the global coordinate system of the rectangular prism. Thus, no transformation is needed. The end of spring p is located at (x_p, y_p, z_p) , measured relative to the COG of the body. The mass of the prism is m and the principal moments of inertia are I_{xx} , I_{yy} , and I_{zz} . A simplified equation of motion of the system in 3-D space may be obtained from Equation 8.59. If one attempts to carry this out, one will realize that some terms will disappear because the z components of the positions are all zero and some will disappear because of the symmetry of points.

FIGURE 8.3 A rectangular prism supported on springs.

The body shown in Figure 8.3 corresponds to $m = 1000$ kg, moments of inertia $I_{xx} = 10$ kg m², $I_{yy} = 20$ kg m², and $I_{zz} = 30$ kg m², supported by four identical (thus, point suffix p is dropped) springs with stiffness values ($k_x = 10,000$ N/m, $k_y = 20,000$ N/m, $k_z = 30,000$ N/m). The positions of the springs are given as follows:

$$P1(1, 2, 0)$$

$$P2(1, -2, 0)$$

$$P3(-1, 2, 0)$$

$$P4(-1, -2, 0)$$

The coordinates imply that the COG is on the bottom plane of the prism. The system has six degrees of freedom and all six natural frequencies will be calculated.

Since stiffness parameters are on the Oxy plane, no coupling will occur between $(x$ and $\beta)$ and $(y$ and $\alpha)$. Similarly, the vertical motion is also uncoupled from the others due to symmetry. Thus,

$$\omega_x = \sqrt{\frac{\sum_{p=1}^4 k_{px}}{m}} = \sqrt{\frac{40,000}{1000}} = 6.32 \text{ rad/sec} = 1.0065 \text{ Hz}$$

$$\omega_y = \sqrt{\frac{\sum_{p=1}^4 k_{py}}{m}} = \sqrt{\frac{80,000}{1000}} = 8.94 \text{ rad/sec} = 1.4235 \text{ Hz}$$

$$\omega_z = \sqrt{\frac{\sum_{p=1}^4 k_{pz}}{m}} = \sqrt{\frac{120,000}{1000}} = 10.95 \text{ rad/sec} = 1.743 \text{ Hz}$$

$$\omega_\alpha = \sqrt{\frac{\sum_{p=1}^4 y_p^2 k_{pz}}{I_{xx}}} = \sqrt{\frac{4 \times 2^2 \times 30,000}{10}} = 219.09 \text{ rad/sec} = 34.87 \text{ Hz}$$

$$\omega_{\beta} = \sqrt{\frac{\sum_{p=1}^4 x_p^2 k_{pz}}{I_{yy}}} = \sqrt{\frac{4 \times 1^2 \times 30,000}{20}} = 77.45 \text{ rad/sec} = 12.32 \text{ Hz}$$
$$\omega_{\gamma} = \sqrt{\frac{\sum_{p=1}^4 (x_p^2 k_{py} + y_p^2 k_{px})}{I_{zz}}} = \sqrt{\frac{4(1^2 \times 20,000 + 2^2 \times 10,000)}{30}} = 89.44 \text{ rad/sec} = 14.23 \text{ Hz}$$

8.3.2 VIBRATIO Output

For the numerical problem given above, the output obtained from the software package VIBRATIO (see Appendix 8A for the full listing) is tabulated below.

Dominant Oscillation Direction	Frequencies
Frequency in X	1.01 Hz (60 CPM)
Frequency in Y	1.42 Hz (85 CPM)
Frequency in Z	1.74 Hz (105 CPM)
Frequency in alpha	34.87 Hz (2092 CPM)
Frequency in beta	12.33 Hz (740 CPM)
Frequency in gamma	14.24 Hz (854 CPM)

8.4 An Industrial Vibration Design Problem

In the analysis of vibration characteristics of an engine or an engine-generator set, flexibly supported rigid-body representations are commonly used. In the case study given here, an engine assembly system is considered. In designing an engine mounting system, engineers consider a number of issues. Particularly useful are: static deflection; natural frequencies and spread of these frequencies relative to the engine speed range; time response under shock or other transient loads; and frequency response of the system, especially when subjected to unbalanced engine-generated excitations.

8.4.1 Static Deflection

This problem involves the selection of mounting geometry and mount stiffness parameters. Here, the design engineer seeks to achieve a pure deflection with as little tilt as possible. In principle, there is nothing wrong with some mounts deflecting more than the others, but an excessive tilt normally indicates other problems such as a high degree of coupling between the modes of motion. However, achieving a pure vertical deflection, at least mathematically, is relatively easy and involves the selection of spring positions/stiffness values to satisfy the following conditions:

$$\sum_{p=1}^{n\text{-spring}} y_p k_{pz} = 0$$

and

$$\sum_{p=1}^{n\text{-spring}} x_p k_{pz} = 0.$$

Here, x_p and y_p are spring mount positions and k_{pz} is the spring stiffness in the z direction. In addition, the designer needs to ensure that the static deflection is well within the allowable deflection range, especially since it needs to account for any additional deflection due to vibration.

8.4.2 Natural Frequencies

Normally, design application demands that the natural frequencies are kept away from the running speed of an engine. Such a requirement is easy to satisfy for single-DoF systems. However, in real-life situations, the number of DoF(s) is six just for a single rigid body. Any change to the mounting configuration or stiffness parameters (or mass distribution) will affect all six natural frequencies. In order to be able to modify a natural frequency corresponding to a particular mode shape (e.g., resonance in the vertical direction), a vibration design engineer will attempt to decouple various modes of oscillation. Such a design requirement, however, is unrealistic for many engineering problems, even for a single rigid body, due to space considerations and is practically impossible for multiple rigid body systems. However, it is possible to achieve partial decoupling. For example, the condition given above for pure vertical deflection will also provide decoupling between the rocking motion about two-coordinate systems (about Ox and Oy) in the horizontal plane and vertical motion.

8.4.3 Transient Response Analysis

Static deflection analysis and modal analysis are normally essential (see Chapter 3). However, there are two more problem-specific analyses that a design engineer may need to perform depending on the problem. For example, in many engineering applications, the response of a flexibly supported system to a shock loading is very important. In this case, coupling among modes as well as stiffness of the system play an important role in determining the levels of shock transmission to the engine system. As a rule of thumb, the softer the spring the smaller the shock transferred to the flexibly mounted structure. Making mounting stiffness elements softer may not be a realistic option (see Chapter 32) as this can result in unacceptable static deflections and may even be in conflict with the requirements discussed above in relation to the positioning of a natural frequency relative to the operating speed of the engine and the static deflection.

8.4.4 Frequency Analysis

Frequency analysis is probably one of the most useful among the various types of analysis listed above. If the vibration problem is not transient, then it is a problem involving a steady-state vibration. The analysis of a steady-state vibration problem under sinusoidal excitation is normally referred to as frequency analysis (see Chapter 2). In mathematical terms, this is the particular solution of the differential equation of motion. Under a sinusoidal excitation, a vibrating system reaches a steady-state vibration and frequency analysis provides information of the amplitude of vibration as a function of excitation frequency. If there is more than one excitation force, then the resulting motion will be a combination of the results due to each excitation. Multiexcitation force analysis is sometimes referred to as harmonics analysis (see Chapter 2). Here, the designer needs to ensure that the highest amplitude of oscillation under harmonic excitation does not exceed the safe limits for the system and, in particular, for the mounts.

Although design considerations linked to static deflection, positioning of natural frequencies, decoupling of modes, and response to shock represent a large proportion of vibration design problems, there are other and more complex design specifications. For example, minimizing vibration at a point on a flexibly supported body may be considered a design objective. Such a requirement may then cause problems where the engineer intends to place a drive shaft coupling or an additional mounting at this position. Because the vibration (or deflection) is at its minimum at the assembly point, a coupling or additional mount will add a minimum constraint to the system.

Obviously, all the design objectives discussed above have to be satisfied within the physical constraints relating to the problem at hand. In general, these constraints are associated with space and the stiffness range of industrially available mountings.

8.4.5 A Flexibly Supported Engine — A Numerical Problem

The example considered here involves a study of an engine-mounting configuration. Mounting configurations are restricted by the geometry and little flexibility exists in modifying these positions. They are located by the engine manufacturer. To perform vibration analysis, the mass/moments of inertia values of the system, the coordinates of the mounting positions relative to the COG, and the forces acting on the system are needed. Although the mass is normally given or easy to obtain, moments of inertia and the COG are not always supplied by engine manufacturers. Even though it is possible to build a solid model of an engine in order to calculate moments of inertia, this is a rather tedious and costly task. The alternative is to define engine moments of inertia in an approximate manner. This can be done by assuming that the main assemblies of the engine are made of regular geometrical primitives representing approximate shapes without going into exact geometrical models. Such an approach works reasonably well, especially since the mass values of these primitives can be obtained in an exact manner. When calculating the moments of inertia and the overall mass of the assembly, its COG can also be calculated. Once these are obtained, the mount positions can be calculated relative to the COG. Having obtained the mass, the moments of inertia, the COG, and the mount position coordinates relative to the COG, the main step of analysis may be started. This involves selecting the mount stiffness parameters in such a way that the various conditions and objectives described above are met. The vibration design, like all engineering problems, involves reconciling many conflicting requirements.

Engine mass and moments of inertia (symmetry of mass distribution is assumed)
 $m = 250 \text{ kg}$ and moments of inertia $I_{xx} = 45 \text{ kg m}^2$, $I_{yy} = 80 \text{ kg m}^2$, and $I_{zz} = 110 \text{ kg m}^2$.

Mounts stiffness values:
($k_x = 150,000 \text{ N/m}$, $k_y = 150,000 \text{ N/m}$, $k_z = 300,000 \text{ N/m}$).

Mount positions (all in mm):

1	0.000	100.000	− 75.000
2	250.000	0.000	− 75.000
3	0.000	− 100.000	− 75.000
4	− 170.000	0.000	− 75.000

8.4.5.1 Satisfying Static Deflection

On running a static analysis under a vertical load of 2500 N (weight), the following results are obtained: (displacements are in mm and angles are in rad)

X	Y	Z	Alpha	Beta	Gamma	xc	yc	zc
0.1392	0.0000	2.1205	0.0000	0.0019	0.0000	1142.5000	0.0000	− 75.0000

In relation to the static deflection, there are two considerations: (i) overall deflection should not be more than what is allowed by the deflection range of the springs selected for the design, and (ii) the static position and orientation of the engine should not be outside what is allowed by spatial and other constraints; i.e., it should not tilt to one side excessively. In either case, stiffer springs will tend to solve

the problem. However, such a choice may not be the best for transients, shocks, and vibration transmission from the supporting frame. “Tilt” level calculated above is assumed to be small (0.0019 rad).

The results from the program also list the deflection at the mount positions (in mm) as: mass no. = 1

Mount no.	Position			Deflection		
	X	Y	Z	x	y	z
1	0.000	100.000	− 75.000	0.000	0.000	2.120
2	250.000	0.000	− 75.000	0.000	0.000	1.656
3	0.000	− 100.000	− 75.000	0.000	0.000	2.120
4	− 170.000	0.000	− 75.000	0.000	0.000	2.436

The maximum deflection is at the fourth mount position and is 2.436 mm. The mount selected should give a deflection range that would extend well beyond this to ensure that any additional deflection due to vibration could be accommodated.

The coordinates *xc*, *yc*, *zc* give the instantaneous center of rotation for this particular static deflection result. This point (as discussed above) may be used in some design applications as it remains stationary during the deflection.

8.4.5.2 Eigenvalue Analysis

The eigenvalue analysis (see Chapter 3 and Appendix 3A) will help ensure that the natural frequencies are not in the vicinity of the idling speed of the engine. It may also help to minimize the number of natural frequencies in the speed range of the engine.

Since the spring positions and their locations are already specified to satisfy the considerations for static deflection, it becomes difficult to modify them to satisfy the “natural frequency” requirements as well. However, all stiffness values could be increased together in the same proportion. This ensures that the “no tilt” condition is maintained. Of course, stiffening now reduces the static deflection and is likely to increase the vibration transmission to the frame.

The eigenvalue analysis results are listed below. Here, the natural frequencies spread from 1.98 to 12.09 Hz. The widest gap between these frequencies is between 3.17 and 8.69 Hz. It would be desirable to have the idling speed in the middle of this range. It is equally important that the cruising speed does not coincide with the two higher frequencies.

X	Y	Z	Alpha	Beta	Gamma
1.0000	0.0000	Frequency in X = 8.63 Hz (518 CPM)			
		− 0.0111	0.0000	− 0.2709	0.0000
0.0000	1.0000	Frequency in Y = 8.69 Hz (521 CPM)			
		0.0000	0.4403	0.0000	0.0484
− 0.0051	0.0000	Frequency in Z = 12.09 Hz (725 CPM)			
		− 1.0000	0.0000	0.0685	0.0000
0.0000	0.0797	Frequency in alpha = 1.98 Hz (119 CPM)			
		0.0000	− 1.0000	0.0000	− 0.0226
0.0869	0.0000	Frequency in beta = 3.17 Hz (190 CPM)			
		0.0215	0.0000	1.0000	0.0000
0.0000	− 0.0163	Frequency in gamma = 2.13 Hz (128 CPM)			
		0.0000	− 0.0625	0.0000	1.0000

In order to achieve decoupling between different motions, one practical technique is to minimize the distance between the COG and the “center of stiffness.” Center of stiffness is a crude term used in industry to ensure that the coupling between different motions of body is minimized. The definition of center of stiffness is similar to that of the COG. The *Ox* axis is located in such a

way that $\sum_p y_p k_{pz} = 0$ holds. Then this axis will pass through the center of stiffness. Similarly, $\sum_p x_p k_{pz} = 0$ will hold for the Oy axis passing through the center of stiffness. If the center of stiffness coincides with the COG and the axes defined by the first moment of stiffness coincide with the principal axis of mass, then full decoupling can be achieved. As far as the horizontal plane is concerned, this also ensures that the assembly is leveled. Note that the relationships are the same as the “no tilt” condition described above for static deflection. Normally, it may not be possible to achieve this in all three planes and the designer may choose to achieve this in one plane where the excitation forces are the greatest. However, it is common among designers to focus on the horizontal plane alone, purely due to deflection under gravity considerations.

8.4.5.3 Time Domain Analysis — Analysis of the System under a Shock Loading

Suppose that a 10 g, 10 msec, half sine shock is applied in the vertical, z , direction. The shock response in the z direction is shown in Figure 8.4. The shock response in the y direction is shown in Figure 8.5.

The results show that, in addition to static deflection, if the mounts were to withstand the applied shock, they should be able to deflect 9 mm in shear and more than 6 mm in the vertical directions.

8.4.5.4 Frequency Analysis

The frequency analysis specifications are given below.

The engine is subjected to an unbalanced force which is known to be proportional to the square of the engine running speed. In other words, this is given as $A\omega^2$. It is measured that when the engine speed is 300 rpm the unbalanced force is 250 N. A simple calculation shows that $A = 1.013$. The force menu option 20 in VIBRATIO provides the required excitation, which increases with the square of the running speed. The option 20 allows the A value to be linearly increased between the start and end frequencies during which the excitation is active. In our case, this is to be taken to be the same (frequency is independent of the A value). The vertical amplitude vs. frequency results are given in Figure 8.6. The amplitudes in other directions are much smaller and are not shown here. The analysis is not carried out beyond 15 Hz as we know already that the maximum resonance is at 12.09 Hz. According to the result, the selected mount should allow a 16 mm deflection on top of static deflection. Now, the designer should be in a position to make a decision on whether the selected

FIGURE 8.4 Shock response in the z direction.

FIGURE 8.5 Shock response in the y direction.

spring type is acceptable or not. If the answer is no, then the whole analysis process has to be repeated to find an acceptable solution.

8.5 Programming Considerations

Equations developed in this chapter are formulated and structured in such a way that they can be used for developing general vibration analysis software. As the equations given above refer to bodies i and j , they can be placed in the global coordinates accordingly. Four submatrices (6×6) will be placed as follows:

$$\begin{bmatrix} \mathbf{K}_r & \mathbf{K}_r \mathbf{R}_{pi} \\ \mathbf{R}_{pi}^T \mathbf{K}_r & \mathbf{R}_{pi}^T \mathbf{K}_r \mathbf{R}_{pi} \end{bmatrix}$$
 will be placed, starting from position $6(i - 1) + 1, 6(i - 1) + 1$

FIGURE 8.6 Frequency response in the z direction for unbalanced engine excitation.

$$\begin{aligned}
& - \begin{bmatrix} \mathbf{K}_r & \mathbf{K}_r \mathbf{R}_{pj} \\ \mathbf{R}_{pi}^T \mathbf{K}_r & \mathbf{R}_{pi}^T \mathbf{K}_r \mathbf{R}_{pj} \end{bmatrix} \text{ will be placed, starting from position } (6(i-1) + 1, 6(j-1) + 1) \\
& - \begin{bmatrix} \mathbf{K}_r & \mathbf{K}_r \mathbf{R}_{pi} \\ \mathbf{R}_{pj}^T \mathbf{K}_r & \mathbf{R}_{pj}^T \mathbf{K}_r \mathbf{R}_{pi} \end{bmatrix} \text{ will be placed, starting from position } (6(j-1) + 1, 6(i-1) + 1) \\
& \begin{bmatrix} \mathbf{K}_r & \mathbf{K}_r \mathbf{R}_{pj} \\ \mathbf{R}_{pj}^T \mathbf{K}_r & \mathbf{R}_{pj}^T \mathbf{K}_r \mathbf{R}_{pj} \end{bmatrix} \text{ will be placed, starting from position } (6(j-1) + 1, 6(j-1) + 1)
\end{aligned}$$

Entry to the global stiffness matrix must be additive (a new entry is added to the previously entered values to account for any contribution coming from other springs). In programming terms, the global stiffness matrix is constructed based on the spring count loop. Therefore, the data structure for a spring must be such that the end of the spring refers to the mass number. Hence, for a spring stiffness, submatrices could be located in the global matrix according to the mass numbers to which the ends of that spring are attached.

To start assembling the equations, the first step is to express the stiffness matrices in global coordinates. Here, it is assumed that the stiffness values are given in three orthogonal axes. These axes will be assumed to be the principal axes of the springs (in practice, this is not strictly correct and the assumption holds only for small deflections). The orientation of the principal axes relative to the global coordinates can be described in terms of Euler angles (or using direction cosines). Once the transformation matrix is obtained, then the stiffness can be expressed in the global coordinate system Equation 8.4. In developing one's own software, it is important to bear in mind the way the transformation matrix is constructed. Euler angles have to be applied one by one and the order in which they are processed is important. For example, to orient a given body, one may assume that, initially, its local coordinates are parallel to the principal coordinate frame. From here, the first Euler angle will rotate the body to a new orientation. Relative to this position, the next rotation will be applied, resulting in yet another orientation. Lastly, the third rotation will be applied relative to this orientation, giving the final position of the body under consideration. Assuming that these rotations are $\alpha \beta \gamma$ in the given order, the transformation matrix is built as

$$T = T(\alpha)T(\beta)T(\gamma)$$

In other words, any vector in the local coordinates will be transformed to the global coordinates in reverse order. To explain further, any vector in the local coordinates is first transformed by $T(\gamma)$, then the resulting vector is transformed by $T(\beta)$, and finally the resulting vector is transformed by $T(\alpha)$. The expression $\mathbf{X} = \mathbf{T}\mathbf{x}$ processes these matrices in that order.

Transformation will apply to spring stiffness matrices and inertia matrices. Therefore, the input to the vibration program has to account for Euler angles for each body and spring, and the order in which these rotations are performed.

Once the transformation is completed, all that remains is to perform the appropriate matrix algebra in order to construct the stiffness matrix for each spring and its location in the global stiffness matrix. The inertia matrix for each mass, after expressing it in the global coordinate frame by performing matrix transformation, will need to be placed in the appropriate location in the global inertia matrix.

8.6 VIBRATIO

8.6.1 Capabilities

VIBRATIO is a vibration analysis program designed to model flexibly supported multibody systems. An educational version is made available free of charge by the author of this chapter for the readers of

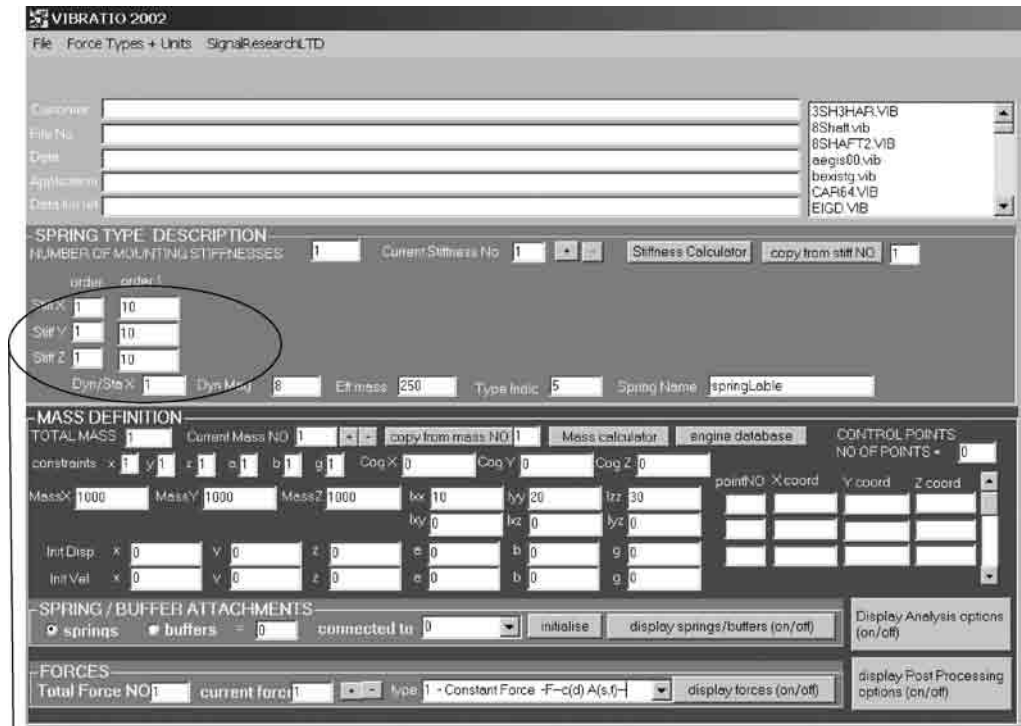

this handbook. The executable file could be downloaded from the website, www.signal-research.com. The educational version will allow analysis of a flexibly supported system not exceeding more than 10 masses (60 dof). For the purpose of supporting the theory presented in this handbook, four types of analysis are activated: static; eigenvalue (both damped and undamped); frequency domain; and time domain. Standard excitations for time and frequency domains will be based on the excitation functions available in the menu. Numerically defined excitations, and all the other modules, such as signal processing, finite-element shaft analysis, fatigue analysis, mass design, etc. are not available in this version.

8.6.2 Modeling on VIBRATIO

Click vibratio2002 from start/programs/vibratio2002 menu. The VIBRATIO screen shown in Figure 8.7 will be displayed. The top part of the frame gives inputs for application details. The date/time box can be double-clicked to produce current date and time. File options are listed in the file box. Only files with a VIB extension are filtered for the listing. You may also use the file menu to load VIBRATIO files. If you use any other extension to save your data, you will have to use the file menu to open it. VIB files are text files and can be read by any text editor. It is not advisable, however, to create these manually by using any editor other than VIBRATIO.

8.6.2.1 Entering Spring Data

The second section on this screen, titled “Spring Type Description,” is for entering spring stiffnesses. Here, the *types* of springs are defined, not the definition of individual springs.

Stiffnesses k_x , k_y and k_z .

FIGURE 8.7 VIBRATIO main window.

Order should always be set to 1. In general, it is assumed that the spring deflections can be described as polynomials, and “order” refers to order of the polynomial. Only linear capability is offered in the present version; thus, order must always be set to 1.

8.6.2.2 Entering Mass Data

When VIBRATIO runs, it automatically loads default mass data. To create a two-mass system, change “total mass” to 2. This is shown in Figure 8.8.

Normally, if these two masses are not the same then you will need to modify accordingly. Also, you may copy mass data from one previously defined mass to another by clicking the “copy from” button. CogX, CogY, CogZ are the centers of mass of the current mass relative to the COG of mass 1. It means that the program will not allow you to change the COG coordinates of mass 1. “Frame” shows that you have massX, massY, massZ values. For normal applications, mass does not have a directional property and values in each direction will be the same. There are applications where directional “effective mass” may be appropriate, such as modeling the ground mass for earthquake analysis.

Moment of inertia elements are calculated relative to the COG of current mass and about coordinates that are parallel to the coordinates of the global frame. The center of the global coordinate system coincides with the center of mass 1. If the principal coordinate system of the current body is not parallel to the global coordinate system, then cross-inertias I_{xy} , I_{xz} , I_{yz} need to be calculated. The full version of

Click “display springs/buffers (on/off)” button; Spring Connections table will appear.

The easiest way of creating spring attachments is to use “Spring Attachment Designer”. Click “Spring Attachment Designer”; the frame shown in Figure 8.10 will appear in the middle of the screen.

FIGURE 8.9 Entering spring data.

VIBRATIO offers a mass calculator that, among other things, can calculate the necessary transformation for given sets of Euler angles.

Control points: Here, you may enter the coordinates of points at which the linear deflection module will calculate the displacements. For time and frequency domain analyses this module is not used. Graphics programs come with options to create point tables for analyzing motions at those points.

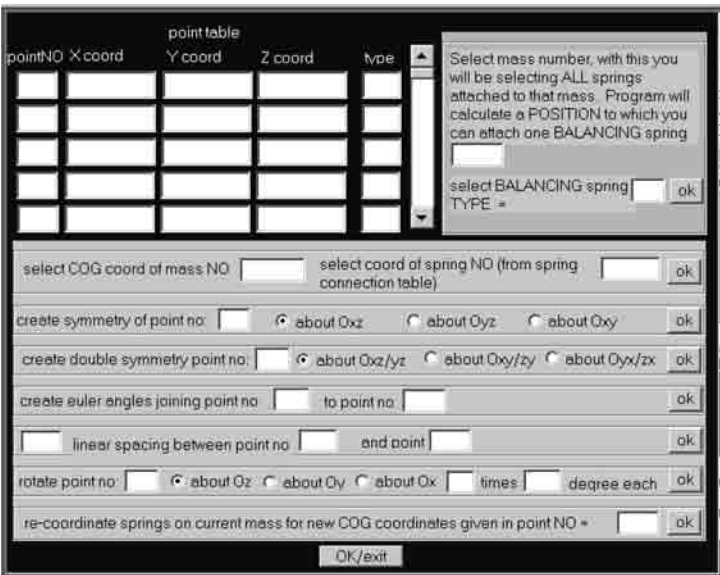

FIGURE 8.10 Spring attachment designer window.

Initial conditions: For each mass, initial conditions may be assigned (displacements and velocities) for time-domain analysis.

Now you have a two-mass system where both masses are identical.

8.6.2.3 Entering Spring Attachment Data

The process of entering spring data is illustrated in Figure 8.9 to Figure 8.11. The first step is to decide how these bodies are connected to the ground and to each other. Connection can be by a spring or a buffer. Buffers are not covered in this chapter. One needs to make sure that the spring option button is selected (spring option is selected as the default). Consider the option buttons. The “text box” refers to the total number of connections to be entered in this frame. Do not modify this one for now. What you enter in this box will depend on how you create these connections. The next very important action is to select “connected to” combo box. This refers to the mass number to which the current mass is connected. If the connection is to the ground, then “0” should be selected. Ground is called mass 0. Once you select a connection mass, “+” will appear in front of the mass number. This makes it easy to identify the masses to which a connection is made. If a “+” character had not been added, then the user would have to search all the mass numbers one by one to view the data. Even in a 10-mass system, this could involve checking 55 possible connections. Note that “connected to” lists mass numbers that are less than the current mass. For example, if the current mass number is 5, then the “connected to” list will have 4, 3, 2, 1, 0.

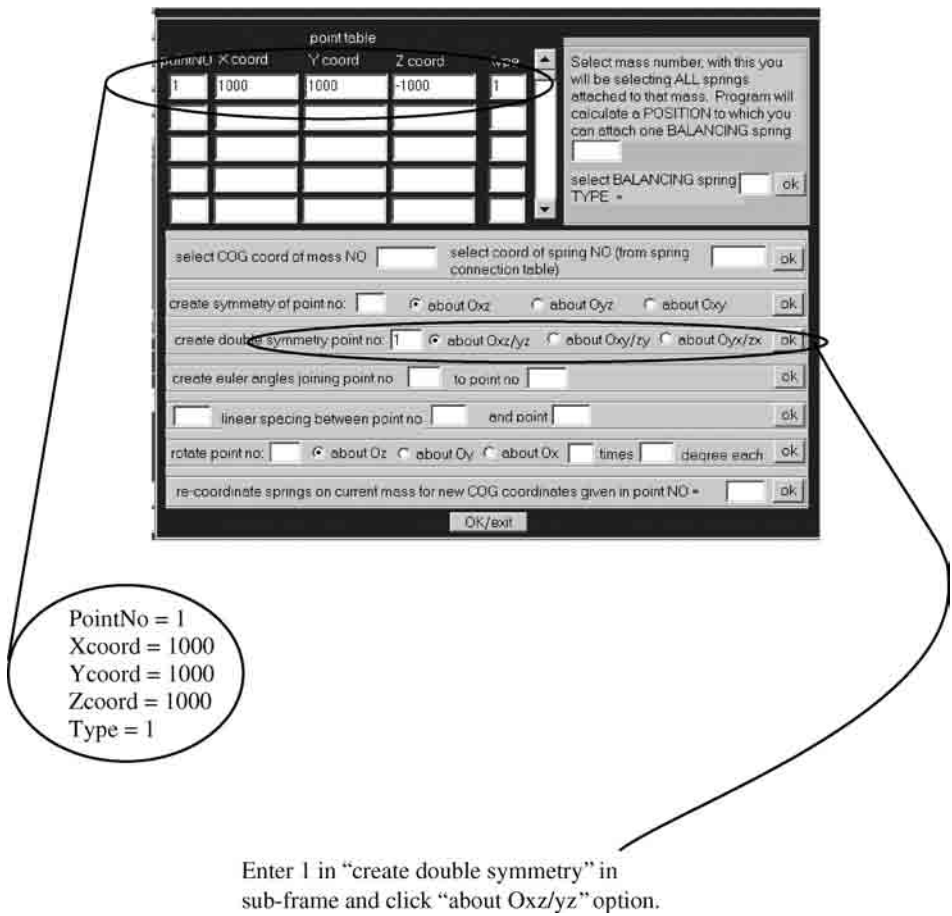

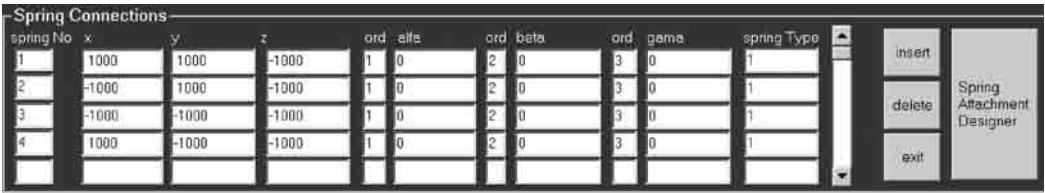

FIGURE 8.11 Spring data entry.

spring No	x	y	z	ord	alfa	ord	beta	ord	gamma	spring Type
1	1000	1000	-1000	1	0	2	0	3	0	1
2	-1000	1000	-1000	1	0	2	0	3	0	1
3	-1000	-1000	-1000	1	0	2	0	3	0	1
4	1000	-1000	-1000	1	0	2	0	3	0	1

Buttons: insert, delete, exit, Spring Attachment Designer

FIGURE 8.12 Four spring attachments generated by “spring attachment designer.”

To start entering connections, make sure that the current mass is 1, the “spring” rather than the “buffer” option is selected, and, in this case, “connected to” would be 0 (the only option). Also, make sure that you have pressed the “display springs/buffers” (on/off) button. Now you have three options:

- 1. Enter the total number of spring connections and start entering the data one by one, but make sure that you enter no more than the total connections you had specified. (This is rather tedious and most of the spring attachments will have identical angle values.)
- 2. Once you have selected the total number of springs, click the “initialize” button. This will fill all the cells with default numbers and you can simply modify these to create your own data.
- 3. An even easier approach is to follow the steps given below.

Enter values as shown in Figure 8.11. Point number is used as a reference in this frame only. Coordinates X, Y, Z are in mm and are relative to the body displayed currently and connecting to the “connected to” mass. If you want to attach springs to the next mass, you must display the mass in your main window (attachment is to the current mass). “Type” is the spring type. Spring type numbers were previously described.

Double symmetry means the point (point number 1, referring to the point above) will be duplicated by its symmetry about the *Oxz* plane. Then these two points will be doubled (four altogether) by taking their symmetry about *Oyz*. Click “ok” (for double symmetry) to complete the operation. The points shown in Figure 8.12 are now generated. Note that all the points have the same spring attachments (the same type). Remember that these four springs are between mass 1 and mass 0 (ground) and the coordinates are relative to mass 1.

To enter spring attachments between the second mass and the first mass, you need to click “+” to increase the Current Mass No. to 2. Having done that, you need to select the “connected to” combo box. When you click “2”, option 1 will appear: 0 and 1, see Figure 8.13. This figure shows how to choose mass number 1 to start creating a new set of spring attachment (between mass 2 and mass 1). As explained previously, mass 2 can connect to mass 1 and mass 0. If we are connecting mass 2 to

FIGURE 8.13 Selecting mass 2 and clicking the “connected to” combo box.

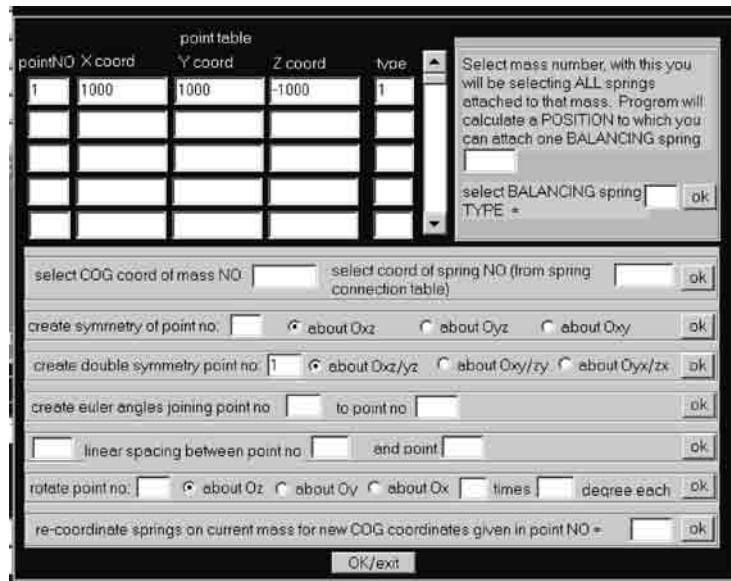

FIGURE 8.14 Use of “spring attachment designer” to create four attachments by double symmetry.

mass 1, then select 1. You may again click the “spring attachment designer” button to create attachment information.

The spring attachment frame will appear with exactly the last set of information (assuming that you have not cleared the text boxes before exiting the frame).

Figure 8.14 shows how to use “spring attachment designer” to create four attachments by double symmetry. Here, click the “ok” button on the “create double symmetry” subframe. Spring attachment information is now generated, between mass 2 and mass 1. Again, coordinates are relative to the current mass 2.

8.6.2.4 Entering Force Data

Make sure that your current mass is 1. When you run VIBRATIO, it assigns a single force of type 1 on mass 1. To see the force data, click “display forces” (on/off). You will see that the “Total Force No.” is 1, “current force” is 1, and “type” is also selected to be 1, as shown in Figure 8.15. In this case, “force” is a term that has a wider meaning. Specifically, “flags” on top of “force” magnitudes identify what is meant by “force.” Note that “flags” can take values between (and including) 0 and 4. Here, 0 means force does not exist; 1 means ordinary force, measured in N; 2 means prescribed displacement, measured in m; 3 means prescribed velocity, measured in m/sec; and 4 means prescribed acceleration, measured in m/sec².

FIGURE 8.15 Default force vector.

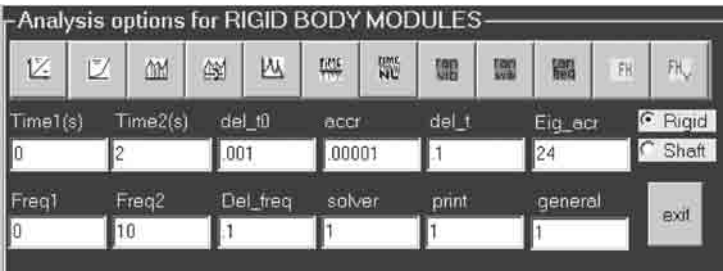

FIGURE 8.16 Analysis options and analysis control parameters.

Note that time 1 and time 2 describe the period in which this force is active. Also, x , y , z , and (α) alpha, (β) beta, (γ) gamma are “force” magnitudes.

Now we have created a two-mass system. Mass 1 is connected to the ground with four springs and mass 2 is connected to mass 1 with four springs. Springs attached to each mass are located at the four corners of the respective masses. There is a constant force acting on mass 1 for 2 sec (although this will be modified according to analysis). Now we are ready to perform analysis.

8.7 Analysis

8.7.1 Analysis Options

To see the analysis frame click the “display analysis options” button.

The analysis option frame as shown in Figure 8.16 will appear. Analysis options offered here are those relevant to the theory presented in this chapter and elsewhere in the handbook (see [Chapters 1 to 3](#)). The theory concerns rigid bodies connected to each other by flexible springs (and dampers). Since flexible shafting analysis is not available in the version provided to the reader, the “rigid” option has to be selected. The frame also contains a number of analysis parameters. Only some of the parameters are needed for a given analysis. For example, for deflection, eigenvalue, and eigenvalue (with damping), no parameters are needed. Once you select your analysis, parameters relevant to the analysis will remain visible and anything else will disappear.

Among analysis options, those shown in Figure 8.17 will be functional in your copy of the software. Starting from the left, the first button is for linear deflection, the third button is for eigenvalue analysis (ignores damping), the fourth button is for eigenvalue analysis (damping included), the fifth button is for frequency analysis, and the sixth and final button is for time-domain analysis. When you place your cursor on a button, the information box will identify its use.

FIGURE 8.17 Analysis options available for the provided version of software.

8.7.2 Eigenvalue Analysis

It is recommended that the first analysis you do is eigenvalue analysis. This will reveal whether you have any inconsistency/error in your data entry and if the created system is physically viable or not.

To perform eigenvalue analysis, click the third button as shown in [Figure 8.18](#). All the analysis parameter data boxes will disappear. The color of the selected button will change to red. This allows the user to enter any appropriate analysis parameter (in this case no parameter is needed).

FIGURE 8.18 Eigenvalue analysis button.

FIGURE 8.19 Postprocessing options.

When the button is clicked a second time, the analysis will be performed. To perform eigenvalue analysis for damped system, the procedure is the same but click the fourth button for this analysis.

To see results, you need to click the “display postprocessing options” (on/off) button. The postprocessing options will appear as shown in Figure 8.19. VIBRATIO has a basic text editor that may be used to display textual results. Click the “DISP TEXT” button to view eigenvalue results.

8.7.2.1 Eigenvalue/Vector Analysis Results

The editor window will open, and from the file menu you can then open “eigftext.txt.” You should obtain the results given below

X	Y	Z	Alpha	Beta	Gamma
Frequency in X = 1.26 Hz (76 CPM)

-0.0100	0.0000	0.0000	0.0000	1.0000	0.0000
Frequency in gamma = 14.57 Hz (874 CPM)					
Relative eigenvector values for mass = 1					
0.0000	0.0000	0.0000	0.0000	0.0000	-1.0000
Relative eigenvector values for mass = 2					
0.0000	0.0000	0.0000	0.0000	0.0000	0.6180
Frequency in gamma = 5.56 Hz (334 CPM)					
Relative eigenvector values for mass = 1					
0.0000	0.0000	0.0000	0.0000	0.0000	0.6180
Relative eigenvector values for mass = 2					
0.0000	0.0000	0.0000	0.0000	0.0000	1.0000

This is the result file created as a result of executing eigenvalue analysis (if you had performed eigenvalue analysis with damping you need to open the "eigdtext.txt" file). A successful eigenvalue analysis normally implies physically feasible data (of course, not always).

Now we are ready to perform other analysis options.

8.7.3 Linear Deflection Analysis

The linear deflection equations may be obtained from vibration equations by simply removing the acceleration and velocity terms. If the excitation (force) vector is made of constant values, then the

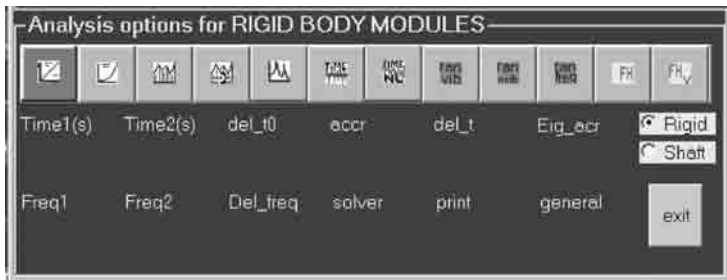

FIGURE 8.20 Linear deflection analysis; no control parameter is needed.

problem is a static deflection problem. By clicking the linear deflection button, you will see that no analysis parameters are needed. Next, click the red button. This will perform a static deflection analysis, as indicated in Figure 8.20.

Numerical results can be displayed using the “DISP TEXT” button from postprocessing options. The deflection results are saved in the “distext.txt” file. This file holds the results given in the next section. Note that, since force is acting on mass 1, mass 2 does not deflect relative to mass 1.

8.7.4 Frequency Analysis

In order to perform a frequency analysis, the force selection must be relevant to the frequency analysis. Force options between 16 and 21 are for frequency analysis. Option 16 (A Sin Wt) is chosen to demonstrate the frequency analysis, as shown in Figure 8.21.

Here, default excitation is in the z direction. Flag = 1 means this is an ordinary sinusoidal force with 1000 N excitation amplitude. It exists in the frequency range from 0 to 2 Hz (freq 1 and freq 2) acting in

FIGURE 8.21 Frequency analysis options 16 to 21.

FIGURE 8.22 Constant force amplitude between 0 and 2 Hz.

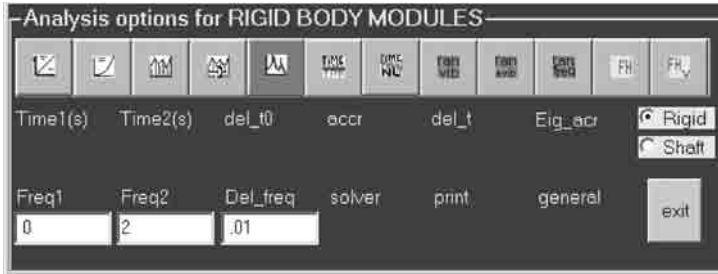

FIGURE 8.23 Frequency analysis parameters.

the z direction, as shown in Figure 8.22. You may have more than one force, with different amplitudes and different frequency ranges. Sweep time, in seconds (any number other than zero), refers to the time taken to sweep from freq 1 to freq 2 (see Chapter 17). If the sweep time is infinitely slow, then a zero entry signifies this (exactly the opposite meaning!). There are two amplitudes for each direction, the top entry refers to the amplitude at freq 1 and the bottom one refers to the amplitude at freq 2. Amplitudes between these frequencies vary linearly.

To execute a frequency analysis, select analysis options and click the button shown in Figure 8.23. Frequency analysis parameters: start frequency, end frequency, and frequency steps are shown in this figure.

Specifically, the options Freq 1 and Freq 2 will appear here. These relate to the frequency range to be analyzed. Del_freq is the frequency step. Your choice of frequency range should not be arbitrary. Either the problem dictates the range or you may be interested in amplitudes of the system at resonant frequencies. In the latter case, you may look at the eigenvalue results to identify which resonant frequencies will be exhibited in the selected range. For the example considered, the excitation force is in the z direction. Therefore, one needs to find out the resonant frequencies in the z direction (or coupled modes which include the z direction). If the eigenvalue results are studied, one can see that the resonant frequencies in the z direction are given as: 0.68 and 1.78 Hz. Therefore, analysis beyond 2 Hz in the z direction will not reveal any other resonances. Clicking the red button a second time will execute the analysis. To see the results you need to click the “display postprocessing” button, and from the postprocessing frame click the “plot freq” button. The frequency-plotting window will appear. The frequency motion in six directions will be plotted for mass 1. “+” can be used to move to the next mass. You may also display motion curves of all bodies together by choosing the “plot all” option. You will end up with the results shown in Figure 8.24.

8.7.5 Time-Domain Analysis

Forces 1 to 14 are for the time domain, although 13 and 14 are not available in this version of VIBRATIO. When option 1 is selected in the force “type” option, the default force would be 1000 N in the z direction, remaining active between 0 and 2 sec. Modify Time 2 to 0.01 sec (10 msec). You can use option 1 for a rectangular shock but there are also other shock options. Figure 8.25 shows a constant force, magnitude 10,000 N acting in the z direction between 0 and 0.1 sec.

To perform a time domain analysis, the button shown in Figure 8.26 needs to be clicked. Relevant analysis parameters will appear as shown in this figure. Time 1 and Time 2 give the range of the time domain analysis. If Time 1 is chosen not to start from 0, even though the resulting data will not be collected until Time 1 reaches, still the solution will be executed starting from start time = 0. In other words, if Time 1 is not zero then this will be the time when data recording starts. Analysis itself, irrespective of Time 1, always starts from 0 sec. del_t0 is the initial step length for integration

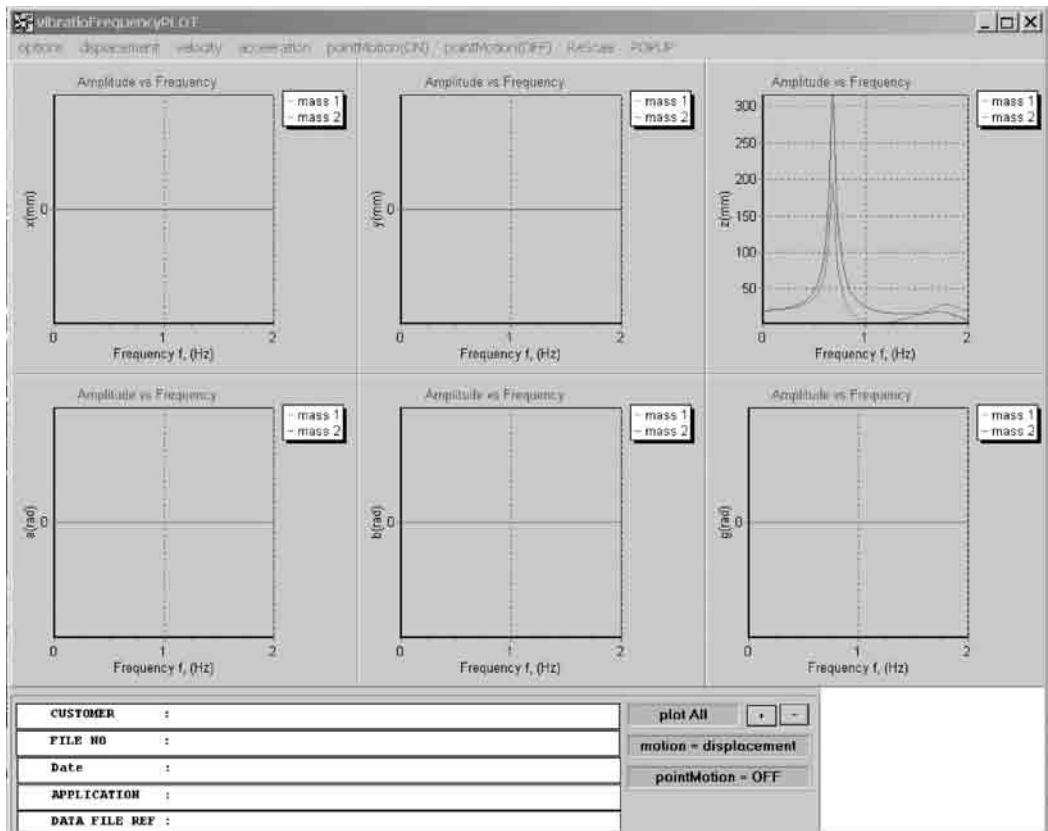

FIGURE 8.24 Frequency analysis results.

(The time-domain analysis uses variable step length Runge–Kutta and the time integration step where an algorithm automatically modifies the integration step to achieve the required accuracy). Accr is the accuracy of integration and del_t is the time step at which data is sampled. To execute, click the button again.

8.7.5.1 Time-Domain Results

Time domain results will be displayed by clicking the plot-time button on the postprocessing frame. The results shown in Figure 8.27 will be obtained, again from the “options” menu, when “plot all” is selected.

FIGURE 8.25 Constant force representation.

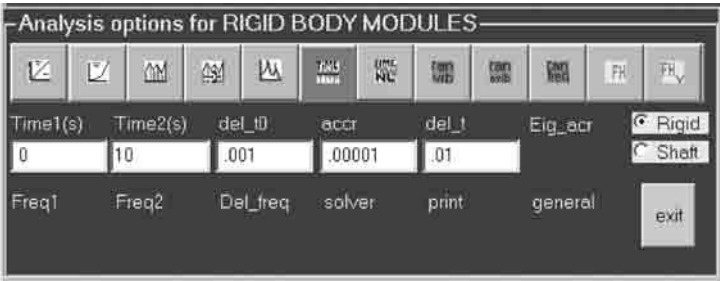

FIGURE 8.26 Time-domain analysis button and analysis control parameters.

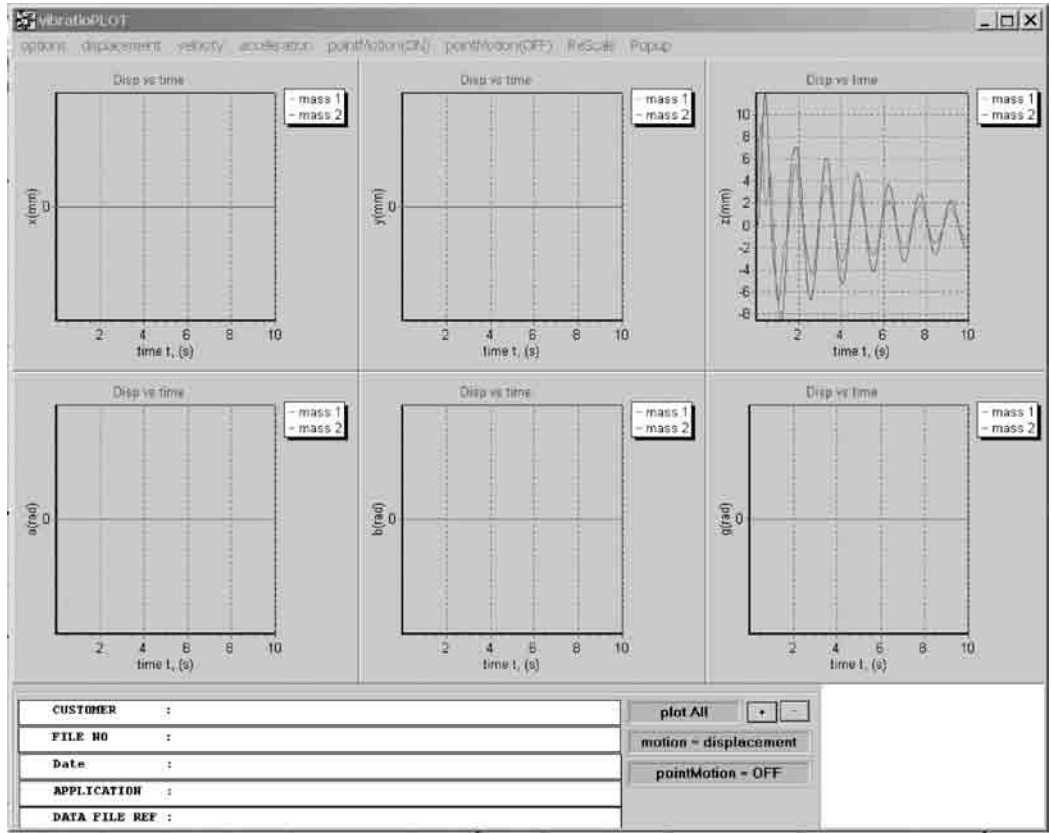

FIGURE 8.27 Time-domain results window.

8.8 Comments

This chapter presented a method of analyzing general multiple rigid-body systems interconnected by linear springs and linear dampers. The mathematical modeling was presented for small vibrations where nonlinear geometry effects and gyroscopic couplings were negligible and the deflection characteristics of the mountings were linear. There is a shortage of published material on general mathematical modeling of flexibly supported rigid multibody systems for vibration analysis. Detailed mathematics of time domain, frequency domain and eigenvalue/eigenvector analyses can be found in

standard vibration textbooks. Some are listed in the references section, but this list is not exhaustive. This chapter also gives a precise and clear formulation suitable for computational implementation. The formulation presented in this chapter forms the core of the vibration analysis suite “VIBRATIO”, a version of which is made available to the users of this handbook, at www.signal-research.com, as indicated in the text.

Summary

This chapter discusses the use of the finite element (FE) method in problems of vibrations and structural dynamics. The first three sections outline the main steps in modeling a physical problem for a specific dynamic analysis. Section 9.1 concentrates on the finite element aspect of the modeling process. The basis for geometric modeling is outlined and an overview of commonly used types of elements in typical commercial programs is presented. A summary of element capabilities is given at the end of the section (Table 9.1). Section 9.2 discusses the basis for classifying and choosing a particular type of dynamic analysis, including modal, harmonic or frequency response, transient and shock, and random analysis. Section 9.3 discusses some special aspects in modeling that are pertinent to dynamic system analysis; namely, choice of master and slave degrees of freedom (DoF), lumped vs. consistent mass modeling, and use of symmetry in dynamic analysis.

The second part of the chapter discusses solution methods and damping considerations, and outlines basic steps for performing various dynamic analyses. Section 9.4 briefly presents the theory and equations for various dynamic analyses. The analysis types included in the discussion are direct integration and modal superposition. In the direct integration analysis, both implicit and explicit schemes are discussed and an example of each is presented. Most of the theory and equations are presented in a summarized form without rigorous mathematical proofs. Section 9.5 describes details of various dynamic analyses and provides a brief discussion of the choice of the solution method for each analysis. Emphasis is placed on the basic steps required to perform a particular analysis type. Modal analysis, transient analysis (direct integration and mode superposition approaches),

frequency response harmonic analysis, and random response analysis are presented. The various methods of combination of modal responses are also discussed. Finally, Section 9.6 provides some general guidelines for a typical dynamic analysis using the FE method.

9.1 Problem and Element Classification

The first step in any finite element (FE) analysis is to build a model of the physical structure to be analyzed. This is an important step and normally requires extensive time and interaction with the analyst. The adequacy of the model, assumptions involved, and types of elements used for a specific structure and analysis type establish the accuracy level of the FE analysis. Much research effort is being devoted to automating this process by providing options for automatic mesh generation, automatic mesh refinement, error estimation, and error bounds. Such research has resulted in a significant reduction in the time needed for this step but the role of the analyst is still dominant and vital in obtaining a good mesh and model for the problem.

The modeling process can be divided into steps as follows:

- Build a geometric database for the structure. This includes description of the characteristic geometric features of the structure, such as boundaries, holes, intersections, curvatures, etc., in the finite element program database. The level of geometric detail has an important effect on the accuracy and the size of the model.
- Build a FE model for the geometric model. This may include important aspects such as:
 - Establishing the type of analysis to be performed,
 - Choosing the appropriate element or elements for building the model,
 - Considering aspects of symmetry in the structure, and
 - Establishing critical areas for increasing mesh density.
- Apply constraints and loading boundary conditions.
- Establish the material model(s) to be used in the analysis.
- Perform various options of model checks.
- Solve sample load cases and compare the results with hand calculations or experimental results in order to check the behavior and response of the model.
- Fine tune the model based on the results obtained from sample load cases.

Most of the time, the above steps are rather linked together, and an overall knowledge of the problem is required to perform a specific step. An important decision that should be made at the beginning of the analysis is to identify the category of the problem. This will have an impact on the first three steps mentioned above. In the first part of the present section, we provide a brief discussion on the geometric modeling aspects of the problem. The rest of the section then provides general guidelines on classifying the problem into one of the main categories available in typical commercial finite element programs; namely, truss, beam, two-dimensional, shell, or three-dimensional problems. We also provide simple examples for each type of problem. The concepts of element choice and problem classification are summarized in a table at the end of the section.

9.1.1 Geometric Modeling

Geometric modeling simply means transforming a physical problem into a geometric database in a FE program. The process is very similar to creating an engineering drawing or a model in a CAD program. Most FE programs have built-in preprocessors that are dedicated to generating the geometry database. Generally, FE preprocessors have similar capabilities to those available in CAD programs. In many cases an existing geometric database may be available for the structure in a CAD program and may be imported into the FE program database. However, there can be translation problems between the two databases, especially in three-dimensional and shell structures. In most cases, it is faster to regenerate the geometric database for the problem directly using the FE program.

FIGURE 9.1 Geometric modeling entities.

Finite element programs use specific building blocks or entities to build the geometry of a structure (Kamel, 1991; *NISA User's Manual*, 1992; *ANSYS User's Manual*, 2003). The theory on which geometry generation is based is quite simple and basically relies on parametric cubic modeling of curves and surfaces in space. Figure 9.1 shows the basic entities used by most programs for building a geometric model. We define these basic geometric entities and briefly discuss their use in practical modeling of structures.

9.1.1.1 Key Point

A key point is a coordinate location in space. In two-dimensional space, a key point is uniquely defined by two coordinates (e.g., x, y ; r, θ). In three-dimensional space, a key point is uniquely defined by three coordinates (e.g., x, y, z ; r, θ, z). Key points are normally the starting building blocks in the geometry. Connection between key points will generate lines, surfaces, or volumes. On the other hand, most programs will be capable of extracting key points from the end points or corners of lines, surfaces, and volumes. Key points should not be confused with nodes, and should be considered only as spatial locations in space. One may place a node at the same location as a key point or leave the location without node generation.

9.1.1.2 Line or Line Segment

A line or line segment is a portion of a cubic spline curve bounded on both ends by a key point. A line may be straight or curved. The curvature of a line is limited only by its parametric cubic equation in the program. If a physical curve in the structure is presented by up to and including a third-order parametric cubic equation, it may be modeled exactly by a single line. In many practical situations, however, this is not the case. As an example, the parametric equation of a circle is not cubic and the recommended way to model a circle accurately is to break it into at least four lines. Breaking a space curve into many lines will always increase the accuracy of the geometric modeling but entails increasing the complexity of the model. The analyst should be careful in situations where the order of the line to be modeled is not known. A common case is the generation of the line of intersection between two surfaces. In such situations, it is important to break the intersection line into a few separate lines.

Most programs provide extensive methods for line generation. These may include generation by joining two grid points, cubic spline fitting of four grid points, best fitting a curve between several grid points, extracting the edges of a surface or a volume, intersection of surfaces, and mirroring and copying other lines.

9.1.1.3 Area or Patch

An area or a patch is a portion of a bi-cubic surface completely bounded by three line segments (for triangular areas) or four line segments (for quadrilateral areas). The same limitations discussed above for using line segments may be extended here by realizing that the area is modeled by parametric cubic equations in two directions representing the two edges of the area.

Most programs provide extensive methods for generating areas or patches. These include generation by sweeping the space between two lines, filling in the area between four edge lines, rotating a line about an axis, extracting the boundary surfaces of a volume, and intersection between volumes.

9.1.1.4 Volume or Hyperpatch

A volume or a hyperpatch is a portion of tri-cubic solid completely bounded by four areas (for tetrahedron volumes) or six areas (for brick volumes). The equations used to model the edge lines of a volume are still parametric cubic equations and the same restrictions discussed for lines can be extended to a volume in the three directions of the volume.

As for line and area generation, most programs provide a wide variety of methods for generating volumes. These may include generation by sweeping the volume between two surfaces, filling the volume between bounding surfaces, rotating an area about an axis, and copying and mirror imaging the existing volume.

An important addition in the generation of volumes is the ability of many programs to use solid primitives as building blocks (Kamel, 1991; *ANSYS User's Manual*, 2003). These solid primitives may include tetrahedrons, cubes, cylinders, conical volumes, spheres, torus elements, and other standard volumes. These may be used as building blocks that may be combined, subtracted, or intersected with each other. Many programs provide simple Boolean operations to use for such processes.

REMARKS

- In most modeling cases, it is faster to regenerate the geometric database of the problem directly using the FE program, especially in complicated and three-dimensional models.
- The basic building blocks in geometric modeling are key points, lines, areas, and volumes.
- Many programs provide the ability to create solid primitives as building blocks. These solid primitives may include tetrahedrons, cubes, cylinders, conical volumes, spheres, toruses, and other standard volumes.
- Boolean operations are normally used to combine, subtract, or intersect various geometric entities.

9.1.2 Discrete Element Types in FE Programs

Most commercial FE programs have extensive element libraries that may be used in static and dynamic analyses. For dynamic analysis, it may be convenient to classify elements into discrete and continuum types. Discrete types include concentrated (lumped) mass and inertia, spring, and damper elements, whereas continuum (distributed) types include all other one-dimensional (1-D), two-dimensional (2-D), and three-dimensional (3-D) deformable elements. In this section, we briefly discuss the discrete type of elements whereas the continuum type will be discussed in detail in subsequent sections.

9.1.2.1 Concentrated Mass/Inertia Element

A concentrated mass/inertia element represents a structural mass and moment of inertia concentrated at one point and has six DoF: three translational and three rotational. The mass and rotary (moment of) inertia may be assigned different values in the three coordinate directions (see Figure 9.2), even though, typically, the mass is the same in all three directions (see Chapter 8). The element is rigid with no geometrical properties and it only contributes to the global mass matrix of the structure. In building up a model, the element may be attached to a structural node of other deformable or elastic elements or be positioned in space and attached to structure nodes through rigid elements or elastic spring and/or damper elements. Most FE programs provide rotary inertia quantities for various components of the geometric model as part of the standard preprocessing data. These can be used to model parts of the structure as lumped mass and inertia that may be connected to the structure through elastic elements.

An example of the use of a concentrated mass and inertia element is the modeling of a heavy, rigid machine mounted on an elastic support. The mass and inertia effects of the machine may be represented by a concentrated or lumped mass/inertia element at the center of the machine. Care must be taken in connecting this element to the deformable elements of the structure or the support. In general, a rigid link may be used to connect the mass/inertia element to the nearest node of a deformable element rather than placing the mass/inertia element directly on that node (Cook et al., 1989). This will generally account for proper interaction between translational and rotational DoF of the mass and the structure.

It should be noted that some computational algorithms might have problems with zero diagonal values of the mass matrix. This happens if the inertia terms of the mass/inertia element are assigned as zero. This can be avoided by always assigning an arbitrary and small value to the rotary inertia terms.

FIGURE 9.2 Three-dimensional mass/inertia element.

FIGURE 9.3 One-dimensional spring/damper element.

9.1.2.2 Spring and Damper Elements

Most programs provide 1-D spring and damper elements that can be used to model hydraulic cylinders, discrete dampers, and shock absorbers. The element normally has one spring constant and one damping coefficient (along the element axis defined by the nodes *I* and *J* as shown in Figure 9.3). It is easy to model 3-D stiffness and damping characteristics by replicating the element in the required directions. A mass may be attached to one or two nodes of the element. The force transmitted through the element nodes is the sum of the spring and the damping forces along the element axis.

REMARKS

- A concentrated mass/inertia element may be used to model lumped mass/inertia at specific points in the structure. Likewise, spring or damper elements may be used to model stiffness and damping characteristics between two points in the structure.
- A concentrated mass/inertia element represents a structural mass and inertia at a point and has six DoF: three translational and three rotational. Different mass and inertia values may be assigned in different directions.
- Three-dimensional stiffness and damping characteristics between two nodes may be modeled by replicating 1-D spring or damper elements in the required directions.

9.1.3 Truss and Beam Problems

Three-dimensional truss and beam elements are shown in Figure 9.4. The main difference between the two elements is the fact that beams may support bending moments and have rotations as extra DoF at

FIGURE 9.4 Three-dimensional truss and beam elements. (Nodal rotations for the beam element are only shown for node-j.)

each node. This means that a beam element may have loads along the beam axis and not necessary only at the end points.

The following conditions should be satisfied for a structure to be classified as a truss or a beam:

- *Geometry:*
 - Thin, slender, straight bars or rods with pin joints at both ends. Depending on the application, the element may be considered as a truss, a link, a cable, a spring, etc.

If the joints are fixed or the bar is curved, the problem will be classified as a beam type. Fixed joints may be created by completely fixing the beam ends to a wall or support, or to another member. This is normally realized if the joint is built-in, welded, or fully bolted to the support or to other members.
 - Geometry may be 1-D, 2-D, or 3-D.
- *Loading:*
 - For truss problems, loading may only be by tension or compression of the members. This may be achieved by having only concentrated loading at the joints (no bending moment) and no loadings along the member.

For beam problems, loading may be in any direction and may be applied along the member axis. This will generally create a bending moment and the member should have rotations as DoF.
 - Thermal loading may also be applied to the member.
 - Body or inertia forces will generally create a bending moment and violate the truss condition and so may be applied only to beam problems. Such loads may be applied, however, to truss elements under the simplification of assuming the inertia effects to be applied only at the nodes or the joints and ignoring the bending moment that will be created on the member.

Degrees of freedom: For 3-D truss elements, the DoF per node are the displacement in the three coordinate directions: u_x , u_y , and u_z . Two-dimensional truss members only have u_x and u_y as DoF. Three-dimensional beam elements have all six DoF: three translational, u_x , u_y , and u_z , as well as three rotational, θ_x , θ_y , and θ_z . Two-dimensional beam elements have u_x , u_y , and θ_z as DoF.

Element shapes: Various element shapes commonly available in commercial finite element programs are shown in Figure 9.5. The cross section of the element may be a solid or hollow prismatic section, e.g., a rectangular, circular, trapezoidal, or thin-walled section or a channel, thin-walled tubular, I-section, etc.

FIGURE 9.5 Various element shapes for truss and beam elements.

FIGURE 9.6 Typical applications for truss and beam elements.

The analyst will generally be required to identify the orientation of the beam cross section by specifying local axes or identifying key points for the program to locate the local axes. Most programs are capable of modeling variable cross section beam elements to avoid excessive subdivision of the beam into smaller elements.

Example applications: Figure 9.6 shows sample applications for the use of truss and beam elements.

REMARKS

- Truss elements have translational DoF whereas beam elements have both translational and rotational DoF at the nodes. Three-dimensional truss elements have 3 DoF/node (u_x , u_y , and u_z), whereas 3-D beam elements have 6 DoF/node (u_x , u_y , u_z , θ_x , θ_y , and θ_z).
- Truss structures may only carry loads at the end of each truss whereas beam structures may also carry loads along the beam length.
- Curved members should be modeled with beam elements.
- Problems with body and inertia forces should generally be modeled as beam elements. If lumping of the body forces is assumed and the effect of the bending moment created by body forces is neglected, the effect may be modeled with truss elements.

9.1.4 Two-Dimensional Problems

9.1.4.1 Two-Dimensional Plane Stress Problems

Figure 9.7 shows a typical structure, which may be considered as a 2-D plane stress problem.

The following geometry and load conditions should be satisfied for a structure to be categorized as a 2-D plane stress structure (Boresi and Chong, 2000).

Conditions:

- *Geometry:*
 - A flat, thin surface in one plane (e.g., xy -plane), simply connected or multiply connected with a small thickness in the third direction (e.g., z -direction).
 - The boundary of the structure in the xy -plane may be straight or curved.
- *Loading:*
 - Loading is restricted to the plane of the structure (e.g., xy -plane).
 - Thermal loading may also be applied to the plane (i.e., $T = T(x, y)$).
 - Body or inertia forces may be due to linear or angular acceleration in the plane of the structure.

Degrees of freedom: For 2-D elements, the DoF per node are the displacements in the two coordinate directions, u_x and u_y .

Typical element shapes (see Figure 9.8): Elements may be triangular or quadrilateral. Most programs provide the option of having 3, 6, or 9 nodes for triangular elements and 4, 8, or 12 nodes for quadrilateral elements. Increasing the number of nodes will increase the element accuracy at the expense of having more DoF and requiring more CPU time to solve the problem. This is normally called a “p-conversion” approach in finite elements. The same goal may be achieved by increasing the number of elements while fixing the number of nodes per element, which is usually called “h-conversion” (Zeng et al., 1992; Babuska and Guo, 1996). The choice of method to obtain greater accuracy is rather arbitrary and mostly depends on the availability of the option in the program. Only a limited number of programs provide extensive “p-conversion” options.

Example applications: Figure 9.9 shows some typical examples that may be modeled using a plane stress assumption. It should be noted such models cannot capture any out-of-plane modes of vibration. If such vibration modes are of concern, the model should be capable of capturing lateral displacement DoF and out-of-plane rotations. This may be realized by using shell or 3-D solid elements as will be discussed in the following sections.

FIGURE 9.7 A general 2-D plane stress structure.

FIGURE 9.8 Typical plane stress elements.

FIGURE 9.9 Typical plane stress examples.

9.1.4.2 Two-Dimensional Plane Strain Problems

Figure 9.10 shows a typical structure that may be considered as a 2-D plane strain.

The following geometry and load conditions should be satisfied for a structure to be categorized as a plane strain structure (Borelli and Chong, 2000).

Conditions:

- **Geometry:**
 - A flat surface in a plane (e.g., xy -plane), simply or multiply connected with large thickness in the third or z -direction (with much larger dimensions than in the xy -plane).
 - The boundary of the structure in the xy -plane may be straight or curved.
- **Loading:**
 - Loading is restricted to the plane of the structure (e.g., xy -plane) with possible uniform loading or constraint in the z -direction. The loading in the z -direction will remain only as a function of the x and y coordinates; i.e., $P_z = P_z(x, y)$.
 - Thermal loading may also be applied to the plane (i.e., $T = T(x, y)$).
 - Body or inertia forces may be applied to the plane.

Degrees of freedom: For 2-D plane strain elements, the DoF per node are the displacement in the two coordinate directions u_x and u_y . The plane strain assumption means that the strain in z -direction will be zero and that the stress will be nonzero, $\epsilon_z = 0$ and $\sigma_z \neq 0$.

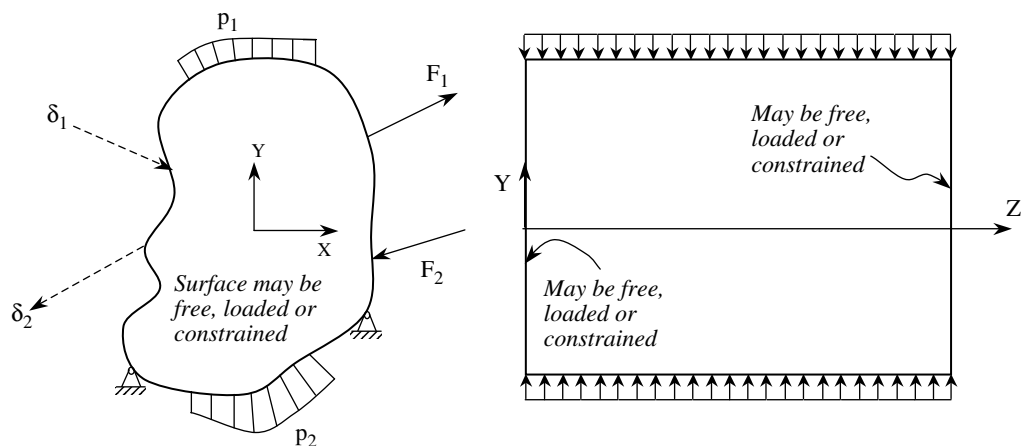

FIGURE 9.10 A general 2-D plane stress structure.

Typical element shapes: The same element shapes as in the case of plane stress are available in most commercial FE programs (see Figure 9.8). The comment above on p-conversion and h-conversion also applies here.

Example applications: Figure 9.11 shows some typical examples that may be modeled using a plane strain assumption. Once again, it should be noted that such a model cannot capture any out-of-plane modes of vibration. If such vibration modes are of concern, the model should be capable of capturing lateral displacement DoF and out-of-plane rotations. This may be realized by using shell or 3-D solid elements as will be discussed in the following sections.

9.1.4.3 Two-Dimensional Axisymmetric Problems

Axisymmetric problems are characterized by having an axis of symmetry or axis of revolution for geometry and loading. Referring to Figure 9.12, any arbitrary plane that passes by the axis of symmetry will be a plane of symmetry. Symmetry means that the two halves of the structure on each side of the plane of symmetry are mirror images of each other. Symmetry must be satisfied for all aspects affecting the response of the structure including geometry, load, constraint, and material properties.

The following conditions summarize the requirements for categorizing a problem as axisymmetric (Boresi and Chong, 2000).

Conditions:

- *Geometry:*
 - A solid of revolution formed by rotating a flat area (e.g., in the rz -plane) around an axis of symmetry (e.g., the z -axis).
 - The boundary of the flat area in the rz -plane may be straight or curved and the area may be simply or multiply connected.
- *Loading:*
 - Loading is restricted to the rz -plane with no variation of loading in the θ -direction. No loading in the θ -direction.
 - Thermal loading may be applied in the rz -plane (i.e., $T = T(r, z)$).
 - Body or inertia forces may be applied in the rz -plane.

Degrees of freedom: For 2-D-axisymmetric elements, the DoF per node are the displacements in the two coordinate directions u_r and u_z . Some programs use x and y coordinates to replace the r and z axes, respectively.

FIGURE 9.11 Typical plane strain examples.

FIGURE 9.12 Axial symmetry conditions.

FIGURE 9.13 Typical axisymmetric elements.

FIGURE 9.14 Typical axisymmetric examples.

Typical element shapes: Figure 9.13 shows typical axisymmetric element shapes that are commonly available in commercial FE programs. The elements are shaped as a torus with various cross sections as shown in the figure.

Application examples: Figure 9.14 shows typical axisymmetric examples.

9.1.5 Shell and Plate Problems

Shell and plate problems are quite similar to plane stress problems (see Figure 9.15). We first recall the conditions for a plane stress problem: (1) that the geometry has to be flat in one plane with a small thickness, and (2) that the load has to be in the same plane. If either of these two conditions is violated, the problem becomes a shell problem. For example, if the load is a moment about any direction other than the z -direction then it has an out-of-plane component, or if the geometry is not flat then the problem ceases to be a plane stress problem and should be modeled as a shell problem. Normally, shell structures would still maintain a small thickness in the direction normal to the surface of the shell. This maintains the condition that the stress normal to the shell surface will be zero, although there may still be a pressure applied to the surface of the shell.

The following summarizes the conditions for a shell structure.

- *Geometry:*
 - Thin surfaces or plates that have a thickness in the direction normal to the surface. The midsurface or midplane of the structure may be flat or curved.
 - The boundary or edges of the structure may be straight or curved.
- *Loading:*
 - Both in-plane and out-of-plane loadings are permitted.
 - Thermal loading may also be applied in all x -, y -, and z -directions.
 - Body or inertia forces may be due to linear or angular acceleration in all three directions.

Degrees of freedom: Three-dimensional shell elements have six DoF: three translational, u_x , u_y , and u_z , and three global rotational, θ_x , θ_y , and θ_z .

REMARKS

- Structures with a flat planar surface of a small thickness and with loading only in the plane (e.g., xy) of the structure (no out-of-plane loading or constraints) are categorized as plane stress structures. Such structures will have three nonzero stress components: σ_{xx} , σ_{yy} , and t_{xy} .
- Structures with a flat planar surface (e.g., xy) but a very large dimension in the third direction and with loading only in the plane of the structure (with possible uniform loading or constraints in the third direction) are categorized as plane strain structures. Such structures will have four nonzero stress components: σ_{xx} , σ_{yy} , σ_{zz} , and t_{xy} .
- Axisymmetric problems are characterized by having an axis of symmetry or axis of revolution (e.g., z -axis) for geometry and loading. Such structures will have four nonzero stress components: σ_{rr} , $\sigma_{\theta\theta}$, σ_{zz} , and t_{rz} .
- Two-dimensional problems may be modeled by elements having two translational DoF per node. The elements may be triangular with 3, 6, or 9 nodes or quadrilateral with 4, 8, or 12 nodes. Axisymmetric elements are shaped as a torus with triangular or quadrilateral cross-sections.
- Increasing the number of elements while fixing the nodes per element is called “h-conversion,” whereas increasing the number of nodes per element while fixing the number of elements is called “p-conversion.”
- Two-dimensional models cannot capture out-of-plane vibration modes. If such vibration modes are of concern, the model should be capable of capturing lateral displacement DoF and out-of-plane rotations.

Element shapes: Figure 9.16 shows some typical shell elements available in most commercial FE programs. To properly model a curved shell with linear elements that are flat requires using a large number of elements to capture the curvature. Quadratic and cubic elements, on the other hand, may have curvature in two directions and a much reduced number of elements will be needed to model a curved shell. Most programs are capable of modeling variable thickness shell and plate elements.

FIGURE 9.15 Shell and plate structures.

Some programs offer shell elements that only have membrane capabilities and others that have both membrane and bending capabilities.

In shell and plate analyses, it is important to note that linear elements, i.e., three-node triangles and four-node quadrilaterals, may behave in an unrealistically stiff manner in shear deformation when the element thickness to size ratio is very small. This phenomenon is normally called “shear locking” (Bathe and Dvorkin, 1985; Bathe, 1996; Luo, 1998; Cesar de Sa et al., 2002). The problem occurs when in-plane displacements are coupled with section rotations in the governing equation of

the element and when low-order interpolations (linear elements) are adopted. The same phenomenon is also evident in beam elements. Similarly, when in-plane displacements are coupled with section rotations in the governing equations and low-order interpolations are used, “membrane locking” will be evident.

Most programs provide various remedies for shear- and membrane-locking problems. These include selective/reduced integration, enhanced assumed strain method, mixed field method, etc. Depending on the availability of a particular method in the program, the user should initiate the remedy. The problem may also be alleviated by switching to higher order elements, such as quadratic or cubic elements.

Example applications: Figure 9.17 shows typical examples of applications for shell problems.

FIGURE 9.16 Typical shell elements.

REMARKS

- Shell structures are general 3-D surfaces of small thickness. Loading can be in plane and out of plane. All stress components except those normal to the surface will be nonzero.
- The shell element may be triangular with 3, 6, or 9 nodes or quadrilateral with 4, 8, or 12 nodes.
- Commercial programs offer shell elements with variable thickness and with membrane and/or bending capabilities.
- Linear elements may experience “shear locking”: nonphysical, high stiffness in shear. Various remedies are available in most programs.

9.1.6 Three-Dimensional Solid Problems

By default, if the problem is not one of those discussed in Section 9.1.3 to Section 9.1.5 then it will be classified as a 3-D problem. Three-dimensional problems are easily identified by their 3-D geometry and loading, as shown in Figure 9.18. Any of the categories of problems discussed above may be solved by using 3-D elements. The critical drawback is the substantial increase in analyst time for modeling and in CPU time in processing the solution (the time needed may be one order of magnitude larger than for a corresponding 2-D problem).

The following summarizes the conditions for a 3-D problem.

- *Geometry:*
 - A 3-D object with no apparent thickness or uniformity in any direction.
 - The boundary of the object may be straight or curved.

FIGURE 9.17 Typical shell and plate examples.

• *Loading:*

- Three-dimensional loading. An important note should be added here: 3-D elements normally have three displacement DoF and no rotational DoF. This means that moments cannot be directly applied to such elements and the moment effect should be simulated via concentrated forces or couples.
- Other loading, including thermal loading and body or inertia forces, may be applied in any direction.

FIGURE 9.18 Three-dimensional problems.

Degrees of freedom: Three-dimensional solid elements have three translational DoF: u_x , u_y , and u_z . As mentioned above, concentrated moments should be modeled by an equivalent system of concentrated forces or couples.

Element shapes: Figure 9.19 shows some typical 3-D element shapes available in most commercial FE programs.

Example applications: Figure 9.20 shows some typical examples of 3-D structures requiring 3-D solid modeling and elements. It should be noted that if out-of-plane vibration modes of a 2-D structure are of concern, then a 3-D solid or shell model should be used even if the loading is in one plane.

Remarks

- Structures that are not classified as truss, beam, 2-D, or shell may be modeled with 3-D solid elements.
- Three-dimensional elements have three translational DoF per node (u_x , u_y , and u_z) and may have 4–32 nodes per element.

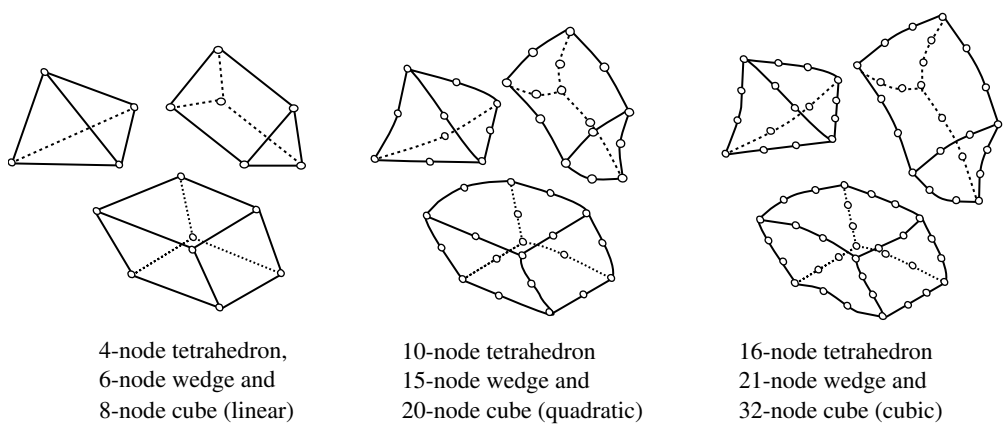

FIGURE 9.19 Typical 3-D solid element shapes.

FIGURE 9.20 Typical 3-D examples.

9.1.7 Synopsis of Problem Classification and Element Choice

Table 9.1 summarizes the concepts discussed above (Section 9.1.2 to Section 9.1.6) for element choice and problem classification. The table also shows displacement and stress variations within each element as well as standard element output quantities. The displacement variation within the element represents the basic element assumption in FE analysis and is called the “shape function” or the “approximation function” assumption. The strain variation within the element follows by differentiating the displacement variation according to the strain–displacement relations. The number of nodes per element is linked to the shape function assumption. For example, in 2-D elements three-node triangles have linear shape functions and in 3-D elements eight-node bricks have linear shape functions. Elements with linear shape function are sometimes called low-order or linear elements. Such elements may be used quite efficiently in both linear and nonlinear analyses.

TABLE 9.1 Summary of Problem Classification and Corresponding Element Characteristics

Characteristics	Element			
	Truss	Beam	Two-Dimensional Plane Elements	
Dimension	1-, 2-, or 3-D	2- or 3-D	2-D	2-D

9.2 Types of Analysis

If the applied loading on the structure is to change with time, the designer should make a decision on whether or not a dynamic analysis is required. To be able to make this decision, information about the loading and the natural frequencies of the structure are required. From the loading point of view, we classify a general loading on a structure into one of four categories: steady, cyclic, transient, and random.

Figure 9.21 shows a schematic presentation of the four loading categories. Figure 9.21b shows two types of cyclic loading, one is a simple harmonic loading with amplitude of oscillation F_o , period $T = 2\pi$, and frequency $f = 1/T$. The second is a periodic loading with a period T . Using Fourier analysis, any periodic function with a period, T , may be decomposed into a series of harmonic sines and cosines with frequencies $f_1 = 1/T, 2f_1, 3f_1, \dots, nf_1$. Figure 9.21c shows a transient load with a duration T .

Some forcing functions do not lend themselves to simple frequency or time specifications. Figure 9.21d shows a typical time history of a forcing function of such a category that may be considered as random excitation. Transient and cyclic forcing functions are normally specified as force vs. time or frequency, respectively. On the other hand, random forcing functions are commonly specified as the magnitude of the input acceleration squared vs. frequency. This input data is normally called a power spectral density (PSD) input curve. Time history input may be used in the analysis of random excitation and the random input may be treated as transient. This would normally require extensive computer resources and CPU time due to the very large number of time steps that would be required to capture the peak response. Random excitation may occur from random sources such as road undulation on vehicles, noise, earthquakes, and seismic events on buildings, and wind and turbulent loading on airplanes. For practical purposes, PSD curves have been compiled for various random events and are normally available in most FE commercial programs.

In addition to the load specification, the second factor affecting the decision on the type of analysis is the natural frequency of the structure. Structures with mass and stiffness characteristics are capable of free vibrations after removing the initial excitation on the structure. Depending on the initial conditions of excitation, the structure may vibrate in one natural frequency or in a combination of more than one

FIGURE 9.21 Various loading types.

natural frequency. In the latter case, the vibration will result in a complex periodic motion that may be decomposed into a series of harmonic motions vibrating at the first natural frequency (fundamental one) and its multiples. As indicated, these frequencies are called the natural or resonant frequencies of the system and they depend on the mass and elastic or stiffness characteristics of the system. In other words, the natural frequencies of a system are those frequencies that the system tends to vibrate under conditions of free vibration. Theoretically, a continuous system or structure has infinite DoF and infinite natural frequencies. From a practical modeling point of view, the structure will have a number of natural frequencies equal to the number of DoF used to model the structure. The mode shapes give the relative displacements of each point in the structure when it vibrates in one of the natural frequencies. Each natural frequency has a corresponding mode shape. The first mode shape corresponding to the first natural frequency of a structure represents the most flexible way in which the structure may deform or vibrate and corresponds to the least strain energy level in all modes. It is important to note that, a symmetric structure will have symmetric and antisymmetric mode shapes. This may be realized by considering the mode shapes of a simple beam as shown in Figure 9.22 where all odd number modes are symmetric and all even number modes are antisymmetric.

The information provided by the natural frequencies and mode shapes of a structure is vital in understanding the behavior of the structure under general excitation. If a structure is excited in one of its natural frequencies, then theoretical analysis of the structure response as an undamped system shows that the amplitude of the resulting vibration response reaches infinity. In practice, all structures possess a certain amount of damping that will limit the amplitude of vibration.

Determining the type of analysis required for a structure depends on the nature of the applied load and the magnitude of the first natural frequency or the fundamental frequency of the structure. The two main categories of analysis types are static and dynamic analyses. A steady load, i.e., a load that does not change with time (Figure 9.21a), would require simple static analysis. If the load varies with time, it does not necessarily mean that dynamic analysis needs to be performed. For example, if the loading is harmonic with a frequency less than approximately one third of the first natural frequency of the structure then static analysis will provide an accurate solution and we only need to solve the static problem for the peak load values. (For this frequency range, static analysis may provide a maximum difference of 12.5% in the response for undamped structures and for a forcing frequency less than one fourth of the natural frequency, the difference is only 6.7%.) In this case, the load is normally called “quasi-static.” We may apply the same rule to periodic loading after decomposing it into its harmonic components. In transient loading, we should consider the time of application of the load or the “rise time.” If the longest natural period corresponding to the first natural frequency of the structure is more than about twice the rise time, the loading should be classified as shock or impact loading and transient dynamic analysis would be required. If the longest natural period of a system is less than about one third of the rise time, it would be sufficient to perform static analysis and consider the loading to be quasi-static. If the longest natural period falls between the quasi-static and shock conditions then a transient dynamic analysis would be required and the load would be classified as transient loading. If the loading cannot be categorized as frequency dependent or time dependent, as for example the one shown schematically in Figure 9.21d, then it should be considered random.

FIGURE 9.22 First four mode shapes of a simple beam.

From the above discussion, the following categories of dynamic analysis may be classified (Mirovitch, 1980):

Modal and natural frequency analysis: This is normally performed before any other type of dynamic analysis and will produce the natural frequencies and mode shapes of the structure. This information is vital for understanding the dynamic behavior of the structure and provides data for decoupling the dynamic equations in other analyses. One objective of this analysis is to make sure that the structure is not operating at a frequency close to one of its natural frequencies. A comfortable range for an operating frequency is three times higher than the nearest natural frequency from the lower side and three times smaller than the nearest natural frequency from the higher side. If the operating frequency is higher than the first natural frequency, then large vibration amplitudes or “shudder” will be evident upon passing the natural frequency and certain startup procedures may have to be devised.

Frequency response analysis: This type of analysis is performed if the loading on the structure is harmonic or periodic. In periodic loading, the loading function is first decomposed into its sine and cosine components using Fourier analysis. In this analysis, the response will be harmonic with the same loading frequency and with a possible phase shift. The output of such analysis would be displacements, velocities, and accelerations that may be used to calculate forces and stresses in the structure. The displacement output of this analysis defines the deformed shape of the structure, which, in general, is different from the structural mode shapes and may be used to calculate stresses and strains in the structure. Assuming linear conditions, the response to multiple frequency inputs may be simply summed up using the superposition technique.

Transient response analysis: This type of analysis is performed if the loading on the structure is classified as transient or shock. There are two general approaches to solving the equation of motion in transient analysis. One is the “direct integration approach” and the other is the “modal superposition approach.” In the direct integration approach, the system equations of motion are integrated directly in the time domain. The required number of time steps depends on the period and the assumptions specified for displacement, velocities, and accelerations within the time step. This number may be quite large and the solution to large size problems may become a computationally difficult task.

In the second method, the modal superposition approach, the equations of motion are first transformed to modal generalized displacements. In order to perform this transformation, the mode shapes of the structure should first be determined through a modal analysis. The transformation yields a set of decoupled second-order differential equations for the system that are easier to solve. The basic assumption in this approach is that the superposition of the structural response due to the first few lower mode shapes adequately represents the dynamic response of the structure under general transient loading. In practice, this means that only a fraction of the mode shapes of the structure are needed to accurately represent the dynamic behavior. This approach will be generally less accurate than the direct integration approach but will provide substantial savings in computation time for large size problems.

The output of transient analysis is time histories of displacements, velocities, and accelerations of the system that may be used to calculate forces and stresses.

Random response analysis: If the loading on the structure cannot be classified as frequency or time dependent, it is considered random. Problems with random loading may be solved using a “time history approach” or a “power spectral density (PSD) approach.” The time history approach treats the random input as a transient one and performs a step-by-step integration over the excitation period. This is normally very costly and requires intensive use of computational resources. If the structure has multiple random inputs in more than one direction, then the transient time history approach is more accurate and may be the preferred approach to solve the problem. Structures with random inputs in more than one direction may be analyzed by a modal superposition approach with special procedures to combine the modal responses (see Section 9.5.4 for details). In the PSD approach, the input will be acceleration as a function of frequency. This is normally specified as a discrete or continuous spectrum by providing values of the (G^2/f) vs. f , where G is the input acceleration and f is the frequency. This approach is most appropriate for a single input in one direction.

As mentioned above, most programs will have standard time history inputs or PSD inputs to simulate commonly used random excitations such as vibrations due to road irregularities, earthquakes and seismic inputs, vibration due to wind loads for aerospace parts, and wind loads for wind tunnel tests.

REMARKS

- Structural loading may be classified into four categories: steady (constant with time), cyclic (harmonic with period $T = 2\pi$ and frequency $f = 1/T$ or general periodic that may be decomposed into harmonics by Fourier analysis), transient with a duration T , and random.
- Random forcing functions are commonly specified as the magnitude of the input acceleration squared vs. frequency (PSD). Typical PSD curves have been compiled for various random events and are normally available in commercial FE programs.
- The natural frequencies of a system are those frequencies that the system tends to vibrate under conditions of free vibration. The mode shapes give the relative displacements of each point in the structure when it vibrates in one of the natural frequencies. Symmetric structures will generally have symmetric and antisymmetric mode shapes.
- If the loading is harmonic with a frequency of less than approximately one third of the first natural frequency of the structure, static analysis for the peak load levels suffices. In transient loading, if the longest natural period of a system is less than about one third of the rise time, loading is quasi-static and static analysis suffices.
- In transient loading, if the longest natural period corresponding to the first natural frequency of the structure is more than about twice the rise time of the load, it is necessary to classify the loading as shock or impact loading and transient dynamic analysis would be required.
- If the longest natural period falls between the quasi-static and shock conditions, a transient dynamic analysis would be required.

9.3 Modeling Aspects for Dynamic Analysis

Section 9.1 and Section 9.2 provide guidelines for problem and analysis classification. Once a decision has been made about the type of problem and the method of analysis to be used, the designer still has to finalize many details to create a working model for the structure. This section provides a brief discussion of the main aspects required to do this. This includes choice of model size and master DoF, lumped and consistent mass modeling, and use of symmetry. Another important aspect of modeling, damping, will be dealt with in Section 9.4.

9.3.1 Model Size and Choice of Master Degrees of Freedom

Using the same model for both static and dynamic analysis will make the FE solution to the dynamic problem more complicated and therefore much more memory and CPU resources will be required. Also, the results may not be necessarily more useful or accurate. Therefore, FE models for dynamic analysis should, in general, be kept simple.

Depending on the type of dynamic analysis, it may be possible to construct a much simpler model for the dynamic problem, possibly using spring, beam, and mass elements. If we consider modal analysis, for example, the objective is to find the mode shapes of the structure and the corresponding natural frequencies. In practice, we seldom need more than the very few lower natural frequencies and mode

FIGURE 9.23 Static and dynamic models for a shaft.

shapes for a structure. Using a static model that may have thousands of DoF in a modal analysis is very time consuming and does not serve the purpose of the mode shape analysis. It may be better and more efficient to construct a mass spring/beam model for the modal analysis. Figure 9.23 shows a static analysis model for a shaft and a corresponding much simpler mode shape analysis model. In the mass/beam model for modal analysis, the beam properties may change to accommodate specific variations in the shaft geometry. It is also possible to extract accurate values for the spring and beam stiffnesses in 3-D using a detailed static model.

Most programs provide means for condensing or reducing the DoF in a dynamic analysis. A common condensation method used is the “Guyan reduction” (see e.g., Freed and Flanigan, 1991; Bouhaddi and Fillod, 1992; Deiters and Smith, 2000). In these condensation methods, the analyst specifies certain DoF to be masters and to be retained by the program, while all other DoF would be considered slaves and would be eliminated or condensed. The dynamic analysis is then carried out using the master DoF. Information pertaining to slave DoF is still available and may be extracted in subsequent runs that may involve stress or other detailed analyses or postprocessing. Reduction has the same effect as modal superposition in terms of reducing the problem size and the required CPU time.

Fundamental differences between the two methods may be realized due to the nature of reducing the system of equations. In the modal superposition technique, reduction is accomplished by assuming that the superposition of the structural response due to the first few lower mode shapes adequately represents the response of the structure. In other reduction methods, such as the Guyan reduction technique, we assume that the response of the system is accomplished from the response of certain predetermined master DoF. In the modal superposition technique, a modal analysis must be performed first and the final equations of motion are decoupled, whereas in the other reduction methods no modal analysis is necessary and the final equations of motion are generally full and coupled. Reduction of the total DoF to a set of master DoF has the effect of imposing displacement constraints on the system that increase the stiffness and subsequently overestimate the natural frequencies. The least affected modes are the lower ones. Therefore, reduction and modal superposition techniques should not be used, in general, for shock and impact loading (the modal superposition technique entirely ignores the response from higher modes).

The choice of master DoF may be performed automatically by the program. There is no assurance, however, that this will always produce the best choice of masters. The analyst may like to use the program for a first choice of master DoF and then augment the choice manually to improve the accuracy. Simple rules may be used to identify the master DoF (see *ANSYS User's Manual*, 2003). The general rule is to choose DoF with large mass and small stiffness or large mass to stiffness ratios as masters. Master DoF should be chosen in the direction of the expected response of the structure, e.g., in a beam or shell model, lateral DoF would be more appropriate than axial or membrane DoF, assuming that the load produces lateral deflections. Rotational DoF are seldom used as masters. It is also important to spread out and not cluster the master DoF so that they will be capable of producing the structural response. Finally, DoF with concentrated mass, a specified input force, or displacement should be retained as masters.

The question of how many master DoF are adequate is not an easy one to answer. The rule of thumb is to have having at least double the number of master DoF compared with the number of modes of interest. The other guideline is to use 10 to 50% of the total DoF as masters. In practice, the only sure way to test the adequacy of the number of master DoF is to run the analysis with two different choices and compare the results to make sure that the modes of interest are not substantially different.

REMARKS

- In general, dynamic analysis models should be simpler and much smaller in terms of the number of DoF (than static analysis ones). In modal analysis, it is better and more efficient to construct a mass spring/beam model for the structure.
- “Guyan reduction” may be used to reduce the model size by selecting master DoF for the analysis and condensing out slave DoF.
- Master DoF may initially be chosen by the program. The analyst should, however, ensure that the choice includes nodes with a large mass to stiffness ratio and with DoF in the direction of the expected response of the structure. Also, it is important to spread out and not cluster the master DoF.
- As a rule of thumb, the number of master DoF should be at least double the number of modes of interest or about 10 to 50% of the total DoF.

9.3.2 Lumped and Consistent Mass Modeling

The mass characteristic of the structure may be modeled as a lumped or consistent mass matrix. Lumped mass simply means dividing the total mass of the element by the number of nodes. This produces a diagonal mass matrix and may significantly reduce the numerical effort required to solve the dynamic equations. Considering rotational inertia terms in lumped mass assumptions is arbitrary and is normally ignored. If the lumped mass matrix has zero diagonal terms, the matrix will be positive semidefinite and the natural periods corresponding to the zero diagonal terms will be zero. This will have serious implications on the choice of the time step in explicit direct integration solution methods and will be discussed in Section 9.4. A lumped mass assumption implies a discontinuous acceleration field in the element and it usually gives good accuracy for lower modes and frequencies (Chan et al., 1993; Jensen, 1996). A consistent mass matrix is derived by introducing inertia forces in the virtual work formulation of a dynamic FE problem. This would normally lead to a full mass matrix making contributions to both translational and rotational DoF as well as coupling terms. Consistent mass representation usually provides better accuracy for higher modes and frequencies (Kim, 1993).

It may be concluded that, if no reduced integration is used to compute element stiffness, the element is compatible, and a consistent mass matrix is used, then the calculated natural frequencies will be an upper bound of the model frequencies (Cook et al., 1989). In some applications such as plates, shells, and 3-D solid elements, it has been found that the convergence rate of the natural frequency calculations for the lumped mass discretization is the same as that for a consistent mass formulation (Chan et al., 1993; Jensen, 1996).

Some FE programs provide a modified lumped mass modeling in which the diagonal translational terms are proportional to the diagonal terms of the corresponding consistent mass matrix. This yields more accurate results, in general, than the traditional lumped mass assumption. Several studies have been published on the merits of combining consistent and lumped mass formulations into some kind of modified lumped mass matrix (Chan et al., 1993; Kim, 1993; Jensen, 1996). The modified lumped mass matrix is generally a linear combination of the lumped and the consistent mass matrices. For an improved accuracy, the consistent mass should be weighted more than the lumped mass.

In building a lumped mass model for the structure, the analyst should realize that one of the objectives is to capture the few lower natural frequencies and mode shapes of the structure. To achieve this, the model should minimize the strain energy and maximize the kinetic energy of the structure. Minimizing the strain energy of the structure may be realized by accurately modeling the soft links in the load path. Structural supports are particularly difficult in this regard. Changing the support model from completely rigid to slightly flexible may shift the first natural frequency by as much as 40% (although it will not have much impact on the mode shape). Maximizing the kinetic energy is simply realized by accurate modeling of the system mass, especially in areas where the mass is large and the stiffness is small.

Care should be exercised when modeling masses attached to the system, e.g., a large “nonstructural” mass on top of a building (e.g., a mass of a machine, reservoir, etc.) or the mass of an engine in a car model. If the stiffness characteristic of the nonstructural mass is not important, it may be simply modeled as a rigid lumped mass with an offset mass center from the nearest node. Most programs have a rigid link capability to connect this mass to the structure. This kind of model is transformed internally to a nondiagonal mass matrix and may only be used with a consistent mass formulation for the structural mass. If the structural mass is modeled as lumped, the nonstructural mass will simply be added to the nearest node, which may not be an accurate representation of the physical model.

REMARKS

- A lumped mass matrix is a diagonal mass matrix that may be obtained by simply dividing the total mass by the number of DoF or alternatively by certain combinations of lumped and consistent mass terms. A consistent mass matrix is derived from FE virtual work equations and is normally a full mass matrix having translational, rotational, and coupling terms.
- Lumped mass may significantly reduce the numerical effort required to solve the dynamic equations without impacting the accuracy.
- Zero diagonal terms in the mass matrix should be avoided as much as possible.
- A lumped mass assumption usually gives good accuracy for lower modes and frequencies, whereas consistent mass representation usually gives better accuracy for higher modes and frequencies.

9.3.3 Use of Symmetry

Use of symmetry to reduce the analysis cost and computer time is rather tricky in modal analysis. As shown in Table 9.2, symmetric structures have both symmetric and nonsymmetrical mode shapes. If we only use a symmetric model with symmetric boundary conditions, all nonsymmetrical modes will be undetected. This will change the interpretation of the results and will have an impact on subsequent analyses using the modal data. If the objective is to perform only a modal analysis, it may be advisable to have a less detailed full model rather than a detailed half or quarter model. Also, if the

TABLE 9.2 Symmetric and Antisymmetric Boundary Conditions

Plane of symmetry	Symmetric Boundary Conditions						Antisymmetric Boundary Conditions					
	u_x	u_y	u_z	θ_x	θ_y	θ_z	u_x	u_y	u_z	θ_x	θ_y	θ_z
XY	—	—	0	0	0	—	0	0	—	—	—	0
XZ	—	0	—	0	—	0	0	—	0	—	0	—
YZ	0	—	—	—	0	0	—	0	0	0	—	—

objective is to perform frequency response or transient analysis using the modal data, it may be advisable to rely on a full model. Experienced analysts may use symmetric models and run the modal analysis with symmetric and antisymmetric boundary conditions to capture the response of all modes. Table 9.2 summarizes symmetric and antisymmetric boundary conditions for translational and rotational DoF.

9.4 Equations of Motion and Solution Methods

In this section, an overview of the equation of motion and the various solution methods available are provided. In most cases, detailed derivation of the equations is not given. The intention is to highlight various solution schemes and the practical aspects of choosing a particular one for a given system or a given dynamic analysis. A consideration of damping and its idealization are also discussed in this section.

9.4.1 Equation of Motion

The equations of motion describing the dynamic behavior of a structural system may be obtained from the extended Hamilton's principle for elastodynamics:

$$\delta \int_{t_0}^{t_f} (U - T) dt - \int_{t_0}^{t_f} \delta W dt = 0 \quad (9.1)$$

where

δ : first variation

t_0, t_f : two arbitrary time points at which the first variation vanishes

U : strain energy of the system

T : kinetic energy of the system

δW : virtual work of the external forces acting on the system during virtual displacements

The external forces may be conservative or nonconservative. Nonconcentrative forces, e.g., damping and follower forces, are deformation dependent, i.e., their magnitudes and/or directions depend on the deformations. Introducing the finite element discretization assumption and substituting expressions for the virtual work and the kinetic and strain energy terms into the above equation, we obtain the Lagrange equation which finally leads to the equations of motion of the system that may be written in the following form:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{p}(t) \quad (9.2)$$

where \mathbf{M} , \mathbf{C} , and \mathbf{K} are, respectively, the global mass, global damping, and global stiffness matrices (made up by proper assembly of the element matrices); $\mathbf{p}(t)$ is the time-dependent applied force vector; and $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, and \mathbf{u} are the nodal acceleration, nodal velocity, and nodal displacement vectors, respectively.

The global mass and damping matrices are assembled from the element matrices that are given by (Cook et al., 1989; Bathe, 1996):

$$\mathbf{M}^{(e)} = \int_V \rho^{(e)} \mathbf{N}^T \mathbf{N} dV \quad (9.3)$$

$$\mathbf{C}^{(e)} = \int_V c_s^{(e)} \mathbf{N}^T \mathbf{N} dV \quad (9.4)$$

where $\rho^{(e)}$ and $c_s^{(e)}$ are the mass density and the viscous damping coefficient for an element e , and \mathbf{N} is the matrix of the element shape functions.

As indicated above, there are two general approaches to solving Equation 9.1. One is the direct integration approach and the other is the modal superposition approach. With the direct integration approach, the equations of motion are integrated directly in the time domain. In the second approach, the modal superposition method, the equations of motion are first transformed to modal generalized displacements through the use of the mode shapes of the structure. The transformation yields a set of

decoupled second-order differential equations for the system that are easier to solve. In the remaining part of this section, we describe the two solution approaches in more detail.

REMARKS

- Equation 9.2 is the general equation of motion for a dynamic system. Two solution methods are available: the direct integration approach and the modal superposition approach.

9.4.2 Direct Integration Method

With this method, the coupled equations of motion are integrated directly without special transformation. Direct integration schemes seek to satisfy the equilibrium equations of motion at discrete time points, $0, \Delta t, 2\Delta t, \dots, t, t + \Delta t, \dots$ etc. This requires assumptions for the variation of $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, and \mathbf{u} within the time step. These assumptions will determine the accuracy and convergence characteristics of a particular time integration scheme. They also govern the variation of these quantities with time and are different from the shape function assumptions for the element, which govern the displacement variation within the element, i.e., with spatial coordinates. Direct integration schemes may be categorized as “explicit” and “implicit” schemes. In explicit schemes, the equilibrium equations at time t are used to solve the unknowns at time $t + \Delta t$. These schemes are usually fast and efficient and require no factorization of the effective stiffness matrix provided that the mass and damping matrices can be formulated as diagonal matrices. The main drawback of these schemes is the requirement that the time step for the analysis has to be smaller than a critical value. On the other hand, in implicit schemes, the equilibrium equations at time $t + \Delta t$ are used to solve unknowns at time $t + \Delta t$. These schemes require factorization of the effective stiffness matrix of the structure at each time step but do not require the condition of a critical time step. In implicit schemes, the number of operations at each time step is proportional to the matrix order times half of the band width, $m = \alpha nb$, where m is the number of operations, n is the number of equations, α is a constant ≥ 2 , and b is half the band width.

Many integration schemes are available in commercial FE programs. These include Euler forward, Euler backward, central difference, Houbolt, Wilson- θ , and Newmark schemes (Belytschko and Hughes, 1983; Zeng et al., 1992). In the following, one example of an explicit scheme and one example of an implicit scheme are discussed.

9.4.2.1 The Central Difference Method

This is an explicit scheme in which the velocity and acceleration assumptions are given by

$$\left. \begin{aligned} {}^t\dot{\mathbf{u}} &= \frac{1}{2\Delta t} \left({}^{t+\Delta t}\mathbf{u} - {}^{t-\Delta t}\mathbf{u} \right) \\ {}^t\ddot{\mathbf{u}} &= \frac{1}{(\Delta t)^2} \left({}^{t+\Delta t}\mathbf{u} - 2 {}^t\mathbf{u} + {}^{t-\Delta t}\mathbf{u} \right) \end{aligned} \right\} \quad (9.5)$$

Using Equation 9.5 in the equilibrium equation at time (t) to obtain a solution at time $(t + \Delta t)$ gives

$$\left[\frac{1}{(\Delta t)^2} \mathbf{M} + \frac{1}{2(\Delta t)} \mathbf{C} \right] {}^{t+\Delta t}\mathbf{u} = {}^t\mathbf{p} - \left[\mathbf{K} - \frac{2}{(\Delta t)^2} \mathbf{M} \right] {}^t\mathbf{u} - \left[\frac{1}{(\Delta t)^2} \mathbf{M} - \frac{1}{2(\Delta t)} \mathbf{C} \right] {}^{t-\Delta t}\mathbf{u} \quad (9.6)$$

If the mass and damping matrices are diagonal, Equation 9.6 requires no assembly and no factorization of the effective stiffness matrix of the structure is required. The scheme is, however, conditionally stable and requires a time step smaller than a critical value given by

$$\Delta t_{cr} \leq T_n / \pi \quad (9.7)$$

where T_n is the smallest period in the FE assembly with n DoF. This is an important condition and should be examined carefully. If the mass matrix has a zero diagonal value, the corresponding period will be zero and Equation 9.7 cannot be satisfied. Introducing very small diagonal values may not provide a practical solution since the time step will be very small and the number of steps will be excessive. The scheme is generally applied when a lumped mass assumption with no zero diagonal terms and velocity-dependent damping are assumed. The initial conditions required for this scheme are the displacements, velocities, and accelerations at time $t = 0$.

9.4.2.2 The Newmark Method

This is a commonly used implicit scheme with the following assumptions:

$${}^{t+\Delta t}\dot{\mathbf{u}} = {}^t\dot{\mathbf{u}} + \left[(1 - \alpha) {}^t\ddot{\mathbf{u}} + \alpha {}^{t+\Delta t}\ddot{\mathbf{u}} \right] \Delta t \quad (9.8)$$

$${}^{t+\Delta t}\mathbf{u} = {}^t\mathbf{u} + {}^t\dot{\mathbf{u}} \Delta t + \left[\left(\frac{1}{2} - \beta \right) {}^t\ddot{\mathbf{u}} + \beta {}^{t+\Delta t}\ddot{\mathbf{u}} \right] (\Delta t)^2 \quad (9.9)$$

where α and β are user input parameters. Equation 9.8 and Equation 9.9 are solved for ${}^{t+\Delta t}\dot{\mathbf{u}}$ and ${}^{t+\Delta t}\ddot{\mathbf{u}}$, then substituted into the equilibrium equations at time $(t + \Delta t)$ to obtain:

$$\left[\mathbf{K} + \frac{\alpha}{\beta \Delta t} \mathbf{C} + \frac{1}{\beta (\Delta t)^2} \mathbf{M} \right] {}^{t+\Delta t}\mathbf{u} = {}^{t+\Delta t}\bar{\mathbf{p}} \quad (9.10)$$

where the right-hand side is a function of the parameters α , β , Δt , \mathbf{K} , \mathbf{M} , \mathbf{C} , ${}^t\mathbf{u}$, ${}^t\dot{\mathbf{u}}$, and ${}^t\ddot{\mathbf{u}}$. Equation 9.10 indicates that the scheme requires assembly and factorization of the effective stiffness matrix of the structure. The choice of parameters α and β will determine the stability of the scheme and may reduce the scheme to be equivalent to other known ones as follows:

- For $2\beta \geq \alpha \geq 1/2$, the scheme is unconditionally stable. This does not guarantee accuracy and only ensures that the results will not grow out of bounds (Belytschko and Hughes, 1983).
- A slightly more stringent criterion for unconditional stability that provides artificial damping in higher modes is given by using (Belytschko and Hughes, 1983):

$$\alpha \geq \frac{1}{2} \quad \text{and} \quad \beta \geq \frac{1}{4} \left(\alpha + \frac{1}{2} \right)^2$$

- A commonly used option gives $\alpha = 1/2$ and $\beta = 1/4$ which corresponds to a trapezoidal rule with constant average acceleration.
- Another option that corresponds to a linear acceleration assumption is given by $\alpha = 1/6$ and $\beta = 1/2$. This method is very good for small Dt but tends to be unstable for large Dt .

Table 9.3 summarizes the above choices for α and β .

TABLE 9.3 Typical Choices of α and β Parameters for the Newmark Scheme

α Value	β Value	Comments
$2\beta \geq \alpha \geq 1/2$	$2\beta \geq \alpha \geq 1/2$	No guarantee of accuracy
$\alpha \geq \frac{1}{2}$	$\beta \geq \frac{1}{4} \left(\alpha + \frac{1}{2} \right)^2$	Improved accuracy Provides artificial damping in higher modes
$\alpha \geq \frac{1}{2}$	$\beta \geq \frac{1}{4} \left(\alpha + \frac{1}{2} \right)^2$	Improved accuracy Corresponds to a trapezoidal rule with constant average acceleration
$\alpha \geq \frac{1}{2}$	$\beta \geq \frac{1}{4}$	Improved accuracy Provides artificial damping in higher modes Good for small Dt
$\alpha = 1/6$	$\beta = 1/2$	Improved accuracy Corresponds to a linear acceleration Very good for small Dt but tends to be unstable for large Dt

REMARKS

- In the direct integration approach, the equations of motion are integrated directly without special transformation. Such schemes may be categorized as explicit and implicit schemes.
- Explicit schemes are usually fast, efficient, and require no factorization of the effective stiffness matrix provided that the mass and damping are diagonal (refer to Equation 9.6 for an example). However, explicit schemes require the time step to be smaller than a critical value (Equation 9.7) that normally leads to very large number of steps.
- Implicit schemes require factorization of the effective stiffness matrix of the structure at each time step (refer to Equation 9.10 for an example) but do not require the condition of a critical time step.
- Although implicit schemes are unconditionally stable, accuracy is not always guaranteed without careful consideration of the step size (refer to Table 9.3).

9.4.3 Modal Superposition Method

In this method, the nodal displacement response is expressed in terms of the normal modes that may be found in an eigenvalue analysis. The coupled equations of motion, Equation 9.2, are first transformed into a set of independent or decoupled differential equations cast in modal generalized coordinates (Mirovitch, 1980). The dynamic response of the original system is then obtained by superimposing the responses of the uncoupled modal equations. The generalized coordinates (modal coordinates) are introduced by the following coordinate transformation

$$\mathbf{u} = \Phi \mathbf{q} \text{ and } u_i = \sum_{j=1}^m \varphi_{ij} q_j \quad (9.11)$$

where Φ is an $n \times m$ matrix called the eigenvector or mode shape matrix, m is the number of eigenvectors ($m \leq n$), n is the number of DoF of the system, and \mathbf{q} is a vector of size $m \times 1$ representing the number of mode-amplitude generalized or normal coordinates. The transformation given by Equation 9.11 represents a change of basis from nodal displacements (\mathbf{u}) to modal generalized coordinates (\mathbf{q}). In order for the equations to be decoupled in the modal generalized coordinate system, the triple product $\Phi^T \mathbf{C} \Phi$ has to be a diagonal matrix and the following orthogonality property is assumed for damping:

$$\Phi^T \mathbf{C} \Phi = \text{diag}(2\xi_i \omega_i) \quad (9.12)$$

where ξ_i is the damping ratio for mode i and $\text{diag}(2\xi_i \omega_i)$ indicates a diagonal matrix with the i th diagonal component of $2\xi_i \omega_i$. This form has been assumed by generalization of damping for a single DoF system. It is practically more convenient to define the damping by the damping ratios of each mode than it is to evaluate the damping matrix explicitly. Introducing Equation 9.11 and Equation 9.12 into the equation of motion, the following decoupled equations of motion are obtained:

$$\ddot{\mathbf{q}} + \text{diag}(2\xi_i \omega_i) \dot{\mathbf{q}} + \text{diag}(\omega_i^2) \mathbf{q} = \Phi^T \mathbf{p}(t) \quad (9.13)$$

If the components of the applied force vector have the same time function, so that $\mathbf{p}(t)$ can be expressed as

$$\mathbf{p}(t) = \bar{\mathbf{p}} g(t) \quad (9.14)$$

where $\bar{\mathbf{p}}$ is a constant vector and $g(t)$ is a function giving the time change of the load vector, then the modal load can be written as

$$f_r(t) = (\varphi_r^T \bar{\mathbf{p}}) g(t) = \Gamma_r g(t) \quad (9.15)$$

where φ_r^T is a row modal vector corresponding to mode r . The quantity Γ_r is referred to as the modal participation factor (*NISA User's Manual*, 1992). A particular use of this quantity is in ground motion types of excitation.

Once the generalized coordinates, \mathbf{q} , are evaluated, the physical response of the original system in terms of nodal displacements, velocities, accelerations, and stresses are recovered from Equation 9.11. For the stress recovery, it is noted that (*NISA User's Manual*, 1992; Kim et al., 1994):

$$\boldsymbol{\sigma}(t) = \mathbf{D}\mathbf{B}\ddot{\mathbf{u}}^{(e)}(t) = \mathbf{D}\mathbf{B}\boldsymbol{\Phi}^{(e)}\mathbf{q} = [\mathbf{D}\mathbf{B}\boldsymbol{\Phi}^{(e)}]\mathbf{q} = \mathbf{A}\mathbf{q} \quad \text{or} \quad \sigma_i(t) = \sum_{r=1}^m \Lambda_{ir}q_r \quad (9.16)$$

where $\sigma_i(t)$ represents a stress component in an element (i.e., σ_{xx} , σ_{yy} , σ_{xy} , etc.), Λ_{ir} lists the stress components corresponding to the r th mode at a typical point. That is, Λ_{ir} , $r = 1, 2, \dots, m$ are modal stresses which should be interpreted as stress shapes rather than absolute values of stress and the matrix \mathbf{D} is the material stress–strain matrix.

The above derivation of the mode superposition method shows the decoupling advantage of the normal coordinates, whereby the change of basis from nodal displacements to normal modes yields a set of uncoupled modal equations, with each equation cast in the form of a single DoF oscillator. As indicated above, another major advantage of the normal mode method is that a good approximation to the response may be obtained using a drastically reduced number of coordinates ($m \ll n$). For most types of loading, with the exclusion of shock and impact loading, the contributions of the lowest few modes are generally more pronounced than the higher modes. Furthermore, practical finite element idealization approximates the lower modes better and tends to be less reliable for higher modes of vibration.

REMARKS

- In the modal superposition approach, the equations of motion are first transformed into a set of decoupled equations cast in modal generalized coordinates. The response of the system is then obtained by superimposing the solutions of the decoupled modal equations (Equation 9.13 and Equation 9.16).
- The modal superposition approach may only be achieved for linear systems with proportional or directly assumed modal damping (refer to Section 9.4.4).
- In the modal superposition approach, a good approximation to the response may be obtained using a drastically reduced number of modes. For most types of loading, with the exclusion of shock and impact loading, the contributions of the lowest few modes are generally more pronounced than the higher modes.
- Practical FE idealization approximates the lower modes better and tends to be less reliable for higher modes of vibration.

9.4.4 Damping Formulation

Damping is a source of energy dissipation in the structure and it leads to decay of the free vibration amplitude with time. Damping sources in a structure include internal friction in the material, Coulomb friction in sliding and pin joints, and other viscous friction forces due to fluid friction (Beards, 1982; Fretzen, 1986). The overall damping of a system is normally quite difficult to obtain and, in general, must be determined experimentally (Kareem and Gurley, 1996). In free vibrations and modal analysis, the damping may be neglected or an overall small value for the system may be assumed. This is a reasonable assumption since in practice damping is small enough and can usually be assumed to be viscous. In forced vibrations, however, and when the forcing frequency is close to one of the system's natural frequencies, the response of the system is dominated by the specified damping values.

Commonly, damping is described in viscous or structural form. Both descriptions are used for their mathematical convenience but may not truly represent the actual damping behavior and mechanism. For viscous damping, the damping force is proportional to and opposes the velocity. With structural damping, the damping force is proportional in magnitude to the internal elastic force (i.e., to the displacement) and is in the opposite direction to the velocity. In practical FE analysis, most programs provide the following damping representation that may be used for dynamic analysis:

1. Discrete viscous damper elements (dashpots). As discussed in Section 9.1.2, these elements are damping counterparts of the spring elements and are discrete idealization of viscous damping in the structure. The damping matrix resulting from these elements, in general, cannot be decoupled as in Equation 9.12. Hence, these elements may be used only with direct integration solution methods.

2. Proportional viscous damping (Rayleigh damping). In this type, the following arbitrary form for the damping matrix is assumed:

$$\mathbf{C} = c_1 \mathbf{K} + c_2 \mathbf{M} \quad (9.17)$$

where c_1 and c_2 are constants to be determined and supplied by the user. A commonly used method in determining the constants c_1 and c_2 is to define two damping ratios ξ_1 and ξ_2 corresponding to two unequal natural frequencies ω_1 and ω_2 , respectively. Since \mathbf{C} is proportional to \mathbf{K} and/or \mathbf{M} , it satisfies the orthogonality property and we have

$$c_1 \omega_i^2 + c_2 = 2 \xi_i \omega_i \quad (9.18)$$

which leads to

$$\xi_i = \frac{c_1 \omega_i}{2} + \frac{c_2}{2 \omega_i} \quad (9.19)$$

Equation 9.19 is then used to calculate the coefficient c_1 and c_2 from the knowledge of the specified damping ratios ξ_1 and ξ_2 and their corresponding natural frequencies ω_1 and ω_2 . For the case when \mathbf{C} is only proportional to \mathbf{K} ($c_2 = 0$), the damping ratio is proportional to the natural frequency, and thus the higher modes will be damped more than the lower modes. Similarly, if \mathbf{C} is only proportional to \mathbf{M} ($c_1 = 0$), the damping ratio is inversely proportional to the natural frequency and the higher modes will have less damping than the lower modes. The relationship of Equation 9.19 is diagrammatically illustrated in Figure 9.24.

The above method for calculating the coefficients c_1 and c_2 should not restrict the use of proportional damping to only modal analysis. Proportional damping may be used in harmonic, modal, and transient analyses, as well as substructure and reduced types of analyses.

For direct transient dynamic analysis, different sets of constants c_1 and c_2 may be assigned to different parts of the model. This may result in a nonorthogonal global damping matrix. The damping orthogonality condition, however, is not required in direct transient dynamic analysis since the governing equations are directly integrated.

FIGURE 9.24 Proportional damping.

TABLE 9.4 Typical Damping Ratios for Various Systems and Materials

System/Material	Damping Ratio
Various metals in elastic range	< 0.01
Small diameter piping systems	0.01–0.02
Large building during earthquake	0.01–0.05
Large diameter piping systems	0.02–0.03
Welded joints and rigid metal structures	0.02–0.04
Prestressed concrete structures	0.02–0.05
Metal structures with joints	0.03–0.07
Transmission lines (aluminum or steel)	0.04
Reinforced concrete structures	0.04–0.07
Rubber	0.05
Bolted joints	0.07
Shock absorbers	0.30

3. Modal viscous damping, in which the damping ratios are directly specified for the participating modes. This type of damping can be used in modal dynamic analyses and usually provides good results for systems with small damping. In this type, the damping matrix is assumed to be diagonal with values of $2\xi_i\omega_i$, where i is the i th diagonal and ξ_i is the damping ratio for mode i with frequency ω_i .

Typical values of overall damping ratios for various systems are given in Table 9.4 (Adams and Askenazi, 1999).

REMARKS

- Damping is a source of energy dissipation in the structure and is generally difficult to quantify. Damping sources in a structure include internal, Coulomb, and viscous friction.
- The most common forms of damping provided by FE programs are discrete, proportional, and modal viscous damping.
- Discrete damping is modeled by special spring and damping elements in FE applications. The damping matrix resulting from these elements cannot, in general, be decoupled as in Equation 9.12. Hence, these elements may be used only with direct integration solution methods.
- Proportional viscous or Rayleigh damping (Equation 9.17) leads to a decoupled damping matrix and may be used in both direct integration as well as modal superposition approaches.
- A commonly used method to determine the coefficient of proportionality is through defining two modal damping ratios (Equation 9.19).
- In modal viscous damping, the damping ratios are directly specified for the participating modes and the damping matrix is assumed to be diagonal.

9.5 Various Dynamic Analyses

9.5.1 Modal Analysis

This is normally the first, and in certain cases the only, type of analysis required for a structure. It is used to obtain the dynamic characteristics of a system in terms of its natural frequencies or eigenvalues

and associated undamped free vibration natural modes or eigenvectors. These eigenmodes may then be used to decouple the general equations of motion in other types of dynamic analyses. Modal analysis is the first step required before performing mode superposition harmonic or transient analysis as well as spectrum analysis. The natural frequencies of the system may be obtained by solving the eigenvalue problem:

$$(\mathbf{K} - \omega^2 \mathbf{M})\bar{\varphi} = 0 \quad (9.20)$$

For a nontrivial solution, the coefficient matrix $(\mathbf{K} - \omega^2 \mathbf{M})$ is singular and its determinant is equal to zero, which yields the values of the natural frequencies. For each eigenvalue, ω_n , a corresponding mode shape, $\bar{\varphi}_i$, can be obtained from Equation 9.20. If the mass matrix has some zero diagonal values, the number of eigenpairs will be less than the total number of DoF by the number of zero entries on the diagonal of the mass matrix. For properly constrained structures, \mathbf{K} is positive definite and all natural frequencies are positive. If the structure is unconstrained or partially constrained, however, \mathbf{K} is positive semidefinite and the eigenvalues will contain zero frequencies representing the rigid-body modes. The calculated mode shapes from Equation 9.20 are normalized and they satisfy the orthogonality properties: $\varphi_i^T \mathbf{M} \varphi_j = 0$ and $\varphi_i^T \mathbf{K} \varphi_j = 0$ for $i \neq j$ and $\varphi_i^T \mathbf{M} \varphi_i = 1.0$ and $\varphi_i^T \mathbf{K} \varphi_i = \omega_i^2$, where $\varphi_i = \bar{\varphi}_i / \sqrt{m_i}$ and $m_i = \bar{\varphi}_i^T \mathbf{M} \bar{\varphi}_i$.

Several eigenvalue extraction methods are available. Among the most commonly used are the block Lanczos, Subspace Iteration, Power Dynamics, and Reduced Householder methods (Mirovitch, 1980; Belytschko and Hughes, 1983; Bathe, 1996). The Lanczos method is recommended for large models with many modes to be extracted (about 50 or more). It is also better suited for models containing different types of elements such as solid, shell, and beam elements with the possibility that some elements are distorted. The method is fast and efficient but requires more memory than the Subspace Iteration method. In contrast, the Subspace Iteration method is well suited for extracting lower numbers of modes (less than 50) in models with well-shaped elements and it requires less memory than the Lanczos method. The Power Dynamics method is used for very large models, with more than 100,000 DoF, and is especially useful for obtaining a solution for the first several modes of the model. The Reduced Householder method is recommended for finding all the modes in small to medium models of less than 10,000 DoF (ANSYS Users Manual, 2003).

The information obtained from an eigenvalue or modal analysis is vital in the analysis of dynamic systems. The designer's goal is to ensure that the loading frequency is not close to any natural frequency of the system and that the mode shapes do not produce excessive deformation in weak sections of the structure. With respect to the mode shapes, it is desirable to avoid mode shapes that are similar to deformation patterns obtained from the static loading on the structure. As stated previously, the comfortable range for an operating frequency is three times higher than the nearest natural frequency from the lower side and three times smaller than the nearest natural frequency from the higher side. The natural frequencies may be altered by changing the mass distribution or adjusting the geometry of the system. If the loading frequency is higher than one or more of the first natural frequencies then large vibrations or "shudder" may occur during startup and in certain cases special startup procedures may have to be devised. If the loading frequency is close to one of the natural frequencies, a large factor of safety should be used. For example, an operating frequency 20% away from a natural frequency may call for doubling the nominal loads applied on a shaft. In some very special applications, it may be desirable actually to operate the system at one of its natural frequencies and utilize the amplification in the response, e.g., ultrasonic welding equipment and certain nanoscale measuring instruments.

Modal analysis requires no special boundary conditions and the structure may be completely free or partially constrained. Special attention should be given to the application of constraints, since overconstraining a system will result in overprediction of the first modes, which are generally nonconservative in a modal analysis.

REMARKS

- Modal dynamic analysis is used to obtain the dynamic characteristics of a system in terms of its natural frequencies (eigenvalues) and natural modes (eigenvectors). It is normally the first (and may be the only) dynamic analysis to be performed and its results are required to decouple the equations of motion for other analyses.
- Common eigenvalue extraction methods include: Lanczos (recommended for large models with many modes to be extracted; about 50 or more); Subspace Iteration (recommended for extracting lower number of modes, less than 50); Power Dynamics (recommended for very large models of more than 100,000 DoF); and Householder (recommended to find all modes in small to medium sized models of less than 10,000 DoF).
- Modal analysis requires no special boundary conditions and the structure may be completely free.

9.5.2 Transient Dynamic Analysis

9.5.2.1 Direct Integration Method

As indicated above, with the direct integration method, the general equation of motion is integrated directly without transformation. The input loads are specified as a function of time and the response is calculated in the time domain. Transient analysis could be viewed as solving an equivalent static analysis problem for each time step in the domain. The response quantities may include the time history of displacements, velocities, and accelerations at each point in the structure. Most programs will also provide a stress history output that is calculated in a postprocessing phase. The output results are straightforward and easy to interpret. As in static analysis, structures undergoing transient analysis should be fully constrained and all rigid-body motion should be eliminated. Initial conditions of displacement and velocity are also required to perform the analysis.

As discussed in Section 9.4.2, direct integration may be performed through explicit or implicit schemes. It should be noted that while implicit schemes do not require a critical time step, the size of the time step will affect the accuracy of the solution. Most programs are capable of automatic time stepping, which should be seriously considered. If automatic time stepping is not available in the program, the rule of thumb is to use a time step that is at least one tenth of the load period. Smaller time steps may be required to capture peak response and sharp changes in the input load.

The equations of motion (Equation 9.2) may first be reduced in size before the start of the integration process by choosing certain master DoF as discussed above. The reduced equations are then solved by one of the direct integration schemes and the results may then be expanded to the full set of DoF.

The following steps may be used as general guidelines in performing direct integration transient dynamic analysis:

- *Build the FE model:* This will include identifying the problem type and the type(s) of elements to be used in the model. The mesh should be fine enough to capture the highest mode required for the analysis. If stresses are required, the intensity of the mesh should be adequate for stress calculations.
- *Apply the loads and boundary conditions:* All rigid-body modes should be constrained and the model should be fully constrained. Time-dependent loads are normally specified in a table format.
- *Specify initial conditions:* Initial conditions of displacement and velocity are required for transient analysis. Most programs assume zero initial conditions for acceleration. If initial accelerations are not zero, the analyst may apply appropriate acceleration loads over a small time interval. It should be noted that initial conditions are required for all unconstrained DoF.

- *Set solution control parameters, start solution and review results:* This includes mass and damping formulation, damping parameters, time integration, and time stepping parameters as well as parameters to control output and postprocessing options.

9.5.2.2 Mode Superposition Method

In this method, the uncoupled modal equation 9.13, repeated here for convenience,

$$\ddot{\mathbf{q}} + \text{diag}(2\xi_r\omega_r)\dot{\mathbf{q}} + \text{diag}(\omega_r^2)\mathbf{q} = \{f_r(t)\} = \Phi^T \mathbf{p}(t) \quad (9.21)$$

consist of m independent second-order differential equations with constant coefficients, where m is the number of the participating modes used in the mode superposition process.

At time $t = 0$, each modal equation is subject to the initial conditions $q_r(0) = \varphi_r^T \mathbf{Mu}_0$ and $\dot{q}_r(0) = \varphi_r^T \mathbf{M}\dot{\mathbf{u}}_0$. For the underdamped case ($\xi_r < 1$), the solution to a typical modal equation (excluding rigid-body modes) is

$$q_r(t) = e^{-\xi_r\omega_r t} [\alpha_r \sin \bar{\omega}_r t + \beta_r \cos \bar{\omega}_r t] + \int_0^t f_r(\tau) h_r(t - \tau) d\tau \quad (9.22)$$

where $h_r(t - \tau)$ is the unit-impulse response function, defined by

$$h_r(t - \tau) = \frac{1}{\bar{\omega}_r} e^{-\xi_r\omega_r(t-\tau)} \sin \bar{\omega}_r(t - \tau) \quad (9.23)$$

The first term in Equation 9.23 represents the free vibration response (homogenous solution) and the second term represents the particular solution (Duhamel integral). α_r and β_r are constants evaluated from the initial conditions and $\bar{\omega}_r$ is the damped natural frequency given by

$$\bar{\omega}_r = \omega_r \sqrt{1 - \xi_r^2} \quad (9.24)$$

The integral in Equation 9.22 may be evaluated in closed form if the applied loading $\mathbf{p}(t)$, and consequently $f_r(t)$, is a step input, ramp input, piecewise linear function of time, or harmonic input; otherwise, numerical integration is utilized to obtain the response.

The general steps of a typical modal transient analysis include building the model, extracting the required modes for the analysis, obtaining the modal transient analysis and, finally, expanding the modal superposition solution. It should be noted that most programs do not allow change of displacement constraints after the mode extraction step is performed; i.e., all displacement constraints should be specified before performing the modal analysis to extract the required modes. Some programs may require the full loading conditions to be specified in the modal extraction step. Initial conditions should be specified before performing the modal transient solution. This may include initial displacement and velocities.

REMARKS

- In transient analysis, the input loads are specified as a function of time and the response (displacement, velocity, acceleration, and stress) is calculated in the time domain. The structure should be fully constrained and initial conditions are required.
- Direct integration transient analysis may be performed with explicit (conditionally stable) or implicit (unconditionally stable) schemes.
- Prior to performing integration, the size of the equations may be reduced by choosing master DoF and condensing out slave DoF.
- Transient analysis with mode superposition requires an initial modal analysis run followed by the superposition of modal responses (Equation 9.22) obtained from the solution of the decoupled equations. The integral in Equation 9.22 may be evaluated in closed form for step, ramp, piecewise linear, and harmonic inputs; otherwise, numerical integration is utilized.

9.5.3 Harmonic Response Analysis

9.5.3.1 Direct Integration Method

Harmonic response analysis involves computing the steady-state response of a structure to a set of harmonic concentrated loads, pressure loads, and harmonic ground motion. The harmonic loads may be defined in terms of different amplitude and phase spectra. In general, the load vector may be represented in the form:

$$p_i(t) = p_i(\Omega)\sin[\Omega t + \Psi_i(\Omega)] \quad (9.25)$$

where $p_i(t)$ is a component of the forcing function having a magnitude, $p_i(\Omega)$, phase shift, $\psi_i(\Omega)$, and forcing frequency, Ω .

Substituting Equation 9.25 into Equation 9.2, we obtain:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{p}(t) = \bar{\mathbf{p}}(\Omega)\sin[\Omega t + \bar{\Psi}(\Omega)] \quad (9.26)$$

Using direct integration schemes to solve Equation 9.26 is theoretically viable but not recommended practically for a few reasons. A large number of time steps would be normally required to obtain a meaningful response to a harmonic excitation and the equations have to be resolved for each forcing frequency. Also, if the damping is zero and a particular forcing frequency coincides with one of the natural frequencies, the matrix becomes singular and the solution process fails. If the forcing frequency is close to one of the natural frequencies, the matrix becomes ill conditioned and poses solution problems even if the damping is not zero. For these reasons, it is recommended to perform harmonic response analyses using the mode superposition method.

9.5.3.2 Mode Superposition Method

In the mode superposition method, Equation 9.26 is transformed into generalized modal coordinates and decoupled. For the r th mode, the equation takes the form:

$$\ddot{q}_r + 2\xi_r\omega_r\dot{q}_r + \omega_r^2 q_r = \bar{f}_r e^{i\Omega t} \quad (9.27)$$

where \bar{f}_r is the amplitude of modal load given by $\bar{f}_r = \boldsymbol{\varphi}_r^T \bar{\mathbf{p}}$. The steady-state modal response is given by

$$q_r(t) = \bar{q}_r e^{i\Omega t} \quad (9.28)$$

which when substituted into Equation 9.27 gives

$$\bar{q}_r(\Omega) = H_r(\Omega)\bar{f}_r(\Omega) \quad (9.29)$$

and

$$H_r(\Omega) = \frac{1}{\omega_r^2 \left[\left(1 - \frac{\Omega^2}{\omega_r^2} \right) + i \left(2\xi_r \frac{\Omega}{\omega_r} \right) \right]} \quad (9.30)$$

Equation 9.29 in the frequency domain is equivalent to Equation 9.22 in the time domain and $H_r(\Omega)$ is the Fourier transform of the unit-impulse response function $h_r(t)$.

The physical response is recovered from the generalized modal response through the transformation $\bar{\mathbf{u}} = \boldsymbol{\Phi}\bar{\mathbf{q}}$. The velocity and acceleration components are obtained from the corresponding displacement component through multiplication by Ω and Ω^2 , respectively. Finally, the stress components are obtained by the use of modal stresses (Equation 9.16). Most programs provide the option that the user can obtain the responses in either an amplitude–phase format or real–imaginary format and the actual value of all responses can also be obtained for a given value of Ωt .

The input to harmonic analysis constitutes the forcing frequency and the magnitude of the load vector at various points of load applications. For each loading case, all forces should have the same frequency. A change in the forcing frequency gives rise to a new load case. In harmonic analysis, as is the case in transient and static analyses, the structure should be fully constrained and all rigid-body motions should be eliminated. If the structure has rigid-body modes in one of the DoF, the analyst may use soft springs to ground the structure or utilize symmetry to provide constraints.

The general steps of a typical modal harmonic analysis are quite similar to those for the modal transient analysis, i.e., they include building the model, extracting the required modes for the analysis, obtaining the modal harmonic analysis and, finally, expanding the modal superposition solution. It should also be noted that most programs do not allow changes in displacement constraints after the mode extraction step, i.e., all displacement constraints should be specified before performing the modal analysis to extract the required modes. Some programs may require the full loading conditions to be specified in the modal extraction step.

REMARKS

- Harmonic response analysis involves computing the steady-state response of a structure to a set of harmonic loads and ground motion (Equation 9.26).
- Using direct integration schemes in harmonic analysis is theoretically viable but not recommended or used practically.
- Harmonic analysis with mode superposition requires an initial modal analysis run followed by the superposition of modal responses (Equation 9.28) obtained from the solution of the decoupled equations.
- The input to harmonic analysis constitutes the frequency and the magnitude of the load vector at all points of load applications. For each load case, all forces should have the same frequency. The structure should be fully constrained.

9.5.4 Response Spectrum Analysis

This analysis is an efficient alternative to transient dynamic analysis for estimating the maximum response under support excitations without regard to the time at which the maximum occurs. If the input loading is classified as a shock or impulse, this analysis is termed “shock spectrum analysis.” In theory, one may use a direct integration scheme to find the response as a function of time and then use the maximum value of the response. This may be prohibitive because of the very large number of time steps that will be required to capture the peak response. As a more efficient alternative, a modal analysis should be performed first and then a sufficient number of modes should be retained for the response spectrum analysis. Then the solution of the individual decoupled modal equation (Equation 9.13) for a viscous underdamped system under ground motion $w(t)$ is

$$q_r(t) = \frac{1}{\bar{\omega}_r} \int_0^t \ddot{w}(\tau) e^{-\xi_r \omega_r(t-\tau)} \sin[\bar{\omega}_r(t-\tau)] d\tau \quad (9.31)$$

The response function in Equation 9.31 is scanned over time to find the maximum scalar value $(q_r)_{\max}$. Then the physical value of the response of the i th DoF due to $(q_r)_{\max}$ may be given by

$$\bar{u}_{ir} = \Phi_{ir}(q_r)_{\max} \quad (9.32)$$

in which Φ_{ir} is the component of the modal vector, r , in direction i . Equation 9.32 is different from Equation 9.11 in which all the components of the modal vector, Φ_i , and the generalized response, q_i , are used and, therefore, actual and accurate physical displacements are obtained.

It can be readily seen that the quantities $(q_r)_{\max}$, and hence \bar{u}_{ir} , are only functions of the natural frequency and damping (in addition to the ground excitation). A shock (or response) spectrum curve for a certain value of damping may be defined as the maximum responses of all such single DoF systems with a given damping and plotted as a function of natural frequency. Similarly, the maximum acceleration and maximum velocity may also be determined and are termed as spectral acceleration and spectral velocity, respectively.

The mass matrix in response spectrum analysis may be lumped or modified lumped based on the consistent mass matrix. Response spectrum analysis using consistent mass generally lowers the resulting internal forces and moments in the structure and therefore produces less stresses and may be considered generally nonconservative (Gregory, 1990).

Unlike transient dynamic analysis, the contributions of the physical responses for each of the modes cannot be directly summed to obtain the total response. This is because the maxima for each mode occur at different times and the information on the time of maxima is not available in the shock spectra. Reasonable, but arbitrary, estimates of the maxima may be obtained by using one of the following commonly used modal combination methods (Wilson et al., 1981; *NISA User's Manual*, 1992; Roussel, 1994; Joshi and Gupta, 1998):

1. *The sum of absolute magnitudes (ABS or PEAK)*: The absolute sum of the modal responses is given by

$$R_{\text{tot}} = \sum_{r=1}^m |R_r| \quad (9.33)$$

in which R_r is the physical response (displacement, velocity, or acceleration) due to mode r and m is the number of modes considered. This method is conservative and is used if the natural frequencies are closely spaced (within 10% of each other) and/or when damping is large. It is also shown that the method may lead to unrealistically high calculated responses, e.g., in the coupled analysis of light secondary systems attached to heavy primary structures or in the decoupled analysis of systems when the centers of mass and stiffness do not coincide (Mertens, 1994).

2. *The square root of the sum of the squares (SRSS or RMS)*: The square root of the sum of the squares of the modal response is given by

$$R_{\text{tot}} = \sqrt{\sum_{r=1}^m R_r^2} \quad (9.34)$$

This method is applicable if the modes are statistically independent, which is the case when the natural frequencies are far apart and/or when damping is small. The SRSS method is commonly used in a wide range of applications. Some studies indicate, however, that the method may underestimate the response of structures with high-frequency modes, e.g., long-span bridges exposed to high wind velocities (Joshi and Gupta, 1998).

3. *The complete quadratic combination (CQC)*: The complete quadratic combination is given by the following formula (Wilson et al., 1981; Der Kiureghian and Nakamura, 1993):

$$R_{\text{tot}} = \sqrt{\sum_{r=1}^m \sum_{s=1}^m R_r \cdot R_s P_{rs}} \quad (9.35)$$

in which

$$P_{rs} = \frac{8\sqrt{\xi_r \xi_s}(\xi_r + \gamma \xi_s)\gamma^{3/2}}{(1 - \gamma^2) + 4\xi_r \xi_s(1 + \gamma^2) + 4\gamma^2(\xi_r^2 + \xi_s^2)} \quad (9.36)$$

where ξ_r and ξ_s are modal damping ratios and $\gamma = \omega_s/\omega_r$. This method encompasses the SRSS and ABS procedures for $\xi_r = \xi_s$. If $\gamma = 0$, the CQC method reduces to the former, and if $\gamma = 1$, it reduces to the latter. Certain modifications of the CQC method exist, aimed at improving response estimates for structures with high frequency modes (Der Kiureghian and Nakamura, 1993).

TABLE 9.5 Common Methods of Combining Modal Responses

Combinational Method	Comments
Sum of absolute magnitudes (ABS or PEAK)	Generally gives conservative results Used if the natural frequencies are closely spaced (within 10% of each other) and/or when damping is large
Square root of the sum of the squares (SRSS or RMS)	Use when natural frequencies are far apart and/or when damping is small May underestimate the response of structures with high frequency modes
Complete quadratic combination (CQC)	Combination of the SRSS and the ABS methods Certain modifications exist to correct the response of structures with high frequency modes
Combination of ABS and SRSS	Another form of combination of the SRSS and the ABS methods employed by simply adding the response of the two methods

4. *Combination of ABS and SRSS*: The absolute maxima of the modal responses is added to the square root of the sum of the squares of the remaining modal responses as follows (*NISA User’s Manual*, 1992):

$$R_{\max} = |R_j| + \sqrt{\sum_{r=1, r \neq j}^m R_r^2}$$

(9.37)

where

$$R_j = \max_r |R_r|$$

(9.38)

The above superposition rules are employed to get the response maxima due to ground excitation in one direction. Similarly, the maximum responses due to ground motions in other directions are computed separately. These maxima are then superimposed by using the SRSS or ABS procedures to get the total response.

A final note is given here on the use of spectrum analysis in earthquake-resistant design. Most building codes require the designer to consider the response of the structure due to simultaneous action of three translational components of ground motion: two in the horizontal plane and one in the vertical direction. Standard design practice is to calculate the peak responses of these inputs independently and then combine these peak responses according to rules similar to those discussed above (Menun and Der Kiureghian, 1998; Lopez et al., 2001).

Table 9.5 summarizes the above modal combination methods, their use and merits.

REMARKS

- Response spectrum and shock analysis are efficient alternatives to transient dynamic analysis for estimating the maximum response under support excitations without regard to the time at which the maximum occurs.
- In response spectrum analysis, the solution of the individual decoupled modal equation (Equation 9.13) for ground motion, $w(t)$, is obtained (Equation 9.31) and the maximum value of the response is recorded (with no reference to the time it occurs).
- Reasonable, but arbitrary, estimates of the maxima for the overall structure may be obtained by using various methods of combining the modal maximums (Table 9.5).

9.6 Checklist for Dynamic FE Analysis

1. Study the physical system and decide on the type of problem, i.e., beam, 2-D, shell, or 3-D, and the type of elements to be used. Typical questions to be addressed are:
 - Can the geometry be idealized as 2-D or shell or do we have to use 3-D analysis? (Section 9.1.2 to Section 9.1.6).
 - Can the loading and constraints be idealized as 2-D?
 - Are we concerned about responses that are not compatible with the loading type?
 - Are we interested in displacements, stresses, or natural frequencies?
 - Can we have a simple spring/mass model?
 - What type of element might be used in the analysis, i.e., linear, quadratic, or cubic (Section 9.1.7)? Generally, linear and quadratic elements are used for the majority of analyses. The choice between linear and quadratic elements is rather arbitrary and may depend on certain advanced analysis aspects. For linear analysis, there is little difference between the response of the two elements if the overall model has the same or similar total DoF.
2. Study all types of loading to identify the required analysis type. Important questions to be addressed are:
 - Is the load steady, cyclic, transient, or random (Section 9.2)?
 - What is the frequency content of the load? A simple Fourier analysis may be required to define the main harmonics of a transient load input.
 - What are the first few natural frequencies of the structure? This question will be answered in detail by performing a modal analysis. It is important, however, to have an approximate idea of the range of frequencies of the structure and to compare this to the loading frequency in order to identify the proper type of analysis (Section 9.2). In order to answer this question adequately, a very simplified mass/spring model and quick hand calculations may be considered.
 - What kind of data is required from the analysis? Data required may be in terms of displacements, velocities, accelerations, stresses, strains, etc. Also, identify if peak values or time histories are required. This decision may have an impact on what analysis type is required.
 - What is the type of analysis required (Section 9.2)?
3. Identify other data required to perform the analysis. This may include:
 - Material properties.
 - Damping consideration, modeling, and values (Section 9.4.4).
 - Identifying all load cases and all constraints of the system. Special attention must be paid to the modeling of constraints and nonstructural masses (Section 9.3).
 - If modal superposition is going to be used, how many modes are required for the analysis?
4. Start the actual modeling process, testing and verification of the model. Important issues to be considered may include:
 - A decision should be made of whether or not a simple or coarse model is required. In general, dynamic analysis of large models is quite costly. Dynamic analysis results (such as natural frequencies, mode shapes, and to some extent displacements, velocities, and accelerations) may be accurately obtained from a coarse model or even a mass/spring model. The main concern would be in obtaining stress and strain responses. In many cases, it may be advisable to have two different models — one for dynamic analysis and the other for stress analysis. The output from the dynamic model may be used as input to the stress model. In any case, if the model is large, it is advisable to have a coarser model for testing and basic understanding of the behavior of the structure (Section 9.3).
 - Choose a program to perform the analysis. The key issue in choosing a program would be the availability of the required analysis type. Other issues that may be considered include ease of model generation, ease of postprocessing, and cost effectiveness. It is always advisable to have the same program for all phases of the analysis, i.e., modeling, solution, and postprocessing.

- Build the model geometry (Section 9.1.1). In 2-D problems, the model geometry may be imported from a CAD program. In 3-D and shell problems, however, this process entails many problems and it may be faster for the analyst to build the model directly in a FE database.
 - Build the finite element model and apply load cases and constraints (Section 9.2).
 - Test the model. Most FE programs provide extensive testing capabilities that may be invoked to test the quality of the mesh and the continuity of the model. It is important to note that additional testing is required. The response of the system to simple load cases should be considered. Testing should involve load cases that may be easily verified. This may include computing structure response due to unit impulse, step input, or sudden release of an initial displacement. Also, simple static analysis runs can be very useful in this regard and may provide initial conditions for the final dynamic run.
5. Analyze the model for the actual load cases. The following important issues should be considered:
 - Identify solution parameters. This includes mass and damping formulation, damping parameters (Section 9.4.4), time integration, and time stepping parameters, as well as parameters to control output and postprocessing options. If modal analysis is considered, identify the modal extraction method (Section 9.5).
 - Check and apply restart capabilities in the program. Large size dynamic analyses should, in general, be done in steps and the restart option should be invoked.
 - If modal analysis is performed, a careful check of mode shapes will provide important information about the validity of the model and the appropriateness of solution steps to follow.
 - Identify solution control parameters that invoke the storage of specific data required for postprocessing.
 6. Postprocess the results. This is the final stage of the analysis and may involve:
 - Graphical and contour plots of various response quantities. This may be done in the form of time history plots, envelopes of maximum responses, or contour plots of stress maxima. The amount of output data associated with large dynamic analysis runs is vast and such graphical display of results is essential.
 - Most programs have extensive capabilities in results animation, search facilities, preparing output summaries, and some can also assist in report writing. Such capabilities may become important in processing the results of large problems.

Summary

This chapter considers the nature and analysis of vibration signals. Both time-domain techniques and frequency-domain techniques are investigated, which are related through Fourier transform. Topics covered include signal types, signal sampling, aliasing error, truncation error, window functions, spectral analysis, bandwidth issues, and order analysis. Several applications of signal analysis in mechanical vibration are discussed.

10.1 Introduction

Numerous examples can be drawn from engineering applications for vibrating (dynamic) systems. A steam generator of a nuclear power plant that undergoes flow-induced vibration; a high-rise building subjected to seismic motions at its foundation; an incinerator tower subjected to aerodynamic disturbances; an airplane excited by atmospheric turbulence; a gate valve under manual operation; and a heating, ventilating, and air conditioning (HVAC) control panel stressed due to vibrations in its support structure are such examples.

FIGURE 10.1 In-flight excitations and responses of an aircraft.

Consider an aircraft in flight, as schematically shown in Figure 10.1. There are many excitations on this dynamic system. For example, jet engine forces and control surface movements are intentional excitations, whereas aerodynamic disturbances are unintentional (and unwanted) excitations. The primary response of the aircraft to these excitations will be the motions in various degrees of freedom (DoF), including rigid-body and flexible (vibratory) mode motions.

Even though the inputs and outputs (excitations and responses) are functions of *time*, they can also be represented as functions of *frequency*, through *Fourier transformation*. The resulting *Fourier spectrum* of a signal can be interpreted as the set of frequency components which the original signal contains. This *frequency-domain* representation of a signal can highlight many salient characteristics of the signal and also those of the corresponding system. For this reason, frequency-domain methods, particularly Fourier analysis, are used in a wide variety of applications such as data acquisition and interpretation, experimental modeling and modal analysis, diagnostic techniques, signal/image processing and pattern recognition, acoustics and speech research, signal detection, telecommunications, and dynamic testing for design development, quality control, and qualification of products. Many such applications involve the study of mechanical vibrations.

10.2 Frequency Spectrum

Excitations (inputs) to a dynamic system progress with time, thereby producing responses (outputs) which themselves vary with time. These are signals that can be recorded or measured. A measured signal is a *time history*. Note that in this case the independent variable is *time* and the signal is represented in the *time domain*. A limited amount of information can be extracted by examining a time history. As an example, consider the time-history record shown in Figure 10.2. It can be characterized by parameters such as the following:

a_p = peak amplitude

T_p = period in the neighborhood of the peak = $2 \times$ interval between successive zero crossings near the peak

T_e = duration of the record

T_s = duration of strong response (i.e., the time interval beyond which no peaks occur that are larger than $a_p/2$)

N_z = number of zero crossings within T_s ($N_z = 14$ in Figure 10.2)

FIGURE 10.2 A time-history record.

It is obviously cumbersome to keep track of so many parameters and, furthermore, not all of them are equally significant in a given application. Note, however, that all the parameters listed above are directly

FIGURE 10.3 Time-domain representation of a periodic signal.

or indirectly related to either the *amplitude* or the frequency of zero crossings within a given time interval. This signifies the importance of a frequency variable in representing a time signal. This is probably the fundamental motivation for using frequency-domain representations. In this context, however, more rigorous definitions are needed for the parameters: amplitude and frequency. A third parameter, known as *phase angle*, is also needed for unique representation of a signal in the frequency domain.

10.2.1 Frequency

Let us further examine the basis of frequency-domain analysis. Consider the *periodic* signal of period T that is formed by combining two *harmonic* (or sinusoidal) components of periods T and $T/2$ and amplitudes a_1 and a_2 as shown in Figure 10.3. The *cyclic frequency* (cycles/sec, or hertz, or Hz) of the two components are $f_1 = 1/T$ and $f_2 = 2/T$. Note that in order to obtain the *angular frequency* (radians/sec), the cyclic frequency has to be multiplied by 2π .

10.2.2 Amplitude Spectrum

An alternative graphical representation of the periodic signal shown in Figure 10.3 is given in Figure 10.4. In this representation, the amplitude of each harmonic component of the signal is plotted against the corresponding frequency. This is known as the *amplitude spectrum* of the signal, and it forms the basis of the frequency-domain representation. Note that this representation is often more compact, and can be far more useful than the time-domain representation. Note further that in the frequency-domain representation, the independent variable is frequency.

10.2.3 Phase Angle

In its present form, Figure 10.4 does not contain all the information of Figure 10.3. For instance, if the high-frequency component in Figure 10.3 is shifted through half its period ($T/4$), the resulting signal is shown in Figure 10.5. This signal is quite different from that in Figure 10.3 but since the amplitudes and the frequencies of the two harmonic components are identical for both signals, they possess the same amplitude spectrum. So, what is lacking in Figure 10.3 in order to make

FIGURE 10.4 The amplitude spectrum of a periodic signal.

FIGURE 10.5 A periodic signal with an identical amplitude spectrum as for Figure 10.2.

it a unique representation of a signal, is the information concerning the exact location of the harmonic components with respect to the time reference or origin ($t = 0$). This is known as the phase information. For example, the distance of the first positive peak of each harmonic component from the time origin can be expressed as an angle (in radians) by multiplying it by $2\pi/T$. This is termed the *phase angle* of the particular component. In both signals (shown in Figure 10.3 and Figure 10.5) the phase angle of the first harmonic component is the same and equals $\pi/2$ according to the present convention. The phase angle of the second harmonic component is $\pi/2$ in Figure 10.3 and zero in Figure 10.5.

10.2.4 Phasor Representation of Harmonic Signals

A convenient geometric representation of a harmonic signal of the form

$$y(t) = a \cos(\omega t + \phi) \quad (10.1)$$

is possible by means of a phasor. This representation is illustrated in Figure 10.6. Specifically, consider a rotating arm of radius a , rotating in the counter-clockwise (ccw) direction at an angular speed of ω rad/sec. Suppose that the arm starts (i.e., at $t = 0$) at an angular position ϕ with respect to the y -axis (vertical axis) in the ccw sense. Then, it is clear from Figure 10.6(a) that the projection of the rotating arm on the y -axis gives the time signal $y(t)$. This is the phasor representation, where we have

Signal amplitude = length of the phasor

Signal frequency = angular speed of the phasor

Signal phase angle = initial position of the phasor with respect to the y -axis

It should be clear that a phase angle makes practical sense only when two or more signals are compared. This is so because for a given harmonic signal we can pick any point as the time reference ($t = 0$). However, when two harmonic signals are compared, as in Figure 10.6(b), we may consider one of those signals that starts (at $t = 0$) at its position peak as the reference signal. This will correspond to a phasor whose initial configuration coincides with the positive y -axis. As is clear from Figure 10.6(b), for this reference signal we have, $\phi = 0$. Then the phase angle ϕ of any other harmonic signal would correspond to the angular position of its phasor with respect to the reference phasor. Note that, in this example, the time shift between the two signals is ϕ/ω , which is also a direct representation of the phase. It should be clear, then, that the phase difference between two signals is also a representation of the *time lead* or *time lag* (delay) of one signal with respect to the other. Specifically, the phase that is ahead of the reference phasor is considered to “lead” the reference signal. In other words, the signal $a \cos(\omega t + \phi)$ has a phase lead of ϕ or a time lead of ϕ/ω with respect to the signal of $a \cos \omega t$.

FIGURE 10.6 Phasor representation of a harmonic signal. (a) A phasor and the corresponding signal; (b) representation of a phase angle (phase lead) ϕ .

Another important observation may be made with regard to the phasor representation of a harmonic signal. A phasor may be expressed as the complex quantity

$$y(t) = a e^{j(\omega t + \phi)} = a \cos(\omega t + \phi) + ja \sin(\omega t + \phi) \quad (10.2)$$

whose real part is $a \cos(\omega t + \phi)$, which is in fact the signal of interest. It is clear from Figure 10.6 that, if we take the y -axis to be real and the x -axis to be imaginary, the complex representation 10.2 is indeed a complete representation of a phasor. By using the complex representation 10.2 for a harmonic signal, significant benefits of mathematical convenience could be derived in vibration analysis. It suffices to remember that practical vibrations are “real” signals, and regardless of the type of mathematical analysis that is used, only the real part of a complex signal of the form 10.2 will make physical sense.

10.2.5 RMS Amplitude Spectrum

If a harmonic signal $y(t)$ is averaged over one period T , the negative portion cancels out the positive portion, giving zero. Consider a harmonic signal of angular frequency ω (or cyclic frequency f), phase angle ϕ , and amplitude a , as given by

$$y(t) = a \cos(\omega t + \phi) = a \cos(2\pi f t + \phi) \quad (10.3)$$

Its average (mean) value is

$$y_{\text{mean}} = \frac{1}{T} \int_0^T y(t) dt = 0 \quad (10.4)$$

which can be verified by direct integration, while noting that

$$T = 1/f = 2\pi/\omega \quad (10.5)$$

For this reason, mean value is not a measure of the “strength” of a signal in general. Now let us define the *root mean square* (RMS) value of a signal. This is the square root of the mean value of the square of the signal. By direct integration, it can be shown that for a sinusoidal (or harmonic) signal; the RMS value is given by

$$y_{\text{RMS}} = \left[\frac{1}{T} \int_0^T y^2(t) dt \right]^{1/2} = \frac{a}{\sqrt{2}} \quad (10.6)$$

It follows that the *RMS amplitude spectrum* is obtained by dividing the amplitude spectrum by $\sqrt{2}$. For example, for the periodic signal formed by combining two harmonic components as in Figure 10.3, the RMS amplitude spectrum is shown in Figure 10.7. This again is a frequency-domain representation of a signal, and the independent variable is frequency.

FIGURE 10.7 The RMS amplitude spectrum of a periodic signal.

10.2.6 One-Sided and Two-Sided Spectra

Mean squared amplitude spectrum of a signal (sometimes called *power spectrum* because the square of a variable such as voltage and velocity is a measure of quantities such as *power* and *energy*, even though it is not strictly the spectrum of power in the conventional sense) is obtained by plotting the mean squared amplitude of the signal against frequency. Note that these are *one-sided spectra* because only the positive *frequency band* is considered. This is a realistic representation because one cannot talk about negative frequencies for a real system. But, from a mathematical point of view, we may consider negative frequencies as well. In a spectral representation it is at times convenient to consider the entire frequency band (consisting of both negative and positive values of frequency). It then becomes a *two-sided spectrum*. In this case the spectral component at each frequency value should be equally divided between the positive and the negative frequency values (hence, the spectrum is *symmetric*), such that the overall mean squared amplitude (or power or energy) remains the same.

We have seen that for a harmonic signal component of amplitude a and frequency f (e.g., $a \cos(2\pi f + \phi)$) the RMS amplitude is $a^2/2$ at frequency f , whereas the two-side spectrum has a magnitude of $a^2/4$ at both the frequency values $-f$ and $+f$.

Note that, even though it is possible to interpret the meaning of a negative time (which represents the past, previous to the starting point), it is not possible to give a realistic meaning to a negative frequency. This concept is introduced primarily for analytical convenience.

10.2.7 Complex Spectrum

We have shown that for unique representation of a signal in the frequency domain, both amplitude and phase information should be provided for each frequency component. Alternatively, the spectrum can be expressed as a *complex* function of frequency, having a *real part* and an *imaginary part*. For instance, for a harmonic component given by $a \cos(2\pi f_i + \phi)$ the two-sided complex spectrum can be expressed as

$$Y(f_i) = \frac{a_i}{2} (\cos \phi_i + j \sin \phi_i) = \frac{a_i}{2} e^{j\phi_i}$$

and,

$$Y(-f_i) = \frac{a_i}{2} (\cos \phi_i - j \sin \phi_i) = \frac{a_i}{2} e^{-j\phi_i} \quad (10.7)$$

in which j is the *imaginary unity* as given by $j = \sqrt{-1}$. Note that the spectral component at the negative frequency is the *complex conjugate* of that at the positive frequency. This concept of complex spectrum is

the basis of (complex) *Fourier series expansion* (FSE), which we shall consider in detail in a later section. It should be clear that the complex conjugate of a spectrum is obtained by changing either j to $-j$ or ω to $-\omega$ (or f to $-f$).

10.3 Signal Types

Signals can be classified into different types depending on their characteristics. Note that the signal itself is a time function, but its frequency-domain representation can bring up some of its salient features. Signals particularly important to us here are the excitations and responses of vibrating systems. These can be divided into two broad classes: *deterministic signals* and *random signals* depending on whether we are dealing with deterministic vibrations or random vibrations. Consider a damped cantilever beam that is subjected to a sinusoidal base excitation of frequency ω and amplitude u_0 in the lateral direction (Figure 10.8). In the steady state, the tip of the beam will also oscillate at the same frequency, but with a different amplitude y_0 and, furthermore, there will be a phase shift by an angle ϕ . For a given frequency and known beam properties, the quantities y_0 and ϕ can be completely determined. Under these conditions the tip response of the cantilever is a deterministic signal in the sense that when the experiment is repeated, the same response is obtained. Furthermore, the response can be expressed as a mathematical relationship in terms of parameters whose values are determined with 100% certainty, and probabilities are not associated with these parameters (such parameters are termed *deterministic parameters*). Random signals are nondeterministic (or *stochastic*) signals. Their mathematical representation requires probability considerations. Furthermore, if the process were to be repeated there would always be some uncertainty as to whether an identical response signal could be obtained again.

Deterministic signals can be classified as *periodic*, *quasi-periodic*, and *transient*. Periodic signals repeat exactly at equal time periods. The frequency (Fourier) spectrum of a periodic signal constitutes a series of equally spaced impulses. Furthermore, a periodic signal will have a Fourier series representation. This implies that a periodic signal can be expressed as the sum of sinusoidal components whose frequency ratios are rational numbers (not necessarily integers). Quasi-periodic (or almost periodic) signals also have discrete Fourier spectra, but the spectral lines are not equally spaced. Typically, a quasi-periodic signal can be generated by combining two or more sinusoidal components, provided that at least two of the components have as their frequency ratio an irrational number. Transient signals have continuous Fourier spectra. These types of signals cannot be expressed as a sum of sinusoidal components (or a Fourier series). All signals that are not periodic or quasi-periodic can be classified as transient. Most often, highly damped (overdamped) signals with exponentially decaying characteristics are termed transient, even though various other forms of signals such as exponentially increasing (unstable) responses, sinusoidal decays (underdamped responses), and sinesweeps (sinewaves with variable frequency) also fall into this category. Table 10.1 gives examples for these three types of deterministic signals. The corresponding amplitude spectra are sketched in Figure 10.9. A general classification of signals, with some examples is given in Box 10.1.

FIGURE 10.8 Response to base excitations of a tall structure (cantilever).

10.4 Fourier Analysis

Fourier analysis is the key to frequency analysis of vibration signals. The frequency-domain representation of a time signal is obtained through the Fourier transform. One immediate advantage

TABLE 10.1 Deterministic Signals

Primary Classification	Nature of the Fourier Spectrum	Example
Periodic	Discrete and equally spaced	$y_0 \sin \omega t + y_1 \sin \frac{5}{3} \omega t + \phi$
Quasi-periodic	Discrete and irregularly spaced	$y_0 \sin \omega t + y_1 \sin(\sqrt{2} \omega t + \phi)$
Transient	Continuous	$y_0 \exp(-\lambda t) \sin(\omega t + \phi)$

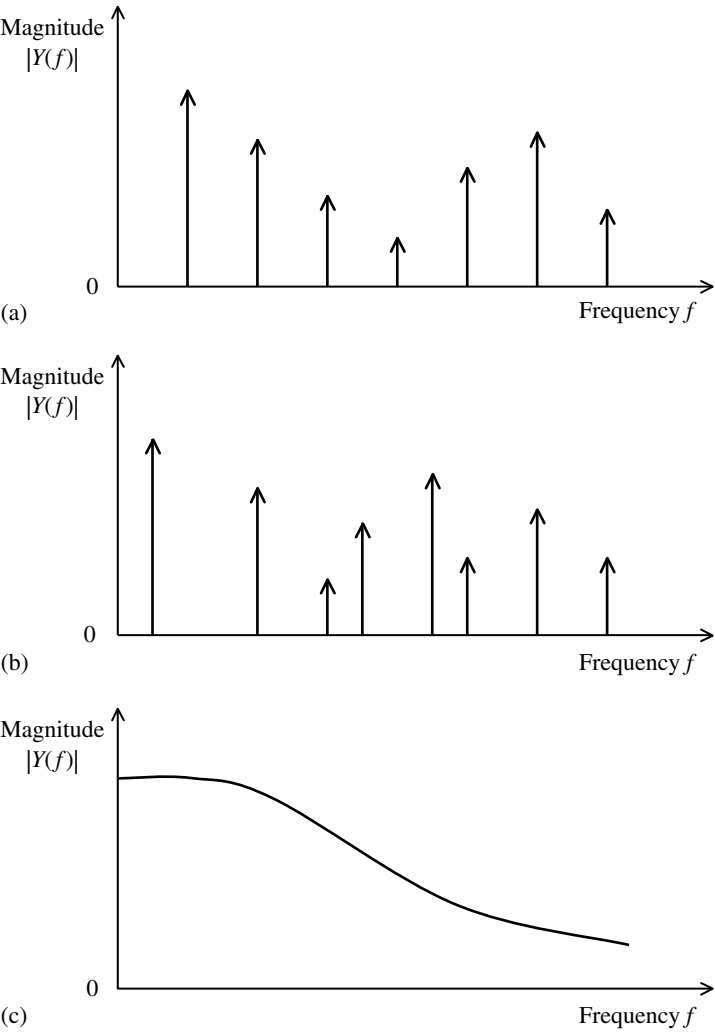

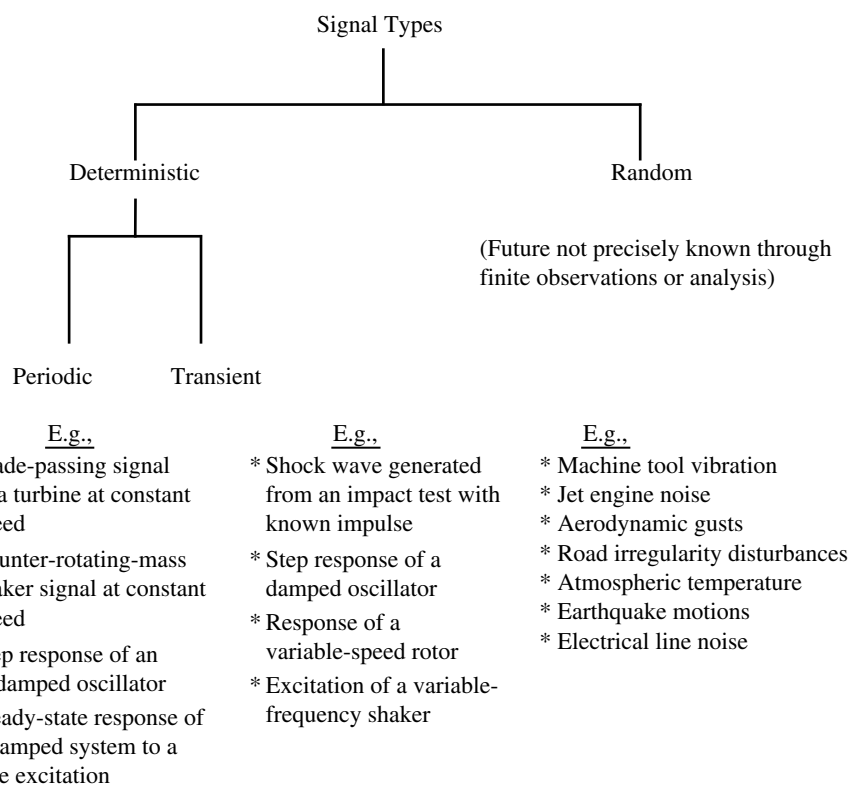

FIGURE 10.9 Magnitude spectra for three types of deterministic signals. (a) Periodic; (b) quasi-periodic; (c) transient.

of the Fourier transform is that, through its use, differential operations (differentiation and integration) in the time domain are converted into simpler algebraic operations (multiplication and division). Transform techniques are quite useful in mathematical applications. For example, a simple, yet versatile transformation from products into sums is accomplished through the use of the *logarithm*. Three versions of Fourier transform are important to us. The Fourier integral transform (FIT) can be applied to any general signal, whereas the FSE is applicable only to periodic signals, and the discrete Fourier

Box 10.1

SIGNAL CLASSIFICATION

transform (DFT) is used for discrete signals. As we shall see, all three versions of transform are interrelated. In particular, we have to use the DFT in digital computation of both FIT and FSE.

10.4.1 Fourier Integral Transform

The *Fourier spectrum* $X(f)$ of a time signal $x(t)$ is given by the *forward transform* relation

$$X(f) = \int_{-\infty}^{\infty} x(t) \exp(-j2\pi ft) dt \tag{10.8}$$

with $j = \sqrt{-1}$ and f the cyclic frequency variable. When Equation 10.8 is multiplied by $\exp(j2\pi f\tau)$ and integrated with respect to f using the *orthogonality property* (which can be considered as a definition of the *Dirac delta function* δ)

$$\int_{-\infty}^{\infty} \exp[j2\pi f(t - \tau)] df = \delta(t - \tau) \tag{10.9}$$

we get the *inverse transform* relation

$$x(t) = \int_{-\infty}^{\infty} X(f) \exp(2j\pi ft) df \quad (10.10)$$

The forward transform is denoted by the operator \mathfrak{F} and the inverse transform by \mathfrak{F}^{-1} . Hence, the Fourier transform pair is given by

$$X(f) = \mathfrak{F}x(t) \text{ and } x(t) = \mathfrak{F}^{-1}X(f) \quad (10.11)$$

Note that for *real* systems, $x(t)$ is a real function but $X(f)$ is a *complex* function in general. Hence, the Fourier spectrum of a signal can be represented by the *magnitude* $|X(f)|$ and the *phase angle* $\angle X(f)$ of the (complex) Fourier spectrum $X(f)$. Alternatively, the *real part* $\text{Re } X(f)$ and the *imaginary part* $\text{Im } X(f)$ together can be used to represent the Fourier spectrum.

According to the present definition, the Fourier spectrum is defined for negative frequency values as well as positive frequencies (i.e., a *two-sided spectrum*). The *complex conjugate* of a complex value is obtained by simply reversing the sign of the imaginary part; in other words, replacing j with $-j$. By noting that replacing j with $-j$ in the forward transform relation is identical to replacing f with $-f$, it should be clear that the Fourier spectrum (of real signals) for negative frequencies is given by the complex conjugate $X^*(f)$ of the Fourier spectrum for positive frequencies. As a result, only the positive-frequency spectrum needs to be specified and the negative-frequency spectrum can be conveniently derived from it, through complex conjugation.

The *Laplace transform* is similar to the FIT. Laplace transform is defined by the forward and inverse relations

$$X(s) = \int_0^{\infty} x(t) \exp(-st) dt \quad (10.12)$$

and

$$x(t) = \frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} X(s) \exp(st) ds \quad (10.13)$$

Since the signal itself is zero for $t < 0$, it is seen that for all practical purposes, Fourier transform results can be deduced from the Laplace transform analysis, simply by substituting $s = j2\pi f = j\omega$ and $\sigma = 0$.

10.4.2 Fourier Series Expansion

For a periodic signal $x(t)$ of period T , the FSE is given by

$$x(t) = \Delta F \sum_{n=-\infty}^{\infty} A_n \exp(j2\pi nt/T) \quad (10.14)$$

with $\Delta F = 1/T$. Strictly speaking (see FIT relations) this is the inverse transform relation. The scaling factor ΔF is not essential but is introduced so that the Fourier coefficients A_n will have the same units as the Fourier spectrum. The Fourier coefficients are obtained by multiplying the inverse transform relation by $\exp(-j2\pi mt/T)$ and integrating with respect to t from 0 to T using the orthogonality condition

$$\frac{1}{T} \int_0^T \exp[j2\pi(n-m)t/T] dt = \delta_{mn} \quad (10.15)$$

Note that the *Kronecker delta* δ_{mn} is defined as

$$\delta_{mn} = \begin{cases} 1 & \text{for } m = n \\ 0 & \text{for } m \neq n \end{cases} \quad (10.16)$$

for integer values of m and n . The forward transform that results is given by

$$A_n = \int_0^T x(t) \exp(-j2\pi nt/T) dt \quad (10.17)$$

Note that A_n are complex quantities in general.

It can be shown that for periodic signals, FSE is a special case of FIT, as expected. Consider a Fourier spectrum consisting of a sum of equidistant impulses separated by the frequency interval $\Delta F = 1/T$:

$$X(f) = \Delta F \sum_{n=-\infty}^{\infty} A_n \delta(f - n \cdot \Delta F) \quad (10.18)$$

This is shown in Figure 10.10 (only the magnitudes $|A_n|$ can be plotted in this figure because A_n is complex in general). If we substitute this spectrum into the inverse FIT relation given earlier, we get the inverse FSE relation 10.14. Furthermore, this shows that the Fourier spectrum of a periodic signal is a series of equidistant impulses.

FIGURE 10.10 Fourier spectrum of a periodic signal and its relation to Fourier series.

10.4.3 Discrete Fourier Transform

The DFT relates an N -element *sequence of sampled (discrete) data signal*

$$\{x_m\} = [x_0, x_1, \dots, x_{N-1}] \quad (10.19)$$

to an N -element sequence of spectral results

$$\{X_n\} = [X_0, X_1, \dots, X_{N-1}] \quad (10.20)$$

through the forward transform relation

$$X_n = \Delta T \sum_{m=0}^{N-1} x_m \exp(-j2\pi mn/N) \quad (10.21)$$

with $n = 0, 1, \dots, N-1$. The values X_n are called the *spectral lines*. It can be shown that these quantities approximate the values of the Fourier spectrum (continuous) at the corresponding discrete frequencies. Let us identify ΔT as the *sampling period* (i.e., the time step between two adjacent points of sampled data).

The inverse transform relation is obtained by multiplying the forward transform relation by $\exp(j2\pi mr/N)$ and summing over $n = 0$ to $N-1$, using the orthogonality property

$$\frac{1}{N} \sum_{n=0}^{N-1} \exp[j2\pi n(r-m)/N] = \delta_{rm} \quad (10.22)$$

Note that this orthogonality relation can be considered as a definition of *Kronecker delta*. The inverse transform is

$$x_m = \Delta F \sum_{n=0}^{N-1} X_n \exp(j2\pi mn/N) \quad (10.23)$$

The data record length is given by

$$T = N \cdot \Delta T = 1/\Delta F \quad (10.24)$$

The DFT is a transform in its own right, independent of the FIT. It is possible, however, to interpret this transformation as the *trapezoidal integration* approximation of FIT. We have deliberately chosen appropriate scaling factors ΔT and ΔF in order to maintain this equivalence, and it is very useful in computing the Fourier spectrum of a general signal or the Fourier coefficients of a periodic signal using a digital computer. Proper interpretation of the digital results is crucial, however, in using DFT to compute (an approximate) Fourier spectrum of a (continuous) signal. In particular, two types of error: aliasing

TABLE 10.2 Unified Definitions for Three Fourier Transform Types

Relation Name	Fourier Integral Transform	Discrete Fourier Transform (DFT)	Fourier Series Expansion (FSE)
Forward transform	$X(f) = \int_{-\infty}^{\infty} x(t) \exp(-j2\pi ft) dt$	$X_n = \Delta T \sum_{m=0}^{N-1} x_m \exp(-j2\pi mn/N),$ $n = 0, 1, \dots, N - 1$	$A_n = \int_0^T x(t) \exp(-j2\pi nt/T) dt$ $n = 0, 1, \dots$
Inverse transform	$x(t) = \int_{-\infty}^{\infty} X(f) \exp(j2\pi ft) df$	$x_m = \Delta F \sum_{n=0}^{N-1} X_n \exp(j2\pi mn/N),$ $m = 0, 1, \dots, N - 1$	$x(t) = \Delta F \sum_{n=-\infty}^{\infty} A_n \times \exp(j2\pi nt/T)$
Orthogonality	$\int_{-\infty}^{\infty} \exp[j2\pi f(\tau - t)] df = \delta(\tau - t)$	$\frac{1}{N} \sum_{n=0}^{N-1} \exp[j2\pi n(r - m)/N] = \delta_{rm}$	$\frac{1}{T} \int_0^T \exp[j2\pi(r - n)t/T] dt = \delta_{rn}$
Notes	$T = N\Delta T$	$\Delta F = 1/T$	$X(f) = \Delta F \sum_{n=-\infty}^{\infty} A_n \delta(f - n/T)$

TABLE 10.3 Important Properties of the Fourier Transform

Function of Time	Fourier Spectrum
$x(t)$	$X(f)$
$k_1 x_1(t) + k_2 x_2(t)$	$k_1 X_1(f) + k_2 X_2(f)$
$x(t) \exp(-j2\pi ta)$	$X(f + a)$
$x(t + \tau)$	$X(f) \exp(j2\pi f\tau)$
$\frac{d^n x(t)}{dt^n}$	$(j2\pi f)^n X(f)$
$\int_{-\infty}^t x(t) dt$	$\frac{X(f)}{j2\pi f}$

and leakage (or truncation error) should be considered. This subject will be addressed later. The three transform relations, corresponding inverse transforms, and the orthogonality relations are summarized in Table 10.2.

The link between the time-domain signals and models and the corresponding frequency-domain equivalents is the FIT. Table 10.3 provides some important properties of the FIT and the corresponding time-domain relations that are useful in the analysis of signals and system models. These properties may be easily derived from the basic FIT relations (Equation 10.8 through Equation 10.10). It should be noted that, inherent in the definition of the DFT given in Table 10.2 is the N -point periodicity of the two sequences; that is, $X_n = X_{n+iN}$ and $x_m = x_{m+iN}$, for $i = \pm 1, \pm 2, \dots$

The definitions given in Table 10.2 may differ from the versions available in the literature by a multiplicative constant. However, it is observed that according to the present definitions, the DFT may be interpreted as the trapezoidal integration of the FIT. The close similarity between the definitions of the FSE and the DFT is also noteworthy. Furthermore, according to the last row in Table 10.2, the FSE can be expressed as a special FIT consisting of an equidistant set of impulses of magnitude A_n/T located at $f = n/T$.

10.4.4 Aliasing Distortion

Recalling that the primary task of digital Fourier analysis is to obtain a discrete approximation to the FIT of a piecewise continuous function, it is advantageous to interpret the DFT as a discrete (digital computer) version of the FIT rather than an independent discrete transform. Accordingly, the results from a DFT must be consistent with the exact results obtained if the FIT were used. The definitions given in Table 10.2 are consistent in this respect because the DFT is given as the trapezoidal integration of the FIT. However, it should be clear that if $X(f)$ is the FIT of $x(t)$, then the sequence of sampled values $\{X(n \cdot \Delta F)\}$ is not exactly the DFT of the sampled data sequence $\{x(m \cdot \Delta T)\}$. Only an approximate relationship exists.

A further advantage of the definitions given in Table 10.2 is apparent when dealing with the FSE. As we have noted, the FIT of a periodic function is a set of impulses. We can avoid dealing with impulses by

relating the complex Fourier coefficients to the DFT sequence of sampled data from the periodic function via the present definitions.

Aliasing distortion is an important consideration when dealing with sampled data from a continuous signal. This error may enter into computation in both the time domain and the frequency domain, depending on the domain in which the results are presented. We will address this issue next.

10.4.4.1 Sampling Theorem

The basic relationships between the FIT, the DFT, and the FSE are summarized in Table 10.4. By means of straightforward mathematical procedures, the relationship between the FIT and the DFT can be established. Even though $\{X(n \cdot \Delta F)\}$ is not the DFT of $\{x(m \cdot \Delta T)\}$, the results in Table 10.4 show that $\{\tilde{X}(n \cdot \Delta F)\}$ is the DFT of $\{\tilde{x}(m \cdot \Delta T)\}$ where the periodic functions $\tilde{X}(f)$ and $\tilde{x}(t)$ are as defined as in Table 10.4. This situation is illustrated in Figure 10.11. It should be recalled that $X(f)$ is a complex function in general, and as such it cannot be displayed as a single curve in a two-dimensional coordinate system. Both the magnitude and the phase angle variations with respect to frequency f are needed. For brevity, only the magnitude $|X(f)|$ is shown in Figure 10.11(a). Nevertheless, the argument presented applies to the phase angle $\angle X(f)$ as well.

It is obvious that in the time interval $[0, T]$, $x(t) = \tilde{x}(t)$ and $x_m = \tilde{x}_m$. However, $\tilde{X}(n \cdot \Delta F)$ is only approximately equal to $X(n \cdot \Delta F)$ in the frequency interval $[0, F]$. This is known as the aliasing distortion in the frequency domain. As ΔT decreases (i.e., as F increases) $\tilde{X}(f)$ will become closer to $X(f)$ in the frequency interval $[0, F/2]$, as is clear from Figure 10.11(c). Furthermore, due to the F -periodicity of $\tilde{X}(f)$, its value in the frequency range $[F/2, F]$ will approximate $X(f)$ in the frequency range $[-F/2, 0]$.

It is clear from the preceding discussion that if a time signal $x(t)$ is sampled at equal steps of ΔT , no information regarding its frequency spectrum $X(f)$ is obtained for frequencies higher than $f_c = 1/(2\Delta T)$. This fact is known as *Shannon's sampling theorem*, and the limiting (cut-off) frequency is called the *Nyquist frequency*. In vibration signal analysis, a sufficiently small sample step ΔT should be chosen in order to reduce aliasing distortion in the frequency domain, depending on the highest frequency of interest in the analyzed signal. This however, increases the signal processing time and the computer storage requirements, which is undesirable, particularly in real-time analysis. It can also result in stability problems in numerical computations. The Nyquist sampling criterion requires that the sampling rate ($1/\Delta T$) for a signal should be at least twice the highest frequency of interest. Instead of making the sampling rate very high, a moderate value that satisfies the Nyquist sampling criterion is used in practice, together with an *antialiasing filter* to remove the distorted frequency components. It should be noted that the DFT results in the frequency interval $[f_c, 2f_c]$ are redundant because they merely approximate the frequency spectrum in the negative frequency interval $[-f_c, 0]$ which is known for real signals. This fact is known as the Hermitian property.

The last column of Table 10.4 presents the relationship between the FSE and the DFT. It is noted that the sequence $\{\tilde{A}_n\}$ rather than the sequence of complex Fourier series coefficients $\{A_n\}$ represents the DFT

TABLE 10.4 Unified Fourier Transform Relationships

Description	Relationship	
	DFT and FIT	DFT and FSE
Given	$x(t) \xrightarrow{\text{FIT}} X(f)$	$x(t) \xrightarrow{\text{FSE}} \{A_n\}$
Form	$\tilde{x}(t) = \sum_{k=-\infty}^{\infty} x(t + kT)$ $\tilde{X}(f) = \sum_{k=-\infty}^{\infty} X(f + kF)$	$\tilde{A}_n = \sum_{k=-\infty}^{\infty} A_{n+kN}$
Then	$\{\tilde{x}_m\} \xrightarrow{\text{DFT}} \{\tilde{X}_n\}$	$\{\tilde{x}_m\} \xrightarrow{\text{DFT}} \{\tilde{A}_n\}$
Where	$\tilde{x}_m = \tilde{x}(m \cdot \Delta T)$, $\tilde{X}_n = \tilde{X}(n \cdot \Delta F)$ $F = 1/\Delta T$, $T = 1/\Delta F$	$x_m = x(m \cdot \Delta T)$ $N = T/\Delta T$

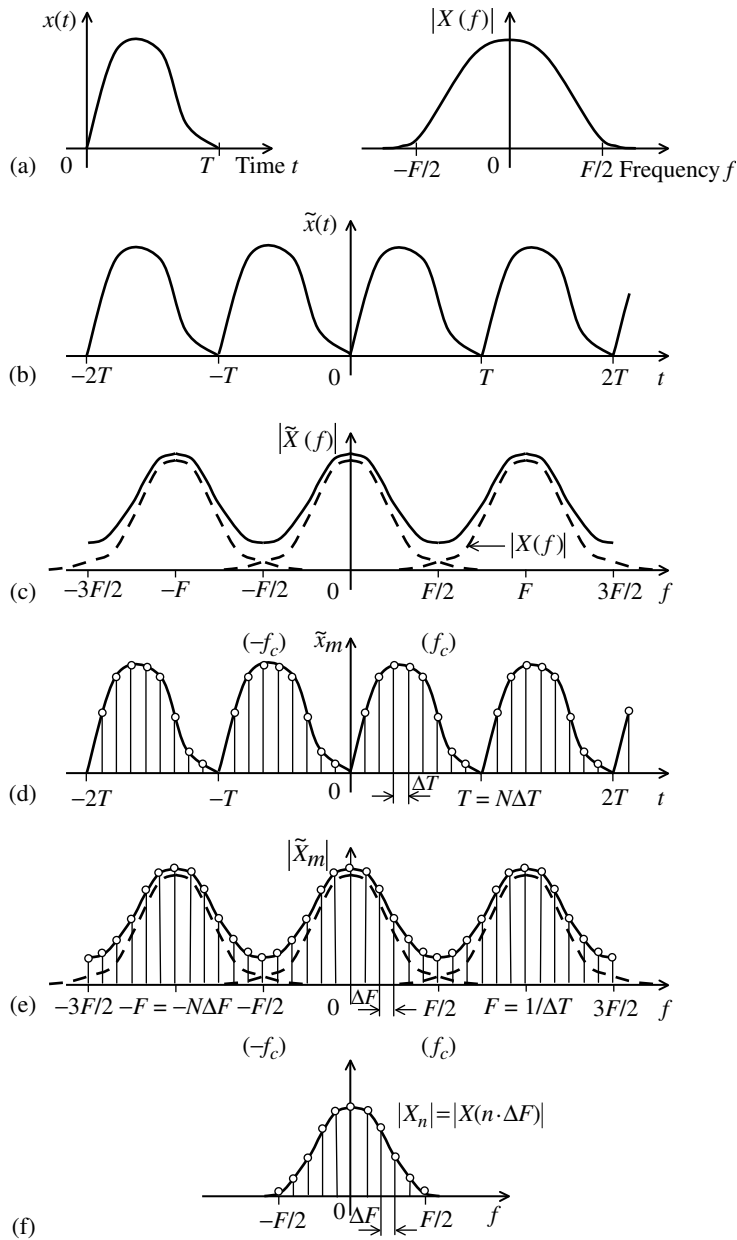

FIGURE 10.11 Relationship between FIT and DFT, with an illustration of aliasing error. (a) Fourier integral transformation (FIT) of a signal; (b) periodicity arranged time signal; (c) periodicity of the frequency spectrum; (d) sampled time signal; (e) sampled frequency spectrum (with aliasing error); (f) sampled original spectrum (no aliasing error).

of the sampled data sequence $\{x(m \cdot \Delta T)\}$. In practice, however, $A_n \rightarrow 0$ as $n \rightarrow \infty$. Consequently, \tilde{A}_n is a good approximator to A_n in the range $[-N/2 \leq n \leq N/2]$ for sufficiently large N . This basic result is useful in determining the Fourier coefficients of a periodic signal using discrete data that are sampled at time steps of $\Delta T = 1/F$, in which F is the fundamental frequency of the periodic signal. Again the aliasing error $(\tilde{A}_n - A_n)$ may be reduced by increasing the sampling rate (i.e., by decreasing ΔT or increasing N).

10.4.4.2 Aliasing Distortion in the Time Domain

In vibration applications it is sometimes required to reconstruct the signal from its Fourier spectrum. Inverse DFT is used for this purpose and is particularly applicable in digital equalizers in vibration testing. Due to sampling in the frequency domain, the signal becomes distorted. The aliasing error ($\tilde{x}_m - x(m\Delta T)$) is reduced by decreasing the sample period ΔF . It should be noted that no information regarding the signal for times greater than $T = 1/\Delta F$ is obtained from the analysis.

By comparing Figure 10.11(a) with (c), or (e) with (f), it should be clear that the aliasing error in \tilde{X} in comparison with the original spectrum X is caused by “folding” of the high-frequency segment of X beyond the Nyquist frequency into the low-frequency segment of X . This is illustrated in Figure 10.12.

10.4.4.3 Antialiasing Filter

It should be clear from Figure 10.12 that, if the original signal is low-pass filtered at a cut-off frequency equal to the Nyquist frequency, then the aliasing distortion would not occur due to sampling. A filter of this type is called an antialiasing filter. In practice, it is not possible to achieve perfect filtering. Hence, some aliasing could remain even after using an antialiasing filter. Such residual errors may be reduced by using a filter cut-off frequency that is slightly less than the Nyquist frequency. The resulting spectrum would then only be valid up to this filter cut-off frequency (and not up to the theoretical limit of Nyquist frequency).

Example 10.1

Consider 1024 data points from a signal, sampled at 1 msec intervals.

$$\text{Sample rate } f_s = 1/0.001 \text{ samples/sec} = 1000 \text{ Hz} = 1 \text{ kHz}$$

$$\text{Nyquist frequency} = 1000/2 \text{ Hz} = 500 \text{ Hz}$$

Due to aliasing, approximately 20% of the spectrum (i.e., spectrum beyond 400 Hz) will be distorted. Here we may use an antialiasing filter.

FIGURE 10.12 Aliasing distortion of frequency spectrum. (a) Original spectrum; (b) distorted spectrum due to aliasing.

Box 10.2

SIGNAL SAMPLING CONSIDERATIONS

The maximum useful frequency in digital Fourier results is half the sampling rate.

Nyquist frequency or cut-off frequency or computational bandwidth:

$$f_c = \frac{1}{2} \times \text{sampling rate}$$

Aliasing distortion:

High-frequency spectrum beyond Nyquist frequency folds on to the useful spectrum, thereby distorting it.

Summary:

1. Pick a sufficiently small sample step ΔT in the time domain, to reduce the aliasing distortion in the frequency domain.
2. The highest frequency for which the Fourier transform (frequency-spectrum) information would be valid, is the Nyquist frequency $f_c = 1/(2\Delta T)$.
3. DFT results that are computed for the frequency range $[f_c, 2f_c]$ merely approximate the frequency spectrum in the negative frequency range $[-f_c, 0]$.

Suppose that a digital Fourier transform computation provides 1024 frequency points of data up to 1000 Hz. Half of this number is beyond the Nyquist frequency and will not give any new information about the signal.

$$\text{Spectral line separation} = 1000/1024 \text{ Hz} = 1 \text{ Hz (approximately)}$$

Keep only the first 400 spectral lines as the useful spectrum.

Note: Almost 500 spectral lines may be retained if an accurate antialiasing filter is used.

Some useful information on signal sampling is summarized in Box 10.2.

10.4.5 Another Illustration of Aliasing

A simple illustration of aliasing is given in [Figure 10.13](#). Here, two sinusoidal signals of frequency, $f_1 = 0.2 \text{ Hz}$ and $f_2 = 0.8 \text{ Hz}$, are shown ([Figure 10.13\(a\)](#)). Suppose that the two signals are sampled at the rate of $f_s = 1 \text{ sample/sec}$. The corresponding Nyquist frequency is $f_c = 0.5 \text{ Hz}$. It is seen that, at this sampling rate, the data samples from the two signals are identical. In other words, the high-frequency signal cannot be distinguished from the low-frequency signal. Hence, a high-frequency signal component of frequency 0.8 Hz will appear as a low-frequency signal component of frequency 0.2 Hz. This is aliasing, as is clear from the signal spectrum shown in [Figure 10.13](#). Specifically, the spectral segment of the signal beyond the Nyquist frequency (f_c) cannot be recovered.

It is apparent from [Figure 10.11\(e\)](#) that the aliasing error becomes increasingly prominent for frequencies of the spectrum closer to the Nyquist frequency. With reference to the expression for $\tilde{X}(f)$ in [Table 10.4](#), it should be clear that when the true Fourier spectrum $X(f)$ has a steep roll-off prior to $F/2$ ($= f_c$), the influence of the $X(f - nF)$ segments for $n \geq 2$ and $n \leq -1$ is negligible in the discrete spectrum in the frequency range $[0, F/2]$. Hence the aliasing distortion in the frequency band $[0, F/2]$ comes primarily from $X(f - F)$, which is the true spectrum shifted to the right through F . Therefore,

FIGURE 10.13 A simple illustration of aliasing. (a) Two harmonic signals with identical sampled data; (b) Frequency spectra of the two harmonic signals.

a reasonably accurate expression for the aliasing error is

$$e_n = X(-(F - n \cdot \Delta F)) = X(n \cdot \Delta F - F) = X_{-(N-n)} = X_{n-N} \quad n = 0, 1, 2, \dots, N/2 \quad (10.25)$$

Note from Equation 10.8 that the spectral value obtained when f in the complex exponential is replaced by $-f$ is the same as the spectral value obtained when j is replaced by $-j$. Since the signal $x(t)$ is real, it follows that the Fourier spectrum for the negative frequencies is simply the complex conjugate of the Fourier spectrum for the positive frequencies; thus

$$X(-f) = X^*(f) \quad (10.26)$$

or, in the discrete case

$$X_{n-N} = X_{N-n}^* \quad (10.27)$$

It follows from Equation 10.25 that the aliasing distortion is given by

$$e_n = X_{N-n}^* \quad \text{for } n = 0, 1, 2, \dots, N/2 \quad (10.28)$$

This result confirms that aliasing can be interpreted as folding of the complex conjugate of the true spectrum beyond the Nyquist frequency $f_c (= F/2)$ over to the original spectrum. In other words, due to aliasing, frequency components higher than the Nyquist frequency appear as lower frequency components (due to folding). These aliasing components enter into the digital Fourier results in the useful frequency range $[0, f_c]$.

Aliasing reduces the valid frequency range in digital Fourier results. Typically, the useful frequency limit is $f_c/1.28$ so that the last 20% of the spectral points near the Nyquist frequency should be neglected.

It should be clear that if a low-pass filter with its cut-off frequency set at f_c is used on the time signal prior to sampling and digital Fourier analysis, the aliasing distortion can be virtually eliminated. Analog hardware filters may be used for this purpose. They are the *antialiasing filters*. Note that sometimes $f_c/1.28 (\cong 0.8f_c)$ is used as the filter cut-off frequency. In this case, the computed spectrum is accurate up to $0.8f_c$ and not up to f_c .

The buffer memory of a typical commercial Fourier analyzer can store $N = 2^{10} = 1024$ samples of data from the time signal. This is the size of the data block analyzed in each digital Fourier transform calculation. This will result in $N/2 = 512$ spectral points (spectral lines) in the frequency range $[0, f_c]$. Out of this only the first 400 spectral lines (approximately 80%) are considered free of aliasing distortion.

Example 10.2

Suppose that the frequency range of interest in a particular vibration signal is 0–200 Hz. We are interested in determining the sampling rate (digitization speed) and the cut-off frequency for the antialiasing (low-pass) filter.

The Nyquist frequency f_c is given by $f_c/1.28 = 200$

Hence, $f_c = 256$ Hz

The sampling rate (or digitization speed) for the time signal that is needed to achieve this range of analysis is $F = 2f_c = 512$ Hz. With this sampling frequency, the cut-off frequency for the antialiasing filter could be set at a value between 200 and 256 Hz.

10.5 Analysis of Random Signals

Random (stochastic) signals are generated by some random mechanism. Each time the mechanism is operated a new time history (sample function) is generated. The chance of any two sample functions becoming identical is governed by some probabilistic law. If all sample functions are identical (with unity probability), then the corresponding signal is a deterministic signal. A random process is denoted by $\tilde{X}(t)$, while any sample function of it is denoted by $x(t)$. No numerical computations can be performed on $\tilde{X}(t)$ because it is not known for certain. Its Fourier transform, for instance, can be written down as an analytical expression, but cannot be numerically computed. However, once the signal is generated, numerical computations can be performed on that sample function $x(t)$ because it is a completely known function of time.

10.5.1 Ergodic Random Signals

At any given time t_1 , $\tilde{X}(t_1)$ is a random variable which has a certain probability distribution. Consider a well-behaved function $f\{\tilde{X}(t)\}$ of this random variable (which is also a random variable). Its expected value (statistical mean) is $E[f\{\tilde{X}(t)\}]$. This is also known as the ensemble average because it is equivalent to the average value at t of a collection (ensemble) of a large number of sample functions $x(t)$.

Consider the function $f\{x(t)\}$ of one sample function $x(t)$. Its temporal (time) mean is expressed by

$$\lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f\{x(t)\} dt$$

Now, if

$$E[f\{\tilde{X}(t_1)\}] = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f\{x(t)\} dt \quad (10.29)$$

then the random signal is said to be ergodic. It should be noted that the right-hand side of Equation 10.29 does not depend on time. Consequently, the left-hand side should also be independent of the time point t_1 .

For analytical convenience, random vibration signals are usually assumed to be ergodic (the ergodic hypothesis). Using this hypothesis, the properties of a random signal could be determined by performing computations on a sufficiently long record (sample function) of the signal. Since the ergodic hypothesis is not exactly satisfied for vibration signals, and since it is impossible to analyze infinitely long data records, the accuracy of the numerical results depends on various factors such as the record length, sampling rate, frequency range of interest, and the statistical nature of the random signal (e.g., closeness to a deterministic signal, frequency content, periodicity, damping characteristics). Accuracy can be improved in general, by averaging the results for more than one data record.

10.5.2 Correlation and Spectral Density

If for a random signal $\tilde{X}(t)$, the joint statistical properties of $\tilde{X}(t_1)$ and $\tilde{X}(t_2)$ depend on the time difference $(t_2 - t_1)$ and not on t_1 itself, then the signal is said to be stationary. Consequently, the statistical properties of a stationary $\tilde{X}(t)$ will be independent of t . It is noted from Equation 10.29 that ergodic random signals are necessarily stationary. However, in general the converse is not true.

The cross-correlation function of two random signals $\tilde{X}(t)$ and $\tilde{Y}(t)$ is given by $E[\tilde{X}(t)\tilde{Y}(t + \tau)]$. If the signals are stationary, this expected value is a function of τ (not t) and is denoted by $\phi_{xy}(\tau)$. In view of the ergodic hypothesis, the cross-correlation function may be expressed as

$$\phi_{xy}(\tau) = \lim_{T \rightarrow \infty} \left[\frac{1}{T} \int_0^T x(t)y(t + \tau)dt \right] \quad (10.30)$$

The FIT of $\phi_{xy}(\tau)$ is the cross-spectral density function which is denoted by $\Phi_{xy}(f)$. When the two signals are identical, we have the autocorrelation function $\phi_{xx}(\tau)$ in the time domain and the power spectral density (PSD) $\Phi_{xx}(f)$ in the frequency domain. The continuous and the discrete versions of the correlation theorem are given in the first row of Table 10.5. It follows that the cross-spectral density may be estimated using the DFT (FFT) of the two signals, as $[X_n]^* Y_n / T$ in which T is the record length and $[X_n]^*$ is the complex conjugate of $[X_n]$.

Parseval's theorem (second row of Table 10.5) follows directly from the correlation theorem. Consequently, the mean square value of a random signal may be obtained from the area under the PSD curve. This suggests a hardware-based method of estimating the PSD as illustrated by the functional diagram in Figure 10.14(a). Alternatively, a software-based digital Fourier analysis could be used (Figure 10.14(b)). A single sample function would not give the required accuracy, and averaging is usually needed. In real-time digital analysis, the running average as well as the current estimate is usually computed. In the running average, it is desirable to give a higher weighting to the more recent estimates. The fluctuations in the PSD estimate about the local average could be reduced by selecting a large filter

TABLE 10.5 Some Useful Fourier Transform Results

Description	Continuous	Discrete
Correlation theorem	If $z(\tau) = \int_{-\infty}^{\infty} x(t)y(t + \tau)dt$ Then $Z(f) = [X(f)]^* Y(f)$	$z_m = \Delta T \sum_{r=0}^{N-1} x_r y_{r+m}$ $Z_n = [X_n]^* Y_n$
Parseval's theorem	If $y(t) \xrightarrow{\text{FIT}} Y(f)$ Then $\int_{-\infty}^{\infty} y^2(t)dt = \int_{-\infty}^{\infty} Y(f) ^2 df$	$\{y_m\} \xrightarrow{\text{DFT}} \{Y_n\}$ $\Delta T \sum_{m=0}^{N-1} y_m^2 = \Delta F \sum_{n=0}^{N-1} Y_n ^2$
Convolution theorem	If $y(t) = \int_{-\infty}^{\infty} h(\tau)u(t - \tau)d\tau = \int_{-\infty}^{\infty} h(t - \tau)u(\tau)d\tau$ Then $Y(f) = H(f)U(f)$	$y_m = \Delta T \sum_{r=0}^{N-1} h_r u_{m-r} = \Delta T \sum_{r=0}^{N-1} h_{m-r} u_r$ $Y_n = H_n U_n$

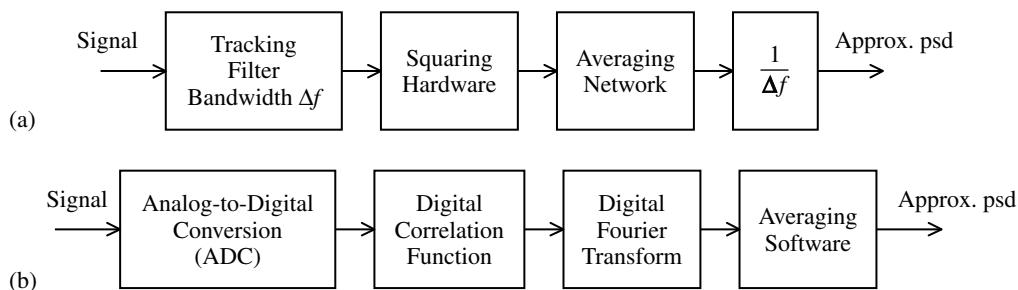

FIGURE 10.14 Power spectral density computation. (a) Narrow-band filtering method; (b) correlation and Fourier transformation method.

bandwidth Δf and a large record length T . A measure of these fluctuations is given by

$$\varepsilon = \frac{1}{\sqrt{\Delta f T}} \quad (10.31)$$

It should be noted that a large Δf results in reduction of the precision of the estimates while improving the appearance. To offset this, T has to be increased further.

10.5.3 Frequency Response Using Digital Fourier Transform

Vibration test programs usually require a resonance search type pretesting. In order to minimize the damage potential, it is carried out at a much lower intensity than the main test. The objective of such exploratory tests is to determine the significant frequency-response functions of the test specimen. These provide the natural frequencies, damping ratios, and mode shapes of the test specimen. Such frequency-response data are useful in planning and conducting the main test. For example, more attention is required when testing in the vicinity of the resonance points (slower sweep rates, larger dwell periods, etc.). Also, the frequency-response data are useful in determining the most desirable test input directions and intensities. The degree of nonlinearity and time variance of the test object can be determined by conducting more than one frequency-response test at different input intensities. If the deviation of the frequency-response function is sufficiently small, then linear, time-invariant analysis is considered to be satisfactory. Often, frequency-response tests are conducted at full test intensity. In such cases, it is considered as a part of the main test rather than a prescreening test. Other uses of the frequency-response function include the following: it can be employed as a system model (experimental model) for further analysis of the test specimen (experimental modal analysis). Most desirable frequency range and sweep rates for vibration testing can be estimated by examining frequency-response functions.

The time response $h(t)$ to a unit impulse is known as the impulse-response function. For each pair of input and output locations (A,B) of the test specimen, a corresponding single response function would be obtained (assuming linearity and time-invariance). Entire collection of these responses would determine the response of the test specimen to an arbitrary input signal. The response $y(t)$ at B to an arbitrary input $u(t)$ applied at A, is given by

$$y(t) = \int_{-\infty}^{\infty} h(\tau)u(t - \tau)d\tau = \int_{-\infty}^{\infty} h(t - \tau)u(\tau)d\tau \quad (10.32)$$

The right-hand side of Equation 10.32 is the convolution integral of $h(t)$ and $u(t)$ and is denoted by $h(t) * u(t)$. By substituting the inverse FIT relations (Table 10.2) in Equation 10.32, the frequency-response function (frequency-transfer function) $H(f)$ is obtained as the ratio of the (complex) FITs of the output and the input. It exists for physically realizable (casual) systems even when the individual FITs of the input and output signals do not converge. The continuous convolution theorem and the discrete

counterpart are given in the last row of Table 10.5. The discrete convolution can be interpreted as the trapezoidal integration of Equation 10.32. Frequency-response function is a valid representation (model) for linear, time-invariant systems. It is related to the system transfer function $G(s)$ (ratio of the Laplace transforms of output and input with zero initial conditions) through

$$H(f) = \frac{Y(f)}{U(f)} = G(2\pi f) \quad (10.33)$$

But for notational convenience, the frequency-response function corresponding to $G(s)$ may be denoted by either $G(f)$ or $G(\omega)$, where ω is the angular frequency and f is the cyclic frequency.

Using Fourier transform theory, three methods of determining $H(f)$ can be established. First, using any transient excitation signal to a system at rest and the corresponding output, $H(f)$ is determined from their FITs (Table 10.5). Second, if the input is sinusoidal, the signal amplification of the steady-state output is the magnitude $|H(f)|$ at the input frequency, and the phase lead of the steady-state output is the corresponding phase angle $\angle H(f)$. Third, using a random input signal and the corresponding input and output spectral density functions, $H(f)$ is determined as the ratio

$$H(f) = \Phi_{yy}(f)/\Phi_{uu}(f) \quad (10.34)$$

10.5.4 Leakage (Truncation Error)

In digital processing of vibration signals (e.g., accelerometer signals), sampled data are truncated to eliminate less significant parts. This is of course essential in real-time processing because, in that case, only sufficiently short segments of continuously acquisitioned data are processed at a time. The computer memory (and buffer) limitations, the speed and cost of processing, the frequency range of importance, the sampling rate, and the nature of the signal (level of randomness, periodicity, decay rate, etc.) should be taken into consideration in selecting the truncation point of data.

The effect of direct truncation of a signal $x(t)$ on its Fourier spectrum is shown in Figure 10.15. In the time domain, truncation is accomplished by multiplying $x(t)$ by the box-car function $b(t)$. This is equivalent to a convolution ($X(f) * B(f)$) in the frequency domain. This procedure introduces ripples (side lobes) into the true spectrum. The resulting error ($X(f) - X(f) * B(f)$) is known as leakage or truncation error. Similar leakage effects arise in the time domain, as a result of truncation of the frequency spectrum. The truncation error may be reduced by suppressing the side lobes, which requires modification of the truncation function (window) from the box-car shape $b(t)$ to a more desirable shape. Commonly used windows are the Hanning, Hamming, Parzen, and Gaussian windows.

10.5.5 Coherence

Random vibration signals $\tilde{X}(t)$ and $\tilde{Y}(t)$ are said to be statistically independent if their joint probability distribution is given by the product of the individual distributions. A special case of this is the uncorrelated signals which satisfy

$$E[\tilde{X}(t_1)\tilde{Y}(t_2)] = E[\tilde{X}(t_1)]E[\tilde{Y}(t_2)] \quad (10.35)$$

In the stationary case, the means $\mu_x = E[\tilde{X}(t)]$ and $\mu_y = E[\tilde{Y}(t)]$ are time independent. The autocovariance functions are given by

$$\psi_{xx}(\tau) = E[\{\tilde{X}(t) - \mu_x\}\{\tilde{X}(t + \tau) - \mu_x\}] = \phi_{xx}(\tau) - \mu_x^2 \quad (10.36)$$

$$\psi_{yy}(\tau) = E[\{\tilde{Y}(t) - \mu_y\}\{\tilde{Y}(t + \tau) - \mu_y\}] = \phi_{yy}(\tau) - \mu_y^2 \quad (10.37)$$

and the cross-covariance function is given by

$$\psi_{xy}(\tau) = E[\{\tilde{X}(t) - \mu_x\}\{\tilde{Y}(t + \tau) - \mu_y\}] = \phi_{xy}(\tau) - \mu_x\mu_y \quad (10.38)$$

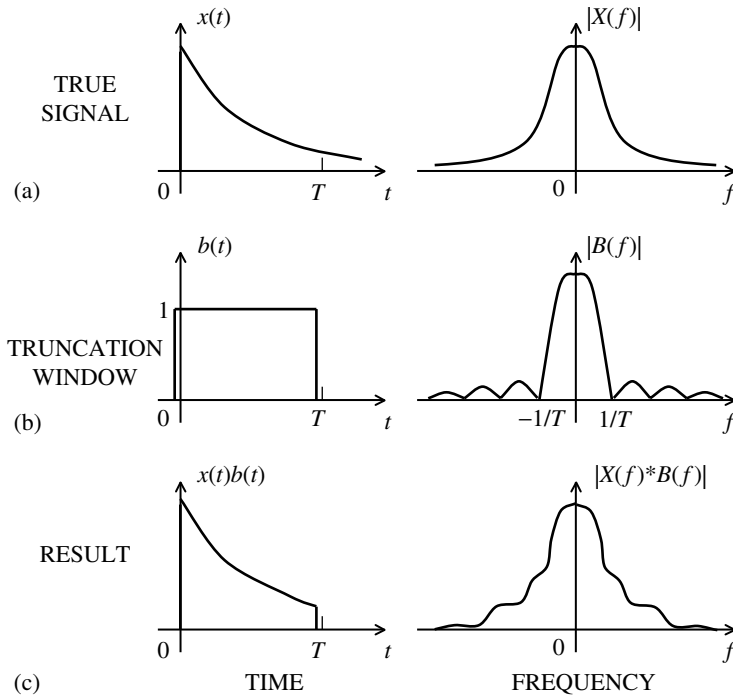

FIGURE 10.15 Illustration of truncation error. (a) Signal and its frequency spectrum; (b) a rectangular (box-car) window and its frequency spectrum; (c) truncated signal and its frequency spectrum.

For uncorrelated signals $\phi_{xy}(\tau) = \mu_x \mu_y$ and $\psi_{xy}(\tau) = 0$. The correlation function coefficient is defined by

$$\rho_{xy}(\tau) = \frac{\psi_{xy}(\tau)}{\sqrt{\psi_{xx}(0)\psi_{yy}(0)}} \quad (10.39)$$

which satisfies $-1 \leq \rho_{xy}(\tau) \leq 1$.

For uncorrelated signals we have $\rho_{xy}(\tau) = 0$. This function measures the degree of correlation of the two signals. In the frequency domain, the correlation is determined by its (ordinary) coherence function

$$\gamma_{xy}^2(f) = \frac{|\Phi_{xy}(f)|^2}{\Phi_{xx}(f)\Phi_{yy}(f)} \quad (10.40)$$

which satisfies the condition $0 \leq \gamma_{xy}^2(f) \leq 1$. In this definition, the signals are assumed to have zero means. Alternatively, the FIT of the covariance functions may be used. If the signals are uncorrelated (or better, independent) the coherence function vanishes. On the other hand, if $\tilde{Y}(t)$ is the response of a linear, time-invariant system to an input $\tilde{X}(t)$, then

$$\Phi_{xy}(f) = \Phi_{xx}(f)H(f) \quad (10.41)$$

$$\Phi_{yy}(f) = \Phi_{xx}(f)|H(f)|^2 \quad (10.42)$$

Consequently, the coherence function becomes unity for this ideal case. In practice, however, the coherence function of an excitation and the corresponding response is usually less than unity. This is due to deviations such as measurement noise, system nonlinearities, and time-variant effects. Consequently, the coherence function is commonly used as a measure of the accuracy of frequency-response estimates.

10.5.6 Parseval's Theorem

For a pair of rapidly decaying (aperiodic) deterministic signals $x(t)$ and $y(t)$, the cross-correlation function is given by

$$\phi_{xy}(\tau) = \int_{-\infty}^{\infty} x(t)y(t + \tau)dt \quad (10.43)$$

This is equivalent to Equation 10.30, for a pair of ergodic, random (stochastic) signals $x(t)$ and $y(t)$. By using the definition of the inverse FIT (see Table 10.2) in Equation 10.43, and by following straightforward mathematical manipulation, it may be shown that

$$\Phi_{xy}(f) = [X(f)]^* Y(f) \quad (10.44)$$

in which the cross-spectral density $\Phi_{xy}(f)$ is the FIT of $\phi_{xy}(\tau)$, as given by

$$\Phi_{xy}(f) = \int_{-\infty}^{\infty} \phi_{xy}(\tau) \exp(-j2\pi f\tau) d\tau \quad (10.45)$$

and $[\]^*$ denotes the complex conjugation operation. This result, which is known as the correlation theorem (see Table 10.5) has applications in the evaluation of the correlation functions and PSD functions of finite-record-length data.

The inverse FIT relation corresponding to Equation 10.45 is

$$\phi_{xy}(\tau) = \int_{-\infty}^{\infty} \Phi_{xy}(f) \exp(j2\pi f\tau) df \quad (10.46)$$

From Equation 10.44, we have

$$\phi_{xy}(\tau) = \int_{-\infty}^{\infty} [X(f)]^* Y(f) \exp(j2\pi f\tau) df \quad (10.47)$$

If we set $\tau = 0$ and $x = y$ in Equation 10.47, we get

$$\phi_{xy}(0) = \int_{-\infty}^{\infty} |Y(f)|^2 df \quad (10.48)$$

Similarly, from Equation 10.43, we get

$$\phi_{xy}(0) = \int_{-\infty}^{\infty} y^2(t) dt \quad (10.49)$$

By comparing Equation 10.48 and Equation 10.49, we obtain Parseval's theorem and thus

$$\int_{-\infty}^{\infty} y^2(t) dt = \int_{-\infty}^{\infty} |Y(f)|^2 df \quad (10.50)$$

By using the discrete correlation theorem in an analogous manner, we can establish the discrete version of Equation 10.50:

$$\Delta T \sum_{m=0}^{N-1} y_m^2 = \Delta F \sum_{n=0}^{N-1} |Y_n|^2 \quad (10.51)$$

These results are listed in the second row of Table 10.5.

10.5.7 Window Functions

Consider the unit box-car function $w(t)$, defined as

$$w(t) = \begin{cases} 1 & \text{for } -0 \leq t < T \\ 0 & \text{otherwise} \end{cases} \quad (10.52)$$

TABLE 10.6 Some Common Window Functions

Function Name	Time-Domain Representation $[w(t)]$	Frequency-Domain Representation $[W(f)]$
Box-car	$\begin{cases} 1 & \text{for } 0 \leq t < T \\ 0 & \text{otherwise} \end{cases}$	$\frac{1}{j2\pi f} [1 - \cos 2\pi fT + j \sin 2\pi fT]$
Hanning	$\begin{cases} \frac{1}{2} + \frac{1}{2} \cos \frac{\pi t}{T} & \text{for } t < T \\ 0 & \text{otherwise} \end{cases}$	$\frac{T \sin 2\pi fT}{2\pi fT[1 - (2fT)^2]}$
Parzen	$\begin{cases} 1 - 6\left[\frac{t}{T}\right]^2 + 6\left[\frac{ t }{T}\right]^3 & \text{for } t < \frac{T}{2} \\ 2\left[1 - \frac{ t }{T}\right]^3 & \text{for } \frac{T}{2} < t \leq T \\ 0 & \text{otherwise} \end{cases}$	$\frac{3}{4} T \left[\frac{\sin \pi fT/2}{\frac{1}{2} \pi fT} \right]^4$
Bartlett	$\begin{cases} 1 - \frac{ t }{T} & \text{for } t \leq T \\ 0 & \text{otherwise} \end{cases}$	$T \left[\frac{\sin \pi fT}{\pi fT} \right]^4$

This is shown in Figure 10.15(b). The FIT of $w(t)$ is

$$W(f) = \frac{1}{j2\pi f} [1 - \cos 2\pi fT + j \sin 2\pi fT]$$

(10.53)

Clearly, this (rectangular) window function produces side lobes (leakage) in the frequency domain.

In spectral analysis of vibration signals, it is often required to segment the time history into several parts, and then perform spectral analysis on the individual results to observe the time development of the spectrum. If segmenting is done by simple truncation (multiplication by the box-car window), the process would introduce rapidly fluctuating side lobes into spectral results. Window functions, or smoothing functions other than the box-car function, are widely used to suppress the side lobes (leakage error). Some common smoothing functions are defined in Table 10.6.

A graphical comparison of these four window types is given in Figure 10.16. Hanning windows are very popular in practical applications. A related window is the Hamming window, which is simply a Hanning window with rectangular cut-offs at the two ends. A Hamming window will have characteristics similar to those of a Hanning window, except that the side lobe fall-off rate at higher frequencies is less in the Hamming window.

From Figure 10.16(b), we observe that the frequency-domain weight of each window varies with the frequency range of interest. Obviously, the box-car window is the worst. In practical applications, the performance of any window could be improved by simply increasing the window length T . In addition, a window in the shape of a Gaussian function may be used when a rapid roll-off without side lobes is desired.

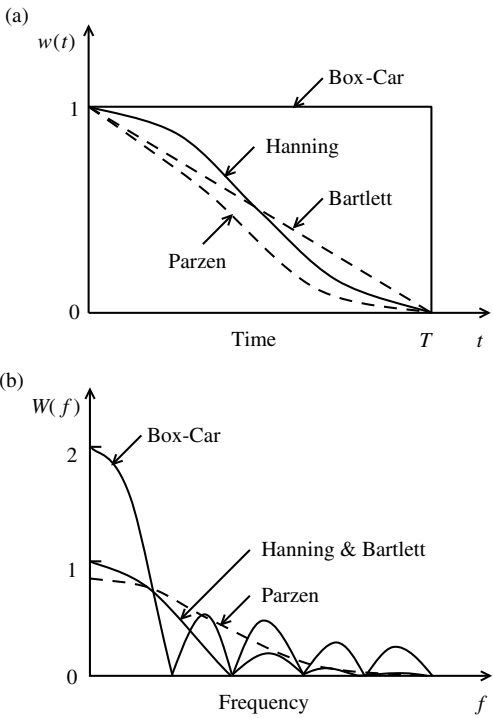

FIGURE 10.16 Some common window functions. (a) Time-domain function; (b) frequency spectrum.

TABLE 10.7 Signal Types and Appropriate Windows

Signal Type	Window
Periodic with period = T	Rectangular
Rapid transients within $[0, T]$	Gaussian
Periodic with period $\neq T$	Flat-top cosine
Quasi-periodic	Hamming
Slow transients beyond $[0, T]$	Hanning
Nonstationary random	Gaussian
Beat-like signals with period $\approx T$	Bartlett (triangular)
Narrow-band random	Rectangular
Stationary random	Hamming
Important low-level components mixed with widely spaced high-level spectral components	Parzen
Broad-band random (white noise, pink noise, etc.)	Gaussian

Characteristics of the signal that is being analyzed and also the nature of the system that generates the signal should be considered in choosing an appropriate truncation window. In particular, the Hanning window is recommended for signals generated by heavily damped systems and the Hamming window is recommended for use with lightly damped systems. Table 10.7 lists some useful signal types and appropriate window functions.

10.5.8 Spectral Approach to Process Monitoring

In mechanical systems, component degradation may be caused by vibrating excitations, which can result in malfunction or failure. In this sense, continuous monitoring during testing of mechanical deterioration in various critical components of a vibratory system is of prime importance. This usually cannot be done by simple visual observation, unless malfunction is detected by operability monitoring of the system. However, since mechanical degradation is always associated with a change in vibration level, by continuously monitoring the development of Fourier spectra in time (during system operation) at various critical locations of the system, it is possible to conveniently detect any mechanical deterioration and impending failure. In this respect, real-time Fourier analysis is very useful in process monitoring and failure detection and prediction. Special-purpose real-time analyzers with the capability of spectrum comparison (often done by an external command) are available for this purpose.

Various mechanical deteriorations manifest themselves at specific frequency values. A change in spectrum level at a particular frequency (and its multiples) would indicate a specific type of mechanical degradation or component failure. An example is given in Figure 10.17, which compares the Fourier spectrum at a monitoring location of a vibratory system at the start of test with the Fourier spectrum after some mechanical degradation has taken place. To facilitate spectrum comparison within a narrow-frequency band, it is customary to plot such Fourier spectra on a linear frequency axis. It is seen that the overall spectrum levels have increased as a result of mechanical degradation. Also, a significant change has occurred near 30 Hz. This information is useful in diagnosing the cause of degradation or malfunction. Figure 10.17 might indicate, for example, impending failure of a component having resonant frequency close to 30 Hz.

FIGURE 10.17 Effect of mechanical degradation on a monitored Fourier spectrum.

10.5.9 Cepstrum

A function known as the *cepstrum* is sometimes used to facilitate the analysis of Fourier spectrum in detecting mechanical degradation. The cepstrum (complex) $C(\tau)$ of a Fourier spectrum $Y(f)$ is defined by

$$C(\tau) = \mathcal{F}^{-1} \log Y(f) \quad (10.54)$$

The independent variable τ is known as quefrency, and it has the units of time.

An immediate advantage of cepstrum arises from the fact that the logarithm of the Fourier spectrum is taken. From Equation 10.33 it is clear that, for a system having frequency-transfer function $H(f)$, and excited by a signal having Fourier spectrum $U(f)$, the response Fourier spectrum $Y(f)$ could be expressed in the logarithmic form:

$$\log Y(f) = \log H(f) + \log U(f) \quad (10.55)$$

Since the right-hand side terms are added rather than multiplied, any variation in $H(f)$ at a particular frequency will be less affected by a possible low-spectrum level in the excitation $U(f)$ at that frequency, when considering $\log Y(f)$ rather than $Y(f)$. Consequently, any degradation will be more conspicuous in the cepstrum than in the Fourier spectrum. Another advantage of cepstrum is that it is better capable of detecting variation in phenomena that manifest themselves as periodic components in the Fourier spectrum (for example, harmonics and sidebands). Such phenomena, which appear as repeated peaks in the Fourier spectrum, occur as a single peak in the cepstrum, and so any variations can be detected more easily.

10.6 Other Topics of Signal Analysis

In this section, we will briefly address some other important topics of signal analysis. We will start by discussing bandwidth in different contexts then we will present several practically useful analysis procedures and results on vibration signals.

10.6.1 Bandwidth

Bandwidth has different meanings depending on the particular context and application. For example, when studying the response of a dynamic system, the bandwidth relates to the fundamental resonant frequency, and correspondingly to the speed of response for a given excitation. In band-pass filters, the bandwidth refers to the frequency band within which the frequency components of the signal are allowed through the filter, the frequency components outside the band being rejected by it. With respect to measuring instruments, bandwidth refers to the range frequencies within which the instrument measures a signal accurately. Note that these various interpretations of bandwidth are somewhat related. For example, if a signal passes through a band-pass filter, then we know that its frequency content is within the bandwidth of the filter; but we cannot determine the actual frequency content of the signal through

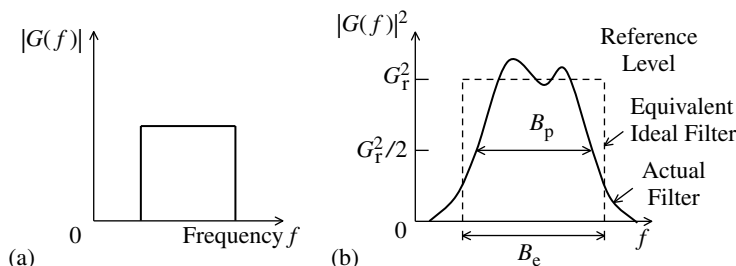

FIGURE 10.18 Characteristics of (a) an ideal band-pass filter; (b) a practical band-pass filter.

such an observation. In this context, the bandwidth appears to represent a frequency uncertainty in the observation (i.e., the larger the bandwidth of the filter, the less certain the actual frequency content of a signal that is allowed through the filter).

10.6.2 Transmission Level of a Band-Pass Filter

Practical filters can be interpreted as dynamic systems. In fact all physical, dynamic systems (e.g., mechanical structures) are analog filters. It follows that the filter characteristic can be represented by the frequency-transfer function $G(f)$ of the filter. A magnitude squared plot of such a filter transfer function is shown in Figure 10.18. In a logarithmic plot the magnitude-squared curve is obtained by simply doubling the corresponding magnitude (Bode plot) curve. Note that the actual filter transfer function (Figure 10.18(b)) is not flat like the ideal filter shown in Figure 10.18(a). The reference level G_r is the average value of the transfer function magnitude in the neighborhood of its peak.

10.6.3 Effective Noise Bandwidth

Effective noise bandwidth of a filter is equal to the bandwidth of an ideal filter that has the same reference level and that transmits the same amount of power from a white noise source. Note that white noise has a constant (flat) PSD. Hence, for a noise source of unity PSD, the power transmitted by the practical filter is given by

$$\int_0^{\infty} |G(f)|^2 df$$

which, by definition, is equal to the power $G_r^2 B_e$ transmitted by the equivalent ideal filter. Hence, the effective noise bandwidth B_e is given by

$$B_e = \int_0^{\infty} |G(f)|^2 df / G_r^2 \quad (10.56)$$

10.6.4 Half-Power (or 3 dB) Bandwidth

Half of the power from a unity-PSD noise source, as transmitted by an ideal filter, is $G_r^2 B_r / 2$. Hence, $G_r / \sqrt{2}$ is referred to as the *half-power level*. This is also known as a 3 dB level because $20 \log_{10} \times \sqrt{2} = 10 \log_{10} 2 = 3$ dB. (Note: 3 dB refers to a power ratio of 2 or an amplitude ratio of $\sqrt{2}$. Furthermore, 20 dB corresponds to an amplitude ratio of 10 or a power ratio of 100). The 3 dB (or half-power) bandwidth corresponds to the width of the filter transfer function at the half-power level. This is denoted by B_p in Figure 10.18(b). Note that B_e and B_p are different in general. However, in an ideal case where the magnitude-squared filter characteristic has linear rise and fall-off segments, these two bandwidths are equal (see Figure 10.19).

FIGURE 10.19 An idealized filter with linear segments.

10.6.5 Fourier Analysis Bandwidth

In Fourier analysis, bandwidth is interpreted, again, as the *frequency uncertainty* in the spectral results. In analytical FIT results, which assume that the entire signal is available for analysis, the spectrum is

continuously defined over the entire frequency range $[-\infty, \infty]$ and the frequency increment df is infinitesimally small ($df \rightarrow 0$). There is no frequency uncertainty in this case, and the analysis bandwidth is infinitesimally narrow.

In digital Fourier transform, the discrete spectral lines are generated at frequency intervals of ΔF . This finite frequency increment ΔF , which is the frequency uncertainty, is therefore the analysis bandwidth B for this analysis. Note that $\Delta F = 1/T$, where T is the record length (or window length for a rectangular window). It follows also that the minimum frequency that has a meaningful accuracy is the bandwidth. This interpretation for analysis bandwidth is confirmed by noting the fact that harmonic components of frequency less than ΔF (or period greater than T) cannot be studied by observing a signal record of length less than T . Analysis bandwidth carries information regarding distinguishable minimum frequency separation in computed results. In this sense bandwidth is directly related to the frequency resolution of analyzed results. The accuracy of analysis increases by increasing the record length T (or decreasing the analysis bandwidth B).

When a time window other than the rectangular window is used to truncate a measured vibration signal, then reshaping of data occurs according to the shape of the window. This reshaping reduces leakage due to suppression of side lobes of the Fourier spectrum of the window. At the same time, however, an error is introduced due to the information lost through data reshaping. This error is proportional to the bandwidth of the window itself. The effective noise bandwidth of a rectangular window is only slightly less than $1/T$, because the main lobe of its Fourier spectrum is nearly rectangular. Hence, for all practical purposes, the effective noise bandwidth can be taken as the analysis bandwidth. Note that data truncation (multiplication in the time domain) is equivalent to convolution of the Fourier spectrum (in the frequency domain). The main lobe of the spectrum uniformly affects all spectral lines in the discrete spectrum of the data signal. It follows that a window main lobe having a broader bandwidth (effective noise bandwidth) introduces a larger error into the spectral results. Hence, in digital Fourier analysis, bandwidth is taken as the effective noise bandwidth of the time window that is employed.

10.6.6 Resolution in Digital Fourier Results

Resolution is the frequency separation between spectral lines in digital Fourier-analysis results. For a data record of length T , the resolution is $\Delta F = 1/T$ irrespective of the type of window used. There is a noteworthy distinction between analysis bandwidth and resolution. Suppose that we have a data record of length T . If we double the length by augmenting it with trailing zeros, digital Fourier analysis of the resulting record of length $2T$ will yield a spectral line separation of $1/(2T)$. Thus, the resolution is halved. But, unless the true signal value is also zero in the second time interval $t[T, 2T]$, no new information is presented in the augmented record of duration $[0, 2T]$ in comparison to the original record of duration $[0, T]$. So, the analysis bandwidth (a measure of accuracy) will remain unchanged. If, on the other hand, the signal itself was sampled over $[0, 2T]$ and the resulting $2N$ data points were used in digital Fourier analysis, the bandwidth as well as the resolution would be halved.

Some relations that are useful in the digital computation of spectral results for signals are summarized in Box 10.3.

10.7 Overlapped Processing

Digital Fourier analysis is performed on blocks of sampled data (e.g., $2^{10} = 1024$ samples at a time). In overlapped processing, each data block is made to include part of the previous data block that was analyzed. After completing a computation, the overlapped data at the end of the computed block is moved to the beginning of the block, and the leading vacancy is filled with new data so that the end data in one block is identical to the beginning data in the next block, in the overlapped region. In other words, the overlapped portions of each data block (the two end portions) are processed twice. It follows that if there is 50% (or more) overlapping then the entire data block is processed twice. Three main reasons can

be given for using overlapped processing in digital Fourier analysis:

1. It is an effective means of averaging spectral results.
2. It reduces the waiting time for assembling the data buffer.
3. It reduces the error caused by the end shaping effect of time windows (when a window other than the rectangle window is used).

From reasons 1 and 2, it is clear that, due to overlapping, the statistical error of computations is reduced for the same speed of computation, and the computing power is more efficiently used. To explain reason 3, let us examine [Figure 10.20](#). This example shows a 50% overlap in data. It is seen that the window function can be assumed to be relatively flat, at least over 50% of the window length (record length). Then the entire data block will correspond to the flat part of the window in three successive analyses. Consequently, the shaping error (or the error due to increased analysis bandwidth) that is caused by a nonrectangular time window is virtually eliminated by overlapped processing. The flatness of a time window is determined by its effective noise bandwidth B_e . The effective record length T_e is defined as

$$T_e = \frac{1}{B_e} \quad (10.57)$$

FIGURE 10.20 Overlapped processing of windowed signals.

which provides a measure for the flat segment of the window. The percentage effective record length is given by T_e as a percentage of the actual record length T . The degree of overlapping is chosen using the relation

$$\% \text{overlap} = 100 \left(1 - \frac{T_e}{T} \right) \quad (10.58)$$

Example 10.3

For a Hamming window, $B_e = 1.4/T$. Hence, a typical value for the percentage overlap is

$$100 \left(1 - \frac{1}{1.4} \right) = 29\%$$

We might want to use a conservative overlap and even go up to 50% in this case because the window is not quite flat.

10.7.1 Order Analysis

Speed related vibrations in rotation machinery may be analyzed through order analysis. Machinery vibrations under start-up (accelerating) and shut-down (decelerating) conditions are analyzed in this manner. Orders represent the rotating-speed-related frequency components in a response signal. The ratio of the response frequency to the rotating speed is termed “order.”

Order analysis is done essentially through digital Fourier analysis of a rotating-speed-related response signal. Practically, this may be accomplished in many ways. The format in which the spectral results are presented will depend on the procedure used in order analysis. Some of the typical formats of data presentation are given below.

10.7.1.1 Speed-Spectral Map

As the rotating speed of a machine is changing in a given range, the Fourier spectrum of the response signal is determined for equal increments of speed. The results are presented as a speed spectral map which is a three-dimensional cascade diagram (or *waterfall display*). The two base axes of the plot are spectral frequency and rotating speed. The third axis gives the spectral magnitude (see Figure 10.21). These types of plots are useful in identifying order-related components during start-up or coast-down conditions. Note that for each speed the frequency band of digital Fourier analysis is kept the same (i.e., fixed sampling rate). Each distinct crest trace denotes an order-related resonance. The fact that these traces are almost straight lines indicates the significance of order (the ratio, frequency/rotating speed) in exciting these resonances.

FIGURE 10.21 A speed-spectral map obtained from order analysis.

10.7.1.2 Time-Spectral Map

Under variable speed conditions (not necessarily accelerating or decelerating) the response signal is Fourier analyzed at equal increments of time. The results are plotted in a *cascade diagram*, with frequency and time as the base axes. The third axis again represents the magnitude of the Fourier spectrum (see Figure 10.22). In this case, the crest traces are not necessarily straight, and can change their orientation arbitrarily. This variation in crest orientation is determined by the degree of speed variation.

FIGURE 10.22 A time-spectral map obtained from order analysis.

10.7.1.3 Order Tracking

In order tracking, a “tracking frequency multiplier” monitors the rotating speed of the machine (as for a speed-spectral map). But, in the present case, the sampling rate of the response signal (for Fourier analysis) is changed in proportion to the rotating speed. Note that, in this manner, the maximum useful frequency (approximately $400/512 \times \text{Nyquist Frequency}$) is increased as the rotating speed increases, so that the aliasing effects are reduced. If the same sampling rate is used for high speeds (as in the Speed-Spectral Map discussed above), aliasing error can be significant at high rotating speeds.

In presenting order tracking spectral results, the frequency axis is typically calibrated in orders. Both speed-spectral maps and time-spectral maps may be presented in this manner. Other types of data presentation may be used as well in order analysis. For example, instead of the Fourier spectrum of the response signal, power spectrum or composite power spectrum (in which the total signal power is computed in specified frequency bands and presented as a function of the rotating speed) may be used in the schemes described in this section.

Order analysis provides information on most severe operating speeds with respect to vibration (and dynamic stress). For example, suppose that, for a given speed of operation, two major resonances occur, one at 10 Hz and the other at 80 Hz. Then, the structure of the system (rotating machine and its support fixtures) should be modified to change and preferably damp out these resonances. Furthermore, the most desirable operating speed can be chosen in terms of the lowest resonant peaks by observing a speed-spectral map.

Summary

Section 11.1 provides a brief introduction to wavelet concepts in vibration-related applications. Aspects of time–frequency analysis are discussed in Section 11.2. Specifically, the Gabor and wavelet transforms are outlined. Further, several wavelet families commonly used in vibration-related applications are presented. Estimation of time-dependent spectra of stochastic processes is considered in Section 11.3. Section 11.4 to Section 11.7 discuss applications of wavelet analysis in vibration-related applications. In particular, applications in random field simulation, system identification, damage detection, and material characterization are examined. Section 11.8 provides an overview and concluding remarks on the applicability and usefulness of the wavelet analysis in vibration theory. To enhance the usefulness of this chapter, a list of readily available references in the form of books and archival articles is provided.

11.1 Introduction

Wavelets-based representations offer an important option for capturing localized effects in many signals. This is achieved by employing representations *via* double integrals (continuous transforms), or *via* double series (discrete transforms). Seminal to these representations are the processes of *scaling* and *shifting* of a generating (*mother*) function. Over a period of several decades, wavelet analysis has been set on a rigorous mathematical framework and has been applied to quite diverse fields. Wavelet families associated with specific mother functions have proven quite appropriate for a variety of problems. In this context, fast decomposition and reconstruction algorithms ensure computational efficiency, and rival classical spectral analysis algorithms such as the fast Fourier transform (FFT). The field of vibration analysis has benefited from this remarkable mathematical development in conjunction with vibration monitoring, system identification, damage detection, and several other tasks. There is a voluminous body

of literature focusing on wavelet analysis. However, this chapter has the restricted objective of, on one hand, discussing concepts closely related to vibration analysis, and on the other hand, citing sources that can be readily available to a potential reader. In view of this latter objective, almost exclusively books and archival articles are included in the list of references. First, theoretical concepts are briefly presented; for more mathematical details, the reader may consult references [1–23]. Next, the theoretical concepts are supplemented by vibration-analysis-related sections on time-varying spectra estimation, random field synthesis, structural identification, damage detection, and material characterization. It is noted that most of the mathematical developments pertain to the interval $[0,1]$ relating to dimensionless independent variables derived by normalization with respect to the spatial or temporal “lengths” of the entire signals.

11.2 Time–Frequency Analysis

A convenient way to introduce the wavelet transform is through the concept of time–frequency representation of signals. In the classical Fourier theory, a signal can be represented either in the time or in the frequency domain, and the Fourier coefficients define the average spectral content over the entire duration of the signal. The Fourier representation is appropriate for signals that are stationary, in terms of parameters which are deemed important for the problem in hand, but becomes inadequate for nonstationary signals, in which important parameters may evolve rapidly in time.

The need for a time–frequency representation is obvious in a broad range of physical problems, such as acoustics, image processing, earthquake and wind engineering, and a plethora of others. Among the time–frequency representations available to date, the wavelet transform has unique features in terms of efficacy and versatility. In mathematical terms, it involves the concept of *scale* as a counterpart to the concept of frequency in the Fourier theory. Thus, it is also referred to as time-scale representation. Its formulation stems from a generalization of a previous time–frequency representation, known as the Gabor transform. For completeness, and to underscore the significant advantages achieved by the development of the wavelet transform, the Gabor transform is briefly discussed in Section 11.2.1. Section 11.2.2 is entirely devoted to the wavelet transform, and the most commonly used wavelet families are described in Section 11.2.3.

11.2.1 Gabor Transform

The first steps in time–frequency analysis trace back to the work of Gabor [24], who applied in signal analysis fundamental concepts developed in quantum mechanics by Wigner a decade earlier [25]. Given a function $f(t)$ belonging to the space of finite-energy one-dimensional functions, denoted by $L^2(\mathbb{R})$, Gabor introduced the transform

$$G_f(\omega, t_0) = \int_{-\infty}^{\infty} f(t) \overline{g(t - t_0)} e^{-i\omega(t - t_0)} dt \quad (11.1)$$

where $g(t)$ is a window and the bar ($\bar{}$) denotes complex conjugation. This transform, generally referred to as the *continuous Gabor transform* (CGT) or the short-time Fourier transform of $f(t)$, is a complete representation of $f(t)$. That is, the original function $f(t)$ can be reconstructed as

$$f(t) = \frac{1}{2\pi \|g\|^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} G_f(\omega, t_0) g(t - t_0) e^{i\omega(t - t_0)} d\omega dt_0 \quad (11.2)$$

where $\|g\|^2 = \int_{-\infty}^{\infty} |g(t)|^2 dt$. The Gabor transform (Equation 11.1) may be seen as the projection of $f(t)$ onto the family $\{g_{(\omega, t_0)}(t); \omega, t_0 \in \mathbb{R}\}$ of *shifted* and *modulated* copies (atoms) of $g(t)$ expressed in the form

$$g_{(\omega, t_0)}(t) = e^{i\omega(t - t_0)} g(t - t_0) \quad (11.3)$$

These time–frequency atoms, also referred to as Gabor functions, are shown in [Figure 11.1](#) for three different values of ω . Clearly, if $g(t)$ is an appropriate window function, then Equation 11.1 may be regarded as the standard Fourier transform of the function $f(t)$, localized at the time t_0 . In this context, t_0 is the

FIGURE 11.1 Plots of Gabor function $g(\omega, t_0)$ versus the independent variable x for three values of the frequency ω ; the effective support is the same for the three values of the frequency.

time parameter which gives the center of the window, and ω is the frequency parameter which is used to compute the Fourier transform of the windowed signal.

As intuition suggests, the accuracy of the CGT representation (Equation 11.2) of $f(t)$ depends on the window function $g(t)$, which must exhibit good localization properties both in the time and the frequency domains. As discussed in Ref. [6], a measure of the localization properties may be obtained by the average and the standard deviation of the density $|g(t)|^2$ in the time domain. That is,

$$\langle t \rangle = \int_{-\infty}^{\infty} t |g(t)|^2 dt \quad (11.4a)$$

$$\sigma_t^2 = \int_{-\infty}^{\infty} (t - \langle t \rangle)^2 |g(t)|^2 dt \quad (11.4b)$$

The counterparts of Equation 11.4a and Equation 11.4b in the frequency domain are

$$\langle \omega \rangle = \int_{-\infty}^{\infty} \omega |\hat{G}(\omega)|^2 d\omega \quad (11.5a)$$

$$\sigma_\omega^2 = \int_{-\infty}^{\infty} (\omega - \langle \omega \rangle)^2 |\hat{G}(\omega)|^2 d\omega \quad (11.5b)$$

where $\hat{G}(\omega)$ denotes the Fourier transform of $g(t)$ given by the equation

$$\hat{G}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} g(t) e^{-i\omega t} dt \quad (11.6)$$

The well-known *Heisenberg uncertainty principle* is in actuality a mathematically proven property and states that the values σ_t and σ_ω cannot be independently small [6]. Specifically, for an arbitrary window normalized so that $\|g\|^2 = 1$, it can be shown that

$$\sigma_t \sigma_\omega \geq \frac{1}{2} \quad (11.7)$$

Thus, high resolution in the time domain (small value of σ_t) may be generally achieved only at the expense of a poor resolution (bigger than a minimum value σ_ω) in the frequency domain and *vice versa*. Note that the optimal time–frequency resolution, that is $\sigma_t \sigma_\omega = 1/2$, may be attained when the Gaussian window

$$g(t) = \frac{1}{\sqrt{4\pi\sigma_t^2}} \exp\left(-\frac{t^2}{4\sigma_t^2}\right) \quad (11.8)$$

is selected.

Clearly, as a time–frequency representation, the Gabor transform exhibits considerable limitations. The time support, governed by the window function $g(t)$, is equal for all of the Gabor functions (Equation 11.3) for all frequencies (see Figure 11.1). In order to achieve good localization of high-frequency components, narrow windows are required; as a result of that, low-frequency components are poorly represented. Thus, a more flexible representation with nonconstant windowing is quite desirable,

to enhance the time resolution for short-lived high-frequency phenomena and frequency resolution for long-lasting low-frequency phenomena.

11.2.2 Wavelet Transform

The preceding shortcomings of the Gabor transform have been overcome with significant effectiveness and efficiency by wavelets-based signal representation. Its two formulations, continuous and discrete, are described in the ensuing sections. Because of the numerous applications of wavelets beyond time–frequency analysis, the t -time domain will be replaced by a generic x -space domain. For succinctness, the formulation will be developed for scalar functions only, but generalization for multidimensional spaces is well established in the literature [1–22].

11.2.2.1 Continuous Wavelet Transform

The concept of wavelet transform was introduced first by Goupillaud et al. for seismic records analysis [26,27]. In analogy to the Gabor transform, the idea consists of decomposing a function $f(x)$ into a two-parameter family of elementary functions, each derived from a basic or *mother wavelet*, $\psi(x)$. The first parameter, a , corresponds to a dilation or compression of the mother wavelet that is generally referred to as *scale*. The second parameter, b , determines a *shift* of the mother wavelet along the x -domain. In mathematical terms

$$W_f(a, b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} f(x) \overline{\psi\left(\frac{x-b}{a}\right)} dx \quad (11.9)$$

where $a \in \mathbb{R}^+$, $b \in \mathbb{R}$. In the literature, Equation 11.9 is generally referred to as *continuous wavelet transform* (CWT). Note that the factor $a^{-1/2}$ is a normalization factor, included to insure that the mother wavelet and any dilated wavelet $a^{-1/2}\psi(x/a)$ have the same total energy [26]. Clearly, alternative normalizations may also be chosen [1].

An example of wavelet functions is shown in Figure 11.2 for different values of the scale parameter a . As a result of scaling, all the wavelet functions exhibit the same number of cycles within the x -support of the mother wavelet. Obviously, the spatial and frequency localization properties of the wavelet transform depend on the value of the parameter a . As a approaches zero, the dilated wavelet $a^{-1/2}\psi(x/a)$ is highly concentrated at the point $x = 0$; the wavelet transform, $W_f(a, b)$, then gives increasingly sharper spatial resolution displaying the small-scale/higher-frequency features of the function $f(x)$, at various locations b . However, as a approaches $+\infty$, the wavelet transform $W_f(a, b)$ gives increasingly coarser spatial resolution, displaying the large-scale/low-frequency features of the function $f(x)$.

For the function $f(x)$ to be reconstructable from the set of coefficients (Equation 11.9), in the form

$$f(x) = \frac{1}{\pi c_\psi} \int_0^\infty \int_{-\infty}^\infty W_f(a, b) \psi_{a,b}(x) \frac{da}{a^2} db \quad (11.10)$$

FIGURE 11.2 Plots versus time of wavelet functions corresponding to three different values of a scale a of the same mother function; the effective time support increases with the magnitude of the scale.

where $\psi_{a,b}(x) = a^{-1/2}\psi[(x-b)/a]$, the wavelet function $\psi(\cdot)$ must satisfy the admissibility condition

$$c_\psi = \int_{-\infty}^{\infty} \frac{|\hat{\Psi}(\omega)|^2}{|\omega|} d\omega < \infty \quad (11.11)$$

where $\hat{\Psi}(\omega)$ denotes the Fourier transform of $\psi(x)$. As pointed out in Ref. [26], the condition 11.11 includes a set of subconditions, such as:

1. The analyzing wavelet $\psi(\cdot)$ is absolutely integrable and square integrable. That is,

$$\int_{-\infty}^{\infty} |\psi(x)| dx < \infty \quad (11.12a)$$

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx < \infty \quad (11.12b)$$

2. The Fourier transform $\hat{\Psi}(\omega)$ must be sufficiently small at the vicinity of the origin $\omega = 0$, or in mathematical terms

$$\int_{-\infty}^{\infty} \frac{|\hat{\Psi}(\omega)|}{|\omega|} d\omega < \infty \quad (11.13)$$

Subcondition 2, then, implies that $\hat{\Psi}(0) = 0$; that is, $\int_{-\infty}^{\infty} \psi(x) dx = 0$. Therefore, for an analyzing wavelet to be admissible, its real and imaginary parts must both be symmetric with respect to the x -axis.

From the reconstruction formula (Equation 11.10), it can be shown that

$$\|f\|^2 = \frac{1}{\pi c_\psi} \int_0^\infty \int_{-\infty}^\infty |W_f(a, b)|^2 \frac{da}{a^2} db \quad (11.14)$$

Based on Equation 11.14, the square modulus of the wavelet transform (Equation 11.9) is often taken as an energy density in a spatial-scale domain. Extensive use of this concept has been made for spectra estimation purposes, as discussed in Section 11.3.

Note that the reconstruction wavelet in Equation 11.10 can be different from the analyzing wavelet used in Equation 11.9. That is, under some admissibility conditions on $\chi(x)$ [1], the original function $f(x)$ may be reconstructed as

$$f(x) = \frac{1}{c_{\psi\chi}} \int_0^\infty \int_{-\infty}^\infty W_f(a, b) \chi_{a,b}(x) \frac{da}{a^2} db \quad (11.15)$$

where $\chi_{a,b}(x) = a^{-1/2}\chi[(x-b)/a]$ and $c_{\psi\chi}$ is a constant parameter depending on the Fourier transforms of both $\psi(x)$ and $\chi(x)$. This property, referred to as redundancy in mathematical terms, may be advantageous in some applications for reducing the error due to noise in signal reconstruction [28,29], but highly undesirable for signal coding or compression purposes [1]. Further, under certain conditions [1], the following simplified reconstruction formula holds

$$f(x) = \frac{1}{k_\psi} \int_0^\infty W_f(a, x) \frac{da}{a^{3/2}} \quad (11.16)$$

where k_ψ is a constant parameter given by the equation

$$k_\psi = \sqrt{2\pi} \int_0^\infty \frac{\hat{\Psi}(\omega)}{\omega} d\omega \quad (11.17)$$

Use of this formula has been made, in a discrete version, in the approximation theory of functional spaces [1] and also in structural identification applications, as discussed in Section 11.5.

11.2.2.2 Discrete Wavelet Transform

For numerical applications, where fast decomposition or reconstruction algorithms are generally required, a discrete version of the CWT is to prefer. In this sense, a natural way to define a *discrete wavelet transform* (DWT) is

$$W_f(j, k) = \frac{1}{\sqrt{a_0^j}} \int_{-\infty}^{\infty} f(x) \overline{\psi(a_0^{-j}x - kb_0)} dx, \quad j, k \in \mathbb{Z} \quad (11.18)$$

Equation 11.18 is derived from a straightforward discretization of the CWT (Equation 11.9) by considering the discrete lattice $a = a_0^j$, $a_0 > 1$, $b = kb_0a_0^j$, $b_0 \neq 0$. In developing Equation 11.18, however, the main mathematical concern is to ensure that *sampling* the CWT on a discrete set of points does not lead to a loss of information about the wavelet-transformed function $f(x)$. Specifically, the original function $f(x)$ must be fully recoverable from a discrete set of wavelet coefficients. That is,

$$f(x) = \sum_{j,k \in \mathbb{Z}} W_f(j, k) \psi_{j,k}(x) \quad (11.19)$$

where $\psi_{j,k}(x) = a_0^{-j/2} \psi(a_0^{-j}x - kb_0)$. Another crucial aspect in Equation 11.18 involves selecting the wavelet functions $\psi_{j,k}(x)$ such that Equation 11.19 may be regarded as the expansion of $f(x)$ in a *basis*, thus eliminating the redundancy of the CWT.

This issues are addressed by using the theory of Hilbert space *frames*, introduced in 1952 by Duffin and Schaeffer in context with non-harmonic Fourier series [30]. In general, if $h_\lambda(x) \in L^2(\mathbb{R})$ and Λ is a countable set, a family of functions $\{h_\lambda(x); \lambda \in \Lambda\}$ constitutes a *frame*, if for any $f(x) \in L^2(\mathbb{R})$

$$A\|f\|^2 \leq \sum_{\lambda \in \Lambda} |\langle f, h_\lambda \rangle|^2 \leq B\|f\|^2 \quad (11.20)$$

where $\langle f, h_\lambda \rangle = \int_{-\infty}^{\infty} f(x) \overline{h_\lambda(x)} dx$ and $A > 0$, $B < \infty$, the so-called *frame bounds*, are independent of $f(x)$ [1]. The concept of frame may be interpreted as an extension of the concept of basis, in the sense that the reconstruction of the original function is possible *via* stable numerical expressions in terms of the set $\{h_\lambda(x); \lambda \in \Lambda\}$. For instance, if the frame is *tight*, that is $A = B$, the simple formula

$$f(x) = \sum_{\lambda \in \Lambda} \langle f, h_\lambda \rangle h_\lambda(x) \quad (11.21)$$

holds [29].

In contrast to a basis, however, the vectors of a frame may be linearly dependent and, for this, a certain degree of redundancy is still retained in the reconstruction formula (Equation 11.21) [29,31].

The concept of frame has played a crucial role in the formulation of the DWT. The first wavelet frames were constructed by Daubechies et al. [32]. Later, Battle [33] constructed orthonormal bases with an exponential decay. The ensemble of these results has demonstrated the advantages of the wavelet transform over the Gabor transform. In fact, it has been shown that discrete versions of Gabor transform are not capable of generating orthonormal bases [32] due to the so-called Balian–Low phenomenon [1].

Mallat [34] has shown that the orthonormal wavelet bases proposed by Battle can all be derived by a *multiresolution analysis*. The latter involves representing an arbitrary $f(x) \in L^2(\mathbb{R})$ as a limit of successive approximations, at different resolutions. That is, if $\{V_j\}_{j \in \mathbb{Z}}$ is a sequence of subspaces of $L^2(\mathbb{R})$, and f_j is the orthogonal projection of $f(x)$ on V_j , in a multiresolution analysis the following conditions hold

$$\lim_{j \rightarrow -\infty} f_j = f \quad (11.22a)$$

$$\lim_{j \rightarrow \infty} f_j = 0 \quad (11.22b)$$

Each approximation f_j , then, represents a smoothed version of $f(x)$ and, in the limit, more and more localized smoothing functions lead to the function $f(x)$. From a mathematical point of view [29,31], a

multiresolution analysis requires that

1. The subspaces V_j 's are closed and embedded, that is

$$\cdots \subset V_2 \subset V_1 \subset V_0 \subset V_{-1} \subset V_{-2} \subset \cdots \quad (11.23)$$

where $V_{-m} \rightarrow L^2(\mathbb{R})$ for $m \rightarrow \infty$ and $f \in V_m \Leftrightarrow f(2 \cdot) \in V_{m-1}$.

2. A scaling function $\phi(x) \in L^2(\mathbb{R})$ exists, such that, for each j , the family of functions

$$\phi_{j,k}(x) = 2^{-j/2} \phi(2^{-j}x - k), \quad k \in \mathbb{Z} \quad (11.24)$$

spans the subspace V_j and constitutes a Riesz basis for V_j , that is, there exists $0 < C' \leq C'' < \infty$ such that

$$C' \sum_k |c_k|^2 \leq \int_{-\infty}^{\infty} \left| \sum_k c_k \phi_{j,k}(x) \right|^2 dx \leq C'' \sum_k |c_k|^2 \quad (11.25)$$

for all sequences of numbers $(c_k)_{k \in \mathbb{Z}}$. Equation 11.25 is a more stringent condition of Equation 11.20 and includes the latter as a special case.

The concept of multiresolution analysis offers a straightforward and mathematically coherent approach to discrete wavelet analysis. Given a scaling function $\phi(x)$ as in 2, in fact, families of orthonormal wavelet bases

$$\psi_{j,k}(x) = 2^{-j/2} \psi(2^{-j}x - k), \quad j, k \in \mathbb{Z} \quad (11.26)$$

can be developed by appropriate algorithms. For this, Mallat has used the frequency response of a high-pass filter [35], while Daubechies has devised a systematic approach to build orthonormal wavelet bases with compact support in the x -domain [36]. Specifically, for each even integer $2M$, the Daubechies scaling function $\phi(x)$ can be computed as

$$\phi(x) = \sqrt{2} \sum_{k=0}^{2M-1} h_{k+1} \phi(2x - k) \quad (11.27)$$

where h_k 's are $2M$ coefficients obtained by imposing M orthogonality conditions and M accuracy conditions to enhance the rate of convergence of the approximation to the original function $f(x)$. In turn, the mother wavelet is related to the scaling function $\phi(x)$ by the equation

$$\psi(x) = \sqrt{2} \sum_{k=0}^{2M-1} g_{k+1} \phi(2x - k) \quad (11.28)$$

where g_k 's are the same as h_k 's but reversed in order and with alternate signs. Numerical values of both series h_k 's and g_k 's are readily available in the literature [16].

Also based on multiresolution analysis concepts, a wavelet decomposition algorithm for image analysis has been developed [34,35]. If associated to Daubechies wavelets, the algorithm becomes quite efficient from a computational point of view, since no numerical integration is involved to compute wavelet and scale coefficients. It relies on the projection of $f(x)$ onto a sufficiently fine scale j of the set 11.24. That is,

$$f(x) \approx f_j(x) = \sum_k c_k^j \phi_{j,k}(x) \quad (11.29)$$

where, for orthogonal wavelets,

$$c_k^j = \int_{-\infty}^{\infty} f(x) \phi_{j,k}(x) dx \quad (11.30)$$

Based on Equation 11.22a and Equation 11.22b, the projection $f_j(x)$ can be rewritten in terms of the projection $f_{j+1}(x)$ onto the coarser scale $(j+1)$ and the incremental *detail* $\delta_{j+1}(x)$, that is the pieces of

information contained in the subspace V_j and lost when “moving” to the subspace V_{j+1} . Therefore,

$$f_j(x) = f_{j+1}(x) + \delta_{j+1}(x) = f_{j+1}(x) + \delta_{j+1}(x) + \cdots + \delta_{j+1}(x) \approx \delta_{j+1}(x) + \cdots + \delta_{j+1}(x) \quad (11.31)$$

As a fundamental result of multiresolution analysis, the details $\delta_j(x)$ can be decomposed in terms of the set of wavelet functions at the same scale. That is,

$$\delta_j(x) = \sum_k d_k^j \psi_{j,k}(x) \quad (11.32)$$

where d_k^j 's are the wavelet coefficients of $f(x)$. Based on Equation 11.28, both wavelet and scale coefficients can be computed recursively by the closed-form expressions

$$c_k^j = \sum_{l=0}^{2M-1} h_{l+1} c_{2k+l-1}^{j-1} \quad (11.33a)$$

$$d_k^j = \sum_{l=0}^{2M-1} g_{l+1} c_{2k+l-1}^{j-1} \quad (11.33b)$$

Similarly, the reconstruction algorithm can be implemented by the formula

$$c_k^{j-1} = \sum_l h_{k-2l+2} c_l^j + g_{k-2l+2} d_l^j \quad (11.34)$$

The reconstruction algorithm described by Equation 11.34 lends itself to interpretation as a scale linear system [37,38]. Based on this concept, applications have also been developed for random field simulation [39].

11.2.3 Wavelet Families

A great number of wavelet families with various properties are available. Selecting an optimal family for a specific problem is not, in general, an easy task and there are properties that prove more important to certain fields of application. For instance, symmetry may be of great help for preventing dephasing in image processing, while regularity is critical for building smooth reconstructed signals or accurate nonlinear regression estimates. Compactly supported wavelets, either in the time or in the frequency domain, may be preferable for enhanced time or frequency resolution. The number of vanishing moments, M , that is the highest integer m for which the equation

$$\int_{-\infty}^{\infty} x^m \psi(x) dx = 0, \quad m = 0, 1, \dots, M-1 \quad (11.35)$$

holds is important in signal processing for compression, or in damage detection for enhancement of singularities in the vibration modes. Also, in some cases, wavelets may be required to be *progressive*. In mathematical terms, this means that their Fourier transform is defined only for positive frequencies. That is,

$$\hat{\Psi}(\omega) = 0, \quad \text{for } \omega < 0 \quad (11.36)$$

The progressive wavelet transform of a real-valued signal $f(t)$ and the associated *analytic signal*

$$z_f(t) = f(t) + iH[f(t)] \quad (11.37)$$

are related by the equation

$$W_f(a, b) = \frac{1}{2} W_{z_f}(a, b) \quad (11.38)$$

where $H[\cdot]$ denotes the Hilbert transform operator [40]. Equation 11.38 is quite useful for structural identification. Note also that significant reduction of computational costs is generally achieved if orthogonal wavelets in the frequency or in the x -domain are used.

A brief description of the most-used families is given below. A distinction is made between real and complex wavelets, and the most relevant properties for application purposes are discussed. A more exhaustive review may be found in Ref. [15].

11.2.3.1 Real Wavelets

1. *Daubechies orthonormal wavelets* — A family of bases, each corresponding to a particular value of the parameter M in Equation 11.27 and Equation 11.28 [36]. Closed-form expressions for $\phi(x)$ in Equation 11.27 are available only for $M = 1$, to which the well-known Haar basis corresponds. In this case, the scaling function and the mother wavelet are

$$\phi(x) = \begin{cases} 1, & 0 \leq x < 1, \\ 0, & \text{elsewhere,} \end{cases} \quad \psi(x) = \begin{cases} 1, & 0 \leq x < \frac{1}{2}, \\ -1, & \frac{1}{2} \leq x < 1, \\ 0, & \text{elsewhere.} \end{cases} \quad (11.39)$$

Various algorithms, however, are available in the literature for determining $\phi(x)$ and $\psi(x)$ numerically for $M > 1$.

Daubechies wavelets support both CWT and DWT, although the latter is most generally performed due to the fast decomposition and reconstruction algorithm mentioned in Section 11.2.2.2. Both $\phi(x)$ and $\psi(x)$ are compactly supported in the x -domain, and the support is equal to the segment $[0; 2M - 1]$. Also, M is equal to the number of vanishing moments of the wavelet function. Note that most Daubechies wavelets are not symmetric; regularity and harmonic-like shape increases with M .

2. *Meyer wavelets* — Families of wavelets [10], each defined for a particular choice of an auxiliary function $v(\omega)$ which appears in the following expression for the Fourier transform of the mother wavelet:

$$\hat{\Psi}(\omega) = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{i\omega/2} \sin\left[\frac{\pi}{2} v\left(\frac{3}{2\pi}|\omega| - 1\right)\right], & \frac{2}{3}\pi \leq |\omega| \leq \frac{4}{3}\pi, \\ \frac{1}{\sqrt{2\pi}} e^{i\omega/2} \cos\left[\frac{\pi}{2} v\left(\frac{3}{4\pi}|\omega| - 1\right)\right], & \frac{4}{3}\pi \leq |\omega| \leq \frac{8}{3}\pi, \\ 0, & |\omega| \notin \left[\frac{2}{3}\pi, \frac{8}{3}\pi\right], \end{cases} \quad (11.40)$$

for $v(\omega)$ to be an admissible auxiliary function it is required that

$$v(\omega) = \begin{cases} 0, & \omega \leq 0, \\ 1, & \omega \geq 1, \end{cases} \quad (11.41a)$$

$$v(\omega) + v(1 - \omega) = 1, \quad 0 \leq \omega \leq 1 \quad (11.41b)$$

The most common form of $v(\omega)$ in the literature is

$$v(\omega) = \omega^4(35 - 84\omega + 70\omega^2 - 20\omega^3), \quad 0 \leq \omega \leq 1 \quad (11.42)$$

The mother wavelet, for which only numerical expressions are available, is then constructed by inverse Fourier-transforming Equation 11.40.

Meyer wavelets are suitable for both CWT and DWT. Unlike Daubechies wavelets, they are compact in the frequency domain but not in the x -domain. Because of their fast decay, however, an effective x -support $[-8, 8]$ is generally assumed. Appealing features of Meyer wavelets are orthogonality, infinite regularity, and symmetry.

3. *Mexican Hat wavelets* — A family of wavelets in the x -domain [15] related to a mother function that is proportional to the second derivative of the Gaussian probability density function.

That is,

$$\psi(x) = \frac{2}{\sqrt{3}} \pi^{-1/4} (1 - x^2) e^{-x^2/2} \quad (11.43)$$

The Mexican Hat wavelets allow CWT only. Unlike Daubechies or Meyer wavelets, Mexican Hat wavelets are not compact both in the frequency and in the x -domain, although an effective support $[-5, 5]$ may be considered for practical calculations. They are infinitely regular and symmetric.

4. *Biorthogonal wavelets* — Families of wavelets derived by generalizing the ordinary concept of wavelet bases, and creating a pair of *dual wavelets*, say $(\psi(x), \tilde{\psi}(x))$, satisfying the following properties [41,42]:

$$\int_{-\infty}^{\infty} \psi_{j,k}(x) \tilde{\psi}_{j',k'}(x) dx = \delta_{jj'} \delta_{kk'} \quad (11.44)$$

where the symbol δ_{mn} denotes the Kronecker delta. One wavelet, say $\psi(x)$, may be used for reconstruction and the dual one, $\tilde{\psi}(x)$, for decomposition. Therefore, Equation 11.18 and Equation 11.19 can be rewritten as

$$W_f(j, k) = 2^{-j/2} \int_{-\infty}^{\infty} f(x) \psi_{j,k}(2^{-j}x - k) dx, \quad j, k \in \mathbb{Z} \quad (11.45)$$

$$f(x) = \sum_{j,k \in \mathbb{Z}} W_f(j, k) \tilde{\psi}_{j,k}(x) \quad (11.46)$$

Biorthogonal wavelets support both CWT and DWT. The properties of a biorthogonal basis are specified in terms of a pair of integers (N_d, N_r) . These integers, in analogy with the Daubechies wavelets, govern the regularity and the number of vanishing moments N_d of the decomposition wavelet $\psi(x)$, and the regularity and the number of vanishing moments N_r of the reconstruction wavelet $\tilde{\psi}(x)$. Obviously, this feature allows a greater number of choices for signal decomposition and reconstruction. Both wavelet functions $\psi(x)$ and $\tilde{\psi}(x)$ are symmetric.

11.2.3.2 Complex Wavelets

5. *Harmonic wavelets* — A Family of bases defined in the frequency domain by the formula [16,43,44]:

$$\hat{\Psi}_{m,n}(\omega) = \begin{cases} \frac{1}{2\pi(n-m)}, & m\pi \leq \omega \leq n\pi, \\ 0, & \text{elsewhere,} \end{cases} \quad (11.47)$$

where m and n are positive numbers but not necessarily integers. The pair of values m, n is referred to as *level* m, n and represents, for harmonic wavelets, the scale index j . A harmonic wavelet basis thus corresponds to a complete set of adjacent levels m, n , spanning all the positive frequency axis. By inverse-Fourier transforming Equation 11.47, the corresponding wavelet functions at a generic step k on the x -domain take the complex form:

$$\psi_{m,n,k}(x) = \frac{\exp\left[in2\pi\left(x - \frac{k}{n-m}\right)\right] - \exp\left[im2\pi\left(x - \frac{k}{n-m}\right)\right]}{i2\pi(n-m)\left(x - \frac{k}{n-m}\right)} \quad (11.48)$$

A common choice for the pairs m, n is $m, n = 0, 1, 2, 4, \dots; 2^j, 2^{j+1}, \dots$. In this case, all the wavelets have octave bands, except for the first one.

Harmonic wavelets have been devised in context with a DWT, for which extremely fast decomposition and reconstruction algorithms exist. They exhibit a compact support in the frequency domain (see Equation 11.47), while in the x -domain their rate of decay away from

the wavelet's center is relatively low and proportional to x^{-1} . Further, they satisfy relevant orthogonality properties [16].

From Equation 11.48, it is seen that the real part of the wavelet is even, while the imaginary part is odd. For signal processing, this ensures that harmonic components in a signal can be detected regardless of the phase. Note that this feature cannot be achieved by real wavelets such as the Meyer wavelets, which are all self-similar, being derived from a unique mother wavelet by scaling and shifting. Also, note that orthonormal basis of real wavelets can be generated by considering either the real or the imaginary parts only of Equation 11.48. For instance, the well-known Shannon wavelets correspond to the imaginary parts of Equation 11.48, for $m, n = 1, 2; 2, 4; 4, 8; \dots$. Harmonic wavelets are used in many mechanics applications such as acoustics, vibration monitoring, and damage detection [45–49].

6. *Complex Gaussian wavelets* — Families of wavelets, each corresponding to a p th order derivative of a complex Gaussian function. That is,

$$\psi_p(x) = C_p \frac{d^p}{dx^p} (e^{-ix} e^{-x^2/2}), \quad p = 1, 2, \dots \quad (11.49)$$

where C_p is a normalization constant such that $\|\psi(x)\|^2 = 1$. Complex Gaussian wavelets support the CWT only. They have no finite support in the x -domain, although the interval $[-5, 5]$ is generally taken as effective support. Despite their lack of orthogonality, they are quite popular in image-processing applications due to their regularity [1].

7. *Complex Morlet wavelets* — Families of [50], each obtained as the derivative of the classical Morlet wavelet $\psi_0(x) = e^{-x^2/2} e^{i\omega_0 x}$. That is,

$$\psi_p(x) = \frac{d^p}{dx^p} (e^{-x^2/2} e^{i\omega_0 x}), \quad p = 1, 2, \dots \quad (11.50)$$

Except for $\psi_0(x)$, which does not satisfy the admissibility condition (Equation 11.11) in a strict sense, all the other members of the family are proper wavelets. For practical purposes, however, $\psi_0(x)$ is generally considered admissible for $\omega_0 \geq 5$. Complex Morlet wavelets support the CWT only and are not orthogonal. However, they are all progressive, that is, they satisfy the condition posed by Equation 11.36. Further, for the Morlet wavelet $\psi_0(x)$, there exists a relation between the scale parameter a and the frequency ω at which its Fourier transform focuses. That is,

$$a = \frac{\omega_0}{\omega} \quad (11.51)$$

Complex Morlet wavelets are then applied for structural identification purposes, as shown in Section 11.5.

11.3 Time-Dependent Spectra Estimation of Stochastic Processes

Wavelets-based approaches are significant tools for joint time–frequency analysis of problems related to vibrations of mechanical and structural systems. This applies both to the characterization of the system excitation, the system identification, and the system response determination. Several examples exist in nature of stochastic phenomena with a time-dependent frequency content. The frequency content of earthquake records, for instance, evolves in time due to the dispersion of the propagating seismic waves [51,52]. Further, sudden changes in the wave frequency at a given location of the sea surface are often induced by fast-moving meteorological fronts [53]. Also, a rapid change in the frequency content is generally associated with waves at the breaking stage. Similarly, turbulent gusts of time-varying frequency content are often embedded in wind fields.

Appropriate description of such phenomena is obviously crucial for design and reliability assessments. In an early attempt, concepts of traditional Fourier spectral theory were generalized to provide spectral estimates, such as the Wigner–Ville method [25,54] or the CGT of Equation 11.1. However, it soon

became clear that the extension of the traditional concept of a spectrum is not unique, and proposed time-varying spectra could have contradictory properties [6,55].

Wavelet analysis is readily applicable for estimating time-varying spectral properties, and a significant effort has been devoted to formulating “wavelet energy principles” that work as alternatives to classical Fourier methods. Measures of a time-varying frequency content were first obtained by “sectioning,” at different time instants, the wavelet coefficients mean square map [49,56–58]. Developing consistent spectral estimates from such sections, however, is not straightforward. From a theoretical point of view, it either requires an appropriate wavelet-based definition of time-varying spectra, or it must relate to well-established notions of time-varying spectra. From a numerical point of view, it involves certain difficulties in converting the scale axis to a frequency axis, especially when the wavelet functions are not orthogonal in the frequency domain; that is, when the frequency content of wavelet functions at adjacent scales do overlap.

Early investigations on wavelet-based spectral estimates may be found in references such as [44,59–64], where wavelet analysis was applied in the context of earthquake engineering problems. In a particular approach, a modified Littlewood Paley (MLP) wavelet basis can be introduced, whose mother wavelet is defined in the frequency domain by the equation

$$\hat{\psi}(\omega) = \begin{cases} \frac{1}{\sqrt{2(\sigma-1)\pi}}, & \pi \leq |\omega| \leq \sigma\pi, \\ 0, & \text{elsewhere} \end{cases} \quad (11.52)$$

In Equation 11.52, the symbol σ denotes a scalar factor, to be adjusted depending on the desired frequency resolution. The MLP wavelets are orthogonal in the frequency domain, that is, wavelets at adjacent scales span nonoverlapping intervals. The MLP wavelets have been used in conjunction with a discretized version of the CWT proposed by Alkemade [65] for a finite-energy process $f(t)$

$$f(t) = \sum_{i,j} \frac{K\Delta b}{a_j} W_f(a_j, b_i) \psi_{a_j, b_i}(t) \quad (11.53)$$

where $a_j = \sigma^j$, Δb is a time step, and K is a constant parameter depending on σ .

In many instances, Equation 11.53 can be construed as representing realizations of a *stochastic process*, and in this case, the following estimate of its instantaneous mean-square value of $f(t)$ has been constructed

$$E[f^2(t)]|_{t=b_i} = K \sum_j \frac{E[W_f(a_j, b_i)]^2}{a_j} \quad (11.54)$$

where $E[\cdot]$ is the mathematical expectation operator over the ensemble of realizations. From Equation 11.54, and based on the orthogonality properties of the MLP wavelets, the following quantity

$$S_f(\omega)|_{t=b_i} = \sum_j K \frac{E[W_f(a_j, b_i)]^2}{a_j} |\hat{\psi}_{a_j, b_i}(\omega)|^2 \quad (11.55)$$

where the symbol $\hat{\psi}_{a_j, b_i}(\omega)$ denotes the Fourier transform of the wavelet function $\psi_{a_j, b_i}(t)$, can be taken as a measure of the time-varying power spectral density (PSD) of the process $f(t)$. Based on Equation 11.55, closed-form expressions can be derived between the input and the output PSDs [63]. In this context, linear-response statistics, such as the instantaneous rate of crossings of the zero level or the instantaneous rate of occurrence of the peaks, have been estimated with considerable accuracy. Analysis of nonlinear systems has also been attempted by an equivalent statistical linearization procedure [61,66].

Wavelet analysis for spectral estimation has also been pursued by Kareem et al., who have used the squared wavelet coefficients of a DWT to estimate the PSD of stationary processes [56]. To improve the frequency resolution of the DWT, where only adjacent octave bands can be accounted for, a CWT can be implemented based on a complex Morlet wavelet basis. The latter is preferable due to the one-to-one

correspondence between the scale a and the center frequency (Equation 11.51), which allows minimizing the overlap between spectral estimates at adjacent scales. Further, the product of wavelet coefficients can be used as a measure of the cross-correlation between two nonstationary signals $x(t)$ and $y(t)$ [56]. This concept can be refined by the introduction of a wavelet *coherence* measure [57,58] expressed by the equation

$$(c^W(a, b))^2 = \frac{|S_{xy}^W(a, b)|^2}{S_{xx}^W(a, b)S_{yy}^W(a, b)} \quad (11.56)$$

In this equation, the local spectrum $S_{ij}^W(a, b)$ is defined as

$$S_{ij}^W(a, b) = \int_T \overline{W_i}(a, b) W_j(a, b) d\tau \quad (11.57)$$

where the time integration window T depends on the desired time resolution. The local spectrum (Equation 11.57), owing to the time average over T , allows smoothing of potential measurement noise effects. Measures of higher-order correlation can also be introduced [56,58], such as the wavelet *bicoherence*

$$(b_{xxy}^W(a_1, a_2, b))^2 = \frac{|B_{xxy}^W(a_1, a_2, b)|^2}{\int_T |W_x(a_1, \tau) W_x(a_2, \tau)|^2 d\tau \int_T |W_y(\tilde{a}, \tau)|^2 d\tau} \quad (11.58)$$

where $1/\tilde{a} = 1/a_1 + 1/a_2$, and

$$B_{xxy}^W(a_1, a_2, b) = \int_T W_x(a_1, \tau) W_x(a_2, \tau) W_y(\tilde{a}, \tau) d\tau \quad (11.59)$$

Related remedies can be adopted to suppress spurious correlations induced by statistical noise, based on a reference noise map created from artificially simulated signals [58].

Signal energy representation concepts have been examined in Ref. [67] by using quasi-orthogonal Daubechies wavelets in the frequency domain to simulate earthquake ground motion accelerations. Further, Massel has used wavelet analysis to capture time-varying frequency composition of sea-surface records due to fast-moving atmospheric fronts in deep water, wave growth, and breaking or disintegration of mechanically generated wave trains [68]. In this regard, absolute value wavelet maps and a spectral measure called global wavelet energy spectrum, defined by the equation

$$E_3(a) = \int_0^\infty E_1(a, b) db \quad (11.60)$$

are used. The symbol $E_1(\tau, b)$ denotes a time-scale energy density

$$E_1(a, b) = \frac{|W_f(a, b)|^2}{a} \quad (11.61)$$

The scale in Equation 11.61 is readily translated into frequency by selecting the Morlet wavelet basis.

Spanos and Failla [69] have applied wavelet analysis to estimate the evolutionary power spectral density (EPSD) of nonstationary oscillatory processes defined as [70]

$$f(t) = \int_{-\infty}^\infty A(\omega, t) e^{i\omega t} dZ(\omega) \quad (11.62)$$

The symbol $A(\omega, t)$ denotes a slowly varying time- and frequency-dependent modulating function, and $Z(\omega)$ is a complex random process with orthogonal increments such that $E[|dZ(\omega)|^2] = S_{f_0f_0}(\omega) d\omega$, where $S_{f_0f_0}(\omega)$ is the two-sided PSD of the zero-mean stationary process

$$f_0(t) = \int_{-\infty}^\infty e^{i\omega t} dZ(\omega) \quad (11.63)$$

The two-sided EPSD of $f(t)$ is then taken as

$$S_{ff}(\omega, t) = |A(\omega, t)|^2 S_{f_0 f_0}(\omega) \quad (11.64)$$

Due to its localization properties, the wavelet transform of $f(t)$ (Equation 11.62) may be approximated as an oscillatory stochastic process. That is,

$$W_f(a, b) \approx \int_{-\infty}^{\infty} A(\omega, b) e^{i\omega b} dZ'(\omega) \quad (11.65)$$

where $dZ'(\omega) = \sqrt{2\pi a} \bar{\Psi}(\omega a) dZ(\omega)$. Based on Equation 11.65, the following integral relation is found between the mean-squared wavelet coefficients at each scale a and the EPSD of $f(t)$. That is,

$$E[W_f(a, b)^2] = 4\pi a \int_0^{\infty} |\hat{\Psi}(\omega a)|^2 S_{ff}(\omega, b) d\omega \quad (11.66)$$

A sufficient number of Equations 11.66, one for each scale a , can be solved by a standard solution algorithm, applicable for both orthogonal and nonorthogonal bases in the frequency domain. This procedure has proved quite accurate using both the Littlewood–Paley and the real Morlet wavelet bases.

11.4 Random Field Simulation

The use of wavelets for random field synthesis can be examined within the more general framework of scale-type methods. The latter have been developed to improve the computational performances of Monte Carlo simulations. Classical methods such as the spectral approach [71] or the autoregressive moving average (ARMA) [72] are not readily applicable for this purpose, especially when using nonuniform meshes or when enhancement of local resolution is desirable. To address these shortcomings, Fournier et al. [73] have proposed a “random midpoint method” to synthesize fractional Brownian motion; that is, a scale-type method where values of the random field for points within a coarser scale are generated first, and then the generated samples are used to determine values for a finer scale. This approach has been extended by Lewis [74] into a “generalized stochastic subdivision method,” suitable for a broad class of stationary processes, and by Fenton and Vanmarcke [75] into a “local average subdivision method,” which includes a random field smoothing procedure producing averages of the field for an increasingly finer scale.

An interpretation of scale-type approaches in the context of random field synthesis has been given by Zeldin and Spanos [39] using compactly supported Daubechies wavelets. Specifically, a synthesis algorithm has been developed that includes the previous methods proposed by Lewis [74] and Fenton and Vanmarcke [75] as a particular case. To synthesize a sample of a given process, the closed-form expressions

$$r_{k,l}^{j,i} = E[d_k^j d_l^i] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_f(x_1, x_2) \psi_{j,k}(x_1) \psi_{i,l}(x_2) dx_1 dx_2 \quad (11.67)$$

$$b_{k,l}^{j,i} = E[c_k^j c_l^i] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_f(x_1, x_2) \phi_{j,k}(x_1) \psi_{i,l}(x_2) dx_1 dx_2 \quad (11.68)$$

$$a_{k,l}^{j,i} = E[c_k^j c_l^i] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_f(x_1, x_2) \phi_{j,k}(x_1) \phi_{i,l}(x_2) dx_1 dx_2 \quad (11.69)$$

given in Refs. [21,39] are considered to relate the autocorrelation function $R_f(x_1, x_2)$ of the process to the coefficients of its wavelet transform, which in this case are random variables. The synthesis algorithm is based on the wavelet reconstruction algorithm developed by Mallat [34,35], which proceeds from coarse to fine scales to determine the wavelet coefficients. Some relevant properties of wavelet ensure the computational efficiency of the algorithm. Specifically, using the quasi-differential properties of wavelets showed by Belkin [76], the coefficients d_k^j 's are derived directly from c_k^j 's by the approximate

linear combination

$$d_k^j = \sum_l \alpha_{k,l}^j c_l^j + \beta_k^j u_k \quad (11.70)$$

where u_k 's are uncorrelated, zero mean, unit variance random variables, statistically independent of c_k^j 's. For a wide class of stochastic processes, wavelet coefficients prove weakly correlated as the difference $k - l$ increases and, for this, the summation in Equation 11.70 is generally restricted to adjacent elements only. The algorithm is completed by an error-assessment procedure which allows refining of the triggering scale j in order to fit the sought target statistical properties of the synthesized field.

Further studies on the role of wavelet analysis in stochastic mechanics applications may be found in Ref. [21], which has showed how wavelet bases can be used in approximate Karhunen–Loève expansions. Any stationary process can then be represented as

$$f(t) = \sum_{j,k} d_k^j \psi_{j,k}(t) \quad (11.71)$$

where d_k^j 's are uncorrelated random variables and $\psi_{j,k}(t)$ are a nonorthogonal wavelet-like basis.

11.5 System Identification

Wavelet analysis lends itself to system-identification applications. For instance, frequency localization properties allow detection and decoupling of individual vibration modes of multi-degree-of-freedom (multi-DoF) linear systems. The wavelet representation of the system response can be truncated to an appropriate scale parameter in order to filter measurement noise. Also, the wavelet transform coefficients can be related directly to the system parameters, as long as specific bases are used.

Early investigations trace back to the work by Robertson et al. [77], who have used the DWT for the estimation of the impulse-response function of multi-DoF systems. Compared with alternative time-domain techniques, the DWT-based extraction procedure offers significant advantages. It is robust since singularities in the procedure-related matrices can generally be avoided by selecting orthonormal wavelet functions. Further, the reconstructed impulse-response function captures the low-frequency components, referred to as static modes and mode shape errors, which ordinarily are difficult to estimate.

An important application of wavelet analysis to structural identification is due to Staszewski [78], who has used complex Morlet wavelets for modal damping estimation. Specifically, Staszewski has interpreted in terms of the wavelet transform some concepts already used in well-established methods, where the Hilbert transform has been applied to a free-vibration linear response [79]. In the case of light damping, the free response in each mode $x_j(t)$ may be approximated in the complex plane by an analytical signal, given by Equation 11.37. The modulus of the Morlet wavelet transform of $x_j(t)$ can be expressed as

$$|W_{x_j}(a, b)| \approx A_j e^{-\zeta_j \omega_j b} |\bar{\Psi}(\pm i a_j \omega_j \sqrt{1 - \zeta_j^2})| \quad (11.72)$$

where A_j is the residue magnitude, and ω_j and ζ_j are the mode natural frequency and damping ratio, respectively. In Equation 11.72, the symbol a_j denotes the specific scale value, related to the mode natural frequency ω_j by the closed-form relation 11.51, typical of Morlet wavelets. Assuming that the natural frequency ω_j has been previously computed, the damping ratio ζ_j can then be estimated as the slope of a straight line, representing the cross section wavelet modulus (Equation 11.72) plotted in a semilogarithmic scale. That is,

$$\ln|(W_{x_j}(a, b))| \approx -\zeta_j \omega_j b + \ln(A_j |\bar{\Psi}(\pm i a_j \omega_j \sqrt{1 - \zeta_j^2})|) \quad (11.73)$$

Staszewski has also proposed an alternative damping estimation method based on the *ridge* and *skeletons* of the wavelet transform. A ridge is a curve of local maxima in the mean-square wavelet map, and the

corresponding skeleton is given by the values of the wavelet transform restricted to the ridge. As a result of the localization properties of the wavelet transform, the ridges and skeletons of the wavelet transform can be detected separately for each mode. Specifically, the real part of the skeleton of the wavelet transform gives the impulse-response function for each single mode from which a straightforward estimate of the damping ratio is obtained from a logarithmic equation analogous to Equation 11.73. A generalization of the method for nonlinear systems can also be formulated [80].

Ruzzene et al. [81] have also presented a damping estimation algorithm based on the same concepts and leading to analogous results. Certain issues have been addressed in detail concerning the frequency resolution of the adopted wavelet basis, crucial for detecting coupled modes, and appropriate algorithms for ridges extraction [50]. Lardies and Gouttebroze [82] have estimated modal parameters *via* ambient records without input measurements. To this end, the random decrement method (see Ref. [83] and the references therein) has been used to convert ambient vibration response into a free vibration response. Also, a modified Morlet wavelet basis has been developed with enhanced properties for modal parameters estimation. The method devised by Staszewski and by Ruzzene et al. has also been implemented by Slavic et al. [84] by replacing the Morlet wavelets by Gabor wavelets, whose time and frequency resolution may be adjusted by an appropriate parameter. Explicit conditions have been given on the frequency *bandwidths* of the Gabor wavelet transform, in order to estimate the instantaneous frequencies of two adjacent modes.

Damping coefficients have been estimated using a logarithmic decrement formula, where the ratio of the wavelet transform at two subsequent extremes of the pseudo-period $T_j = 2\pi/\omega_j$ of the response in each mode is involved for a selected wavelet transform scale [85,86]. For the procedure to estimate the damping coefficient associated with the fundamental mode, it is sufficient to adapt the analyzing scale so that the higher frequency modes are filtered. For an arbitrary mode j , low-pass filtering is used to cancel the fundamental and the first $j - 1$ modes. Ghanem and Romeo [87] have formulated a wavelet-Galerkin method for time-varying systems, where both damping and stiffness parameters are computed by solving a matrix equation. The latter is built by a standard Galerkin method by projecting the solution of the differential equation of motion onto a subspace described by the wavelet scaling functions of a compactly supported Daubechies wavelet basis. The method is accurate for both free and forced vibration responses. A formulation for nonlinear systems has also been proposed [88]. Another application is due to Yu and Xiao [89], who have used wavelet transform to identify the parameters of a Preisach model of hysteresis (see Refs. [69,90] and the references therein). The output function of the Preisach model is expanded in terms of the scaling functions of a given wavelet basis. Then, the coefficients of such an expansion are determined by fitting a number of experimental data points with a minimum energy method. From the output function, the so-called Preisach function can be determined in a closed form.

A comprehensive application of wavelet-analysis concepts to system-identification problems has been given by Le and Argoul [91]. They have developed closed-form expressions to compute the damping ratio, the natural frequency and the shape of each mode, based on ridges and skeletons of the wavelet transformed free vibration response. As an alternative, Yin et al. [92] have proposed to apply the wavelet transform to the frequency response function (FRF) of the system. Specifically, given the FRF of an N -DoF system in the form

$$H(\omega) = \sum_{r=1}^N \left[\frac{A_r}{i\omega - \lambda_r} + \frac{\bar{A}_r}{i\omega - \bar{\lambda}_r} \right] \quad (11.74)$$

where λ_r is the r th complex pole and A_r the r th residue, a complex fractional function

$$\psi_y(x) = \frac{1}{(1 + ix)^{y+1}} = e^{-(y+1)\log(1+ix)}, \quad y \in \mathbb{R}^+ \quad (11.75)$$

is selected as a wavelet basis. Based on Equation 11.75, a closed-form expression can be established for the CWT of Equation 11.74 multiplied by $(\sqrt{a})^{-\gamma}$. Specifically,

$$\begin{aligned} H_\gamma(a, b) &= a^{-(\gamma+1)/2} \int_{-\infty}^{\infty} H(\omega) \bar{\psi}_\gamma \left(\frac{\omega - b}{a} \right) d\omega \\ &= 2\pi a^{(\gamma+1)/2} \sum_{r=1}^N \left(\frac{A_r}{(a + ib - \lambda_r)^{\gamma+1}} + \frac{\bar{A}_r}{(a + ib - \bar{\lambda}_r)^{\gamma+1}} \right) \end{aligned} \quad (11.76)$$

Natural frequencies and damping ratios can be estimated by locating the maxima of Equation 11.76 in the (a, b) plane.

11.6 Damage Detection

Properties of the wavelet transform are also quite appealing for damage-detection purposes. Early investigations in this field [93,94] used wavelet analysis to detect local faults in machineries. Specifically, visual inspection of the modulus and phase of the wavelet transform was used to localize the fault [93]. Further, it was shown that transient vibrations due to developing damage are disclosed by the local maxima of the mean-square wavelet map [94]. These investigations gave a qualitative approach to damage detection as no estimate of the damage amplitude was provided. Additional studies have confirmed the correlation between local maxima of the wavelet transform and damage in beams and plates [95–97], and a first attempt to estimate the damage amplitude was made by Okafor and Dutta [98]. Specifically, Daubechies wavelets were used to wavelet transform the mode shapes of a damaged cantilever beam, and a regression analysis by a least-square method was conducted to correlate the peaks of the wavelet coefficients with the corresponding damage amplitude.

A consistent mathematical framework for wavelet analysis of damaged beams is due to Hong et al. [99]. The focal concept is that defects in structures, even if small, may affect significantly the vibration mode shapes, depending on the location and the kind of damage. Such variations may not be apparent in the measured data but become detectable as singularities if wavelet analysis is used due to its high resolution properties. Specifically, Hong et al. have shown that the singularity of the vibration modes can be described in terms of Lipschitz regularity, a concept also encountered in the theory of differential equations, widely used in image processing where object contours correspond to irregularities in the intensity [100,101]. In mathematical terms, a function $f(x)$ is Lipschitz $\alpha \geq 0$ at $x = x_0$ if there exists $K > 0$, and a polynomial of order m (m is the largest integer satisfying $m \leq \alpha$), $p_m(x)$, such that and a polynomial of order m , $p_m(x)$, such that

$$f(x) = p_m(x) + \varepsilon(x) \quad (11.77)$$

$$|\varepsilon(x)| \leq K|x - x_0|^\alpha \quad (11.78)$$

The wavelet transform of Lipschitz α functions enjoys some properties. Mallat and Hwang [100] have shown that for a wavelet basis with a number of vanishing moments $\alpha \leq n$, a local Lipschitz singularity at x_0 corresponds to maxima lines of the wavelet transform modulus. That is, local maxima with asymptotic decay across scales. Near the cone of influence $x = x_0$, such moduli satisfy the equation

$$|W_f(a, x)| \leq Aa^{\alpha+1/2}, \quad A > 0 \quad (11.79)$$

from which the Lipschitz exponent is computed as

$$\log_2 |W_f(a, x)| \leq \log_2 A + \left(\alpha + \frac{1}{2} \right) \log_2 a \quad (11.80)$$

By plotting the wavelet coefficients on a logarithmic scale, A and α may be computed by setting the equality sign in Equation 11.80 and minimizing the error in the least-square sense. Hong et al. have

applied Equation 11.79 to the first mode shape of a damaged cantilever beam *via* a Mexican Hat wavelet transform. The first mode shape is preferable since it is the most accurately determined by modal testing; it features the lowest curvature; and sets off the singularity better. A correlation between damage size and the magnitude of the Lipschitz exponent has been found from a number of beams with different damage parameters.

Some of the ideas presented by Hong et al. may also be found in the work by Douka et al., who have pursued crack identification in beams and plates using Daubechies wavelets [102,103]. The first mode vibration response has been considered and the singularity induced by local defects has been characterized in terms of Equation 11.79. The Lipschitz exponent has been used to describe the kind of singularity, and the parameter A has been taken as the factor relating the depth of the crack to the amplitude of the wavelet transform. Specifically, a second-order polynomial law has been found for the intensity factor as a function of the crack depth. The work by Douka et al. has pointed out the importance of the number of vanishing moments M of the chosen wavelet basis. It is intuitive that the capability of setting off singularities in a regular function increases with M . However, wavelet functions with high M exhibit a long support and lack space resolution. A compromise, then, must be achieved, depending on the application in hand. Further insight into some mathematical details of both the methods developed by Hong et al. and Douka et al. may be found in Haase and Widjajakusuma [50]. Specifically, a fast algorithm to determine the maxima lines of the wavelet transform has been devised. Also, the performance of various wavelet bases, such as the Gaussian family of wavelets, has been assessed versus Daubechies wavelets used by Douka et al.

Another approach for damage-detection problems has been proposed by Yam et al. [104]. Clearly, detection of small and incipient damage cannot be pursued by computing modal parameters that change only if the amount of damage is significant. Thus, a method has been devised based on the energy variation of the vibration response due to the occurrence of damage. The method is implemented in two steps. The first involves the construction of damage feature proxy vectors using the energy at various scales of the wavelet transformed vibration response. Then, classification and identification of the structural damage status is pursued by using artificial neural networks (ANNs), which offer significant advantages compared with genetic algorithms (GAs) developed by Moslem and Nafaspour for damage-identification purposes [105]. Genetic-algorithm-based damage detection, in fact, requires repeatedly searching among numerous damage parameters to find the optimal solution of the objective function.

Yet another approach for applications of wavelet analysis to damage detection has been discussed by Paget et al. [106], who have developed a procedure to detect impact damage in composite plates. It is based on Lamb waves generated and received by embedded piezoceramic transducers. The Lamb waves can be quite effective since they can propagate over long distances in the composite material and can interfere with damage. To characterize the damage, the Lamb waves are wavelet transformed using an original wavelet basis, devised from the recurrent waveforms of the Lamb waves. The changes in the Lamb waves interacting due to the occurrence of damage are captured by the amplitude change of the wavelet coefficients. From this effect, an estimate of the impact energy and the damage level is obtained based on experimental results.

11.7 Material Characterization

Material properties description is another application for wavelet analysis. Intuition suggests that multiscale analysis is a natural way of describing microstructure or material heterogeneity. Various, in fact, are the examples of multiscale microstructures, such as porosity distributions in ceramics, defects, dislocations, grain boundaries, and pores. It is important, however, to understand how information at different scales is related, and whether large or small scales affect macroscopic material properties such as deformation, toughness, and electrical conductance. Further interest towards a multiscale description of material properties is motivated by the need of alternatives to the standard finite element method (FEM).

The latter, although capable in principle, cannot simulate the actual behavior of materials such as aluminum alloys, where pores may attain a size up to $500\text{ }\mu\text{m}$ and inclusions may attain a size of 3 to $6\text{ }\mu\text{m}$ in diameter. Further, in FEM-based methods, the constitutive response of the material at increasing scales is not the result of microstructural analysis at smaller scales, but it is rather assumed on the basis of macroscopic experiments.

Willam et al. [107] have performed *multiresolution* homogenization based on a recursive Schur reduction method in conjunction with the Haar wavelet transform. The method allows coarse-grained parameters, such as Young's modulus of elasticity, to be extracted from fine-grained properties at the meso- and micro-scales. Also, progressive elastic degradation can be modeled, which initiates at a quite fine scale and evolves into a macroscopic zero stiffness at the continuum level.

Frantziskonis [108] has focused on stationary and isotropic porous media. The geometry of porous media is generally described in terms of a fundamental function, defined as unity for spatial locations in the matrix, and as zero for locations in the pores or flaws. At a solid-flaw interface, the porous medium is represented mathematically through a local jump in the fundamental function. It has been found that such a jump can be captured by a wavelet transform, as long as the finest scale is small enough relative to the size of the pores. From this fact, a relationship between the energy of the wavelet transform of the porous medium, and the variance and the correlation distance of the solid phase can be derived. In the presence of heterogeneous materials, with multiscale porosity, the role of porosity at each scale has been identified through the variation of the energy of the wavelet transform as a function of scale. Peaks of the energy reveal the dominant scale in determining macroscopic properties of the materials, such as mechanical failure. Specifically, a biorthogonal spline with four vanishing moments has been employed as a wavelet basis. The results obtained have been subsequently extended in a second study, addressing the crack formation in an aluminum alloy with distributed pores and inclusions [109]. The problem, implemented for a one-dimensional solid, is tackled by wavelet transforming the flexibility function, assumed to vary along the longitudinal axis of the one-dimensional solid. The relationship between the energy of the wavelet transform and the variance of the flexibility is used to detect the dominant scale in the crack-formation process.

Note that an application of a two-dimensional wavelet transform has been described in Ciliberto et al. [110] for porosity classification on carbon fiber-reinforced plastics.

11.8 Concluding Remarks

Concepts of wavelets-based continuous and discrete representations have been reviewed. Further, an overview of vibration-related applications for evolutionary spectrum estimation, random field simulation, system identification, damage detection, and material characterization has been included. The list of references is not exhaustive. However, these references can serve as readily available resources for canvassing the multitude of concepts and applications of this remarkable tool for capturing and representing localization features of many physical phenomena. Wavelets-based algorithms and commercial codes are an indispensable family of tools of vibration analysis and offer, in many cases, a potent improvement over the classical Fourier-transform-based approaches.

Nomenclature

Symbol	Quantity	Symbol	Quantity
$E[\cdot]$	the operator of mathematical expectation	ω	frequency
$R(\cdot, \cdot)$	correlation function	ζ	damping ratio
$H[\cdot]$	Hilbert transform operator	a	scale
$\langle \cdot, \cdot \rangle$	inner product	b	shift
\subset	inclusion	$\psi(x)$	mother wavelet
$\{; ; \}$	set of all elements with a specified property	$\phi(x)$	scale function
$ \cdot $	absolute value	x	spatial variable
$\ \cdot\ $	norm	W	wavelet transform
\mathbb{Z}	the set of integer numbers	i	$\sqrt{-1}$
\mathbb{C}	the set of complex numbers	δ_{mn}	Kronecker delta defined as
$\overline{(\cdot)}$	complex conjugate		$\delta_{mn} = \begin{cases} 0 & \text{for } m \neq n \\ 1 & \text{for } m = n \end{cases}$

Summary

Transported or on-board equipment is very frequently subjected to mechanical shocks in the course of its useful lifetime (in material handling, transportation, etc.). This kind of environment, although of extremely short duration (from a fraction of a millisecond to a few dozen milliseconds), is often severe and cannot be neglected. What is presented in this chapter is summarized here. After a brief recapitulation of the shock shapes most widely used in tests, the shock response spectrum (SRS) is presented with its numerous definitions and calculation methods. The main properties of the spectrum are described, showing that important characteristics of the original signal can be drawn from it, such as its amplitude or the velocity change associated with the movement during a shock.

The SRS is the ideal tool for comparing the severity of several shocks and for drafting specifications. Recent standards require writing test specifications from real environment measurements associated with the life profile of the material (test tailoring). The process that makes it possible to transform a set of recorded shocks into a specification of the same severity is detailed.

Packages must protect the equipment contained within them from various forms of disturbance related to handling and possible free fall drop and impact onto a floor. A method to characterize the shock fragility of the packaged product, using the "damage boundary curve" (DBC), and to choose the characteristics of the cushioning material constituting the package is described.

The principle of shock machines that are currently most widely used in laboratories is described. To reduce costs by restricting the number of changes in test facilities, specifications expressed in the form of a simple shock (half-sine, rectangle, sawtooth with a final peak) can occasionally be tested using an electrodynamic exciter. The problems encountered, which stress the limitations of such means, are set out together with the consequences of modifications, that have to be made to the shock profile on the quality of the simulation.

Determining a simple shape shock of the same severity as a set of shocks on the basis of their response spectrum is often a delicate operation. Thanks to progress in computerization and control facilities, this difficulty can sometimes be overcome by expressing the specification in the form of a response spectrum and by controlling the exciter directly from that spectrum. In practical terms, as the exciter can only be driven with a signal that is a function of time, the software of the control rack determines a time signal with the same spectrum as the specification displayed. The principles of composition of the equivalent shock are described with the shapes of the basic signals commonly used, while their properties and the problems that can be encountered, both in the generation of the signal and with respect to the quality of the simulation obtained, are emphasized.

Pyrotechnic devices or equipment (cords, valves, etc.) are frequently used in satellite launchers due to the very high degree of accuracy that they provide in operating sequences. Shocks induced in structures by explosive charges are extremely severe, with very specific characteristics. It is shown that they cannot be correctly simulated in the laboratory by conventional means and that their simulation requires specific tools.

12.1 Definitions

12.1.1 Shock

Shock occurs when a force, a position, a velocity, or an acceleration is abruptly modified and creates a transient state in the system considered. The modification is normally regarded as *abrupt* if it occurs in a time period that is short compared with the natural period concerned (AFNOR, 1993). Shock is defined as a vibratory excitation having a duration between the natural period of the excited mechanical system and two times that period (Figure 12.1).

12.1.2 Simple (or Perfect) Shock

A shock whose signal can be represented exactly in simple mathematical terms is called a simple (or perfect) shock. Standards generally specify one of the three following: half-sine (approached by a versed sine waveform), terminal peak sawtooth, and rectangular shock (approached by a trapezoidal waveform).

12.1.3 Half-Sine Shock

This is a simple shock for which the acceleration–time curve has the form of a half-period (part positive or negative) of a sinusoid.

12.1.4 Versed-Sine (or Haversine) Shock

This is a simple shock for which the acceleration–time curve has the form of one period of the curve representative of the function $[1 - \cos(\)]$, with this period starting from the zero value of this function. It is thus a signal ranging between two minima of a sine wave.

FIGURE 12.1 Example of a shock. (Source: Lalanne, *Chocs Mécaniques*, Hermes Science Publications. With permission.)

12.1.5 Terminal Peak Sawtooth Shock or Final Peak Sawtooth Shock

This is a simple shock for which the acceleration–time curve has the shape of a triangle, where acceleration increases linearly up to a maximum value and then instantly decreases to zero.

12.1.6 Rectangular Shock

This is a simple shock for which the acceleration–time curve increases instantaneously up to a given value, remains constant throughout the signal, and decreases instantaneously to zero. In practice, what is carried out are trapezoidal shocks.

12.1.6.1 Trapezoidal Shock

This is a simple shock for which the acceleration–time curve grows linearly up to a given value, remains constant during a certain time period, after which it decreases linearly to zero.

12.2 Description in the Time Domain

Three parameters are necessary to describe a shock in the time domain: its amplitude, its duration, τ , and its form.

The physical parameter expressed in terms of time is generally an acceleration, $\ddot{x}(t)$, but can be also a velocity, $\dot{v}(t)$, a displacement, $x(t)$, or a force, $F(t)$.

In the first case, which we will consider in particular in this chapter, the *velocity change* corresponding to the shock movement is equal to (Table 12.1)

$$\Delta V = \int_0^{\tau} \ddot{x}(t) dt \quad (12.1)$$

TABLE 12.1 Main Simple Shock Waveforms (Amplitude, \bar{x}_m , Duration, τ , Velocity Change, ΔV)

Waveform		Function	ΔV
Half-sine		$\bar{x}(t) = \bar{x}_m \sin\left(\frac{\pi}{\tau}t\right)$	$\frac{2}{\pi} \bar{x}_m \tau$
Versed-sine		$\bar{x}(t) = \frac{\bar{x}_m}{2} \left(1 - \cos \frac{2\pi}{\tau}t\right)$	$\frac{1}{2} \bar{x}_m \tau$
Rectangle		$\bar{x}(t) = \bar{x}_m$	$\bar{x}_m \tau$
Terminal peak sawtooth		$\bar{x}(t) = \bar{x}_m \frac{t}{\tau}$	$\frac{1}{2} \bar{x}_m \tau$

12.3 Shock Response Spectrum

12.3.1 Need

Very often, the problem is to evaluate the relative severity of several shocks (shocks measured in the real environment, measured shocks with respect to standards, establishment of a specification, etc.).

A shock is an excitation of short duration, which induces transitory dynamic stress in structures. These stresses are a function of the following:

- The characteristics of the shock (amplitude, duration, and shape).
- The dynamic properties of the structure (resonant frequencies, Q factors; [see Chapter 19](#)).

The severity of a shock can thus be estimated only according to the characteristics of the system that undergoes it. The evaluation of this severity requires in addition the knowledge of the mechanism leading to a degradation of the structure. The two most common mechanisms are as follows:

- The exceeding of a value threshold of the stress in a mechanical part can lead to either a permanent deformation (acceptable or not) or a fracture, or at any rate, a functional failure.
- If the shock is repeated many times (e.g., the shock recorded on the landing gear of an aircraft, the operation of an electromechanical contactor), the fatigue damage accumulated in the structural elements can lead in the long term to fracture (Lalanne, 2002c).

The comparison would be difficult to carry out if one used a fine model of the structure, and in any case this is not always available, particularly at the stage of the development of the specification of dimensioning. One searches for a method of general nature, which leads to results that can be extrapolated to any structure.

12.3.2 Shock Response Spectrum Definition

In a thesis on the study of earthquakes' effects on buildings, Biot (1932) proposed a method consisting of applying the shock under consideration to a "standard" mechanical system, which thus does not claim to be a model of the real structure. It is composed of a support and of N linear one-degree-of-freedom (one-DoF) resonators, comprising each one are a mass, m_i a spring of stiffness, k_i and a damping device, c_i , chosen such that the fraction of critical damping (damping ratio) $\xi = c_i / (2\sqrt{k_i m_i})$ is the same for all N resonators. A model for the shock response spectrum (SRS) is shown in [Figure 12.2](#) ([also see Chapter 17](#)).

When the support is subjected to the shock, each mass, m_i , has a specific movement response according to its natural frequency, $f_{0i} = (1/2\pi)\sqrt{k_i/m_i}$ and to the chosen damping ratio, ξ , while a

FIGURE 12.2 Model of the SRS. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

stress, σ_i , is induced in the elastic element. The analysis consists of seeking the largest stress, σ_{m_i} , observed at each frequency in each spring.

For applications deviating from the assumptions of definition of the SRS (linearity, only one DoF), it is desirable to observe a certain prudence if one wishes to estimate quantitatively the response of a system starting from the spectrum (Bort, 1989). The response spectra are more often used to compare the severity of several shocks.

It is known that the tension static diagram of many materials comprises a more-or-less linear arc on which the stress is proportional to the deformation. In dynamics, this proportionality can be allowed within certain limits for the peaks of the deformation.

If a mass–spring–damper system is supposed to be linear, it is then appropriate to compare two shocks by the maximum response stress, σ_m , that they induce or by the maximum relative displacement, z_m , that they generate. This occurs since it is supposed

$$\sigma_m = Kz_m \quad (12.2)$$

z_m is a function only of the dynamic properties of the system, whereas σ_m is also a function, via K , of the properties of the materials which constitute it.

The curve giving the largest relative displacement, z_{sup} multiplied by ω_0^2 ($\omega_0 = 2\pi f_0$) according to the natural frequency, f_0 , for a given damping ratio ξ , is the SRS.

12.3.3 Response of a Linear One-Degree-of-Freedom System

12.3.3.1 Shock Defined by a Force

Consider a mass–spring–damping system subjected to a force, $F(t)$, applied to the mass (Figure 12.3). The differential equation of the movement is written as

$$m \frac{d^2 z}{dt^2} + c \frac{dz}{dt} + kz = F(t) \quad (12.3)$$

where $z(t)$ is the relative displacement of the mass, m , relative to its support in response to the shock, $F(t)$. This equation can be expressed in the form (Lalanne, 2002b):

$$\frac{d^2 z}{dt^2} + 2\xi\omega_0 \frac{dz}{dt} + \omega_0^2 z = \frac{F(t)}{m} \quad (12.4)$$

where $\xi = c/2\sqrt{km}$ (damping ratio) and $\omega_0 = \sqrt{k/m}$ (natural frequency).

FIGURE 12.3 Linear one-Dof system subjected to a force. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.3.3.2 Shock Defined by an Acceleration

Let us set $\ddot{x}(t)$ as an acceleration applied to the base of a linear one-DoF mechanical system, with $\ddot{y}(t)$ the absolute acceleration response of the mass, m , and $z(t)$ the relative displacement of the mass, m , with respect to the base (Figure 12.4).

The equation of the movement is written as above:

$$m \frac{d^2 y}{dt^2} = -k(y - x) - c \left(\frac{dy}{dt} - \frac{dx}{dt} \right) \quad (12.5)$$

that is

$$\frac{d^2 y}{dt^2} + 2\xi\omega_0 \frac{dy}{dt} + \omega_0^2 y = \omega_0^2 x(t) + 2\xi\omega_0 \frac{dx}{dt} \quad (12.6)$$

or while setting $z(t) = y(t) - x(t)$

$$\frac{d^2 z}{dt^2} + 2\xi\omega_0 \frac{dz}{dt} + \omega_0^2 z = -\frac{d^2 x}{dt^2} \quad (12.7)$$

The differential equation (Equation 12.7) can be integrated by parts or by using the Laplace transformation. If the excitation is an acceleration of the support, the response relative displacement is given, for zero initial conditions, by an integral called *Duhamel's integral*:

$$z(t) = \frac{-1}{\omega_0 \sqrt{1 - \xi^2}} \int_0^t \ddot{x}(\alpha) e^{-\xi\omega_0(t-\alpha)} \sin \omega_0 \sqrt{1 - \xi^2} (t - \alpha) d\alpha \quad (12.8)$$

where α is an integration variable homogeneous with time.

The absolute acceleration of the mass is given by

$$\begin{aligned} \ddot{y}(t) = & \frac{\omega_0}{\sqrt{1 - \xi^2}} \int_0^t \ddot{x}(\alpha) e^{-\xi\omega_0(t-\alpha)} [(1 - 2\xi^2) \sin \omega_0 \sqrt{1 - \xi^2} (t - \alpha) \\ & + 2\xi \sqrt{1 - \xi^2} \cos \omega_0 \sqrt{1 - \xi^2} (t - \alpha)] d\alpha \end{aligned} \quad (12.9)$$

12.3.4 Definitions

12.3.4.1 Response Spectrum

This is a curve representative of the variations of the largest response of a linear one-DoF system subjected to a mechanical excitation, plotted against its natural frequency, $f_0 = \omega_0/2\pi$, for a given value of its damping ratio (see Chapter 17).

12.3.4.2 Absolute Acceleration Shock Response Spectrum

In the most usual cases where the excitation is defined by an absolute acceleration of the support or by a force applied directly to the mass, the response of the system can be characterized by the absolute acceleration of the mass (which can be measured using an accelerometer fixed to this mass). The response spectrum is then called the *absolute acceleration SRS*.

12.3.4.3 Relative Displacement Shock Spectrum

In similar cases, we often calculate the relative displacement of the mass with respect to the displacement of the base of the system. This displacement is proportional to the stress created in the

FIGURE 12.4 Linear one-DoF system subjected to acceleration. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

spring (since the system is regarded as linear). In practice, one generally expresses in ordinates the quantity $\omega_0^2 z_{\text{sup}}$, which is called the *equivalent static acceleration* (Biot, 1941). This product has the dimensions of acceleration, but does not represent the absolute acceleration of the mass, except when damping is zero. However, when damping is close to the current values observed in mechanics, and in particular when $\xi = 0.05$, as a first approximation one can assimilate $\omega_0^2 z_{\text{sup}}$ to the absolute acceleration \ddot{y}_{sup} of the mass, m (Lalanne, 1975, 2002b).

The quantity $\omega_0^2 z_{\text{sup}}$ is termed *pseudo-acceleration*. In the same way, one terms the product $\omega_0 z_{\text{sup}}$ *pseudo-velocity*. The spectrum giving $\omega_0^2 z_{\text{sup}}$ vs. the natural frequency is named the *relative displacement shock spectrum*.

In each of these two important categories, the response spectrum can be defined in various ways according to how the largest response at a given frequency is characterized.

12.3.4.4 Primary Positive Shock Response Spectrum or Initial Positive Shock Response Spectrum

This is the highest positive response observed during the shock.

12.3.4.5 Primary (or Initial) Negative Shock Response Spectrum

This is the highest negative response observed during the shock.

12.3.4.6 Secondary (or Residual) Shock Response Spectrum

This is the largest response observed after the end of the shock. Here also, the spectrum can be positive or negative.

Example

An example giving standardized primary and residual relative displacement SRS curves for a half-sine pulse is shown in Figure 12.5.

12.3.4.7 Positive (or Maximum Positive) Shock Response Spectrum

This is the largest positive response due to the shock, without reference to the duration of the shock. It thus corresponds to the envelope of the positive primary and residual spectra.

FIGURE 12.5 Standardized primary and residual relative displacement SRS of a half-sine pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.3.4.8 Negative (or Maximum Negative) Shock Response Spectrum

This is the largest negative response due to the shock, without reference to the duration of the shock. As before, it corresponds to the envelope of the negative primary and residual spectra.

12.3.4.9 Maximax Shock Response Spectrum

This is the envelope of the absolute values of the positive and negative spectra.

12.3.4.10 Choice of Shock Response Spectrum

Which spectrum must be used? Absolute acceleration SRS can be useful when absolute acceleration is the parameter easiest to compare with a characteristic value (as in a study of the effects of a shock on a man, a comparison with the specification of an electronics component, etc.).

In practice, it is very often the stress (and thus the relative displacement) which seems the most interesting parameter. The spectrum is primarily used to study the behavior of a structure, to compare the severity of several shocks (the stress created is a good indicator), to write test specifications (as it is also a comparison between the real environment and the test environment), or to dimension a suspension (relative displacement and stress are then useful).

The damage is assumed to be proportional to the largest value of the response, i.e., to the amplitude of the spectrum at the frequency considered, and it is of little importance for the system whether this maximum, z_m , takes place during or after the shock. The most interesting spectra are thus the positive and negative spectra that are most frequently used in practice, with the maximax spectrum.

The distinction between positive and negative spectra must be made each time the system, if dissymmetrical, behaves differently, for example under different tension and compression. It is, however, useful to know these various definitions so as to be able to correctly interpret the curves published.

The *Shock Response Spectrum* is a curve representative of the variations of the largest response of a linear one-DoF system subjected to a mechanical excitation, plotted against its natural frequency, for a given value of its damping ratio.

The response can be defined by the pseudo-acceleration, $\omega_0^2 z_{sup}$ (*relative displacement shock spectrum*) or by the absolute acceleration of the mass (*absolute acceleration SRS*). For the usual values of Q , the spectra are very close.

The most interesting spectra are the positive and negative spectra, which are most frequently used in practice, with the maximax spectrum.

The relation between the various types of SRS that have been discussed here is shown in Figure 12.6.

FIGURE 12.6 Relation between the different types of SRS.

12.3.5 Standardized Shock Response Spectrum

12.3.5.1 Definition

For a given shock, the spectra plotted for various values of the duration and the amplitude are similar in shape. It is thus useful, for simple shocks, to have a standardized or reduced spectrum plotted in dimensionless coordinates, while plotting on the abscissa the product $f_0 \tau$ (instead of f_0) or $\omega_0 \tau$ and on the ordinate the spectrum/shock pulse amplitude ratio, $\omega_0^2 z_m / \ddot{x}_m$, which, in practice, amounts to tracing the spectrum of a shock of duration equal to 1 sec and amplitude 1 m/sec². This is shown in Figure 12.7.

These standardized spectra can be used for two purposes:

- Plotting of the spectrum of a shock of the same form, but of arbitrary amplitude and duration.
- Investigating the characteristics of a simple shock of which the spectrum envelope is a given spectrum (resulting from measurements from the real environment).

FIGURE 12.7 Standardized positive SRS of a terminal peak sawtooth pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.3.5.2 Standardized Shock Response Spectra of Simple Shocks

Figure 12.8 to Figure 12.15 give the reduced SRSs for various pulse forms, with unit amplitude and unit duration, for several values of damping. To obtain the spectrum of a particular shock of arbitrary amplitude, \ddot{x}_m , and duration, τ (different from 1) from these spectra, it is enough to regraduate the scales as follows:

- For the amplitude, multiply the reduced values by \ddot{x}_m .
- For the abscissae (x -axis values), replace each value $\phi (= f_0 \tau)$ by $f_0 = \phi / \tau$.

We will see later on how these spectra can be used for the calculation of test specifications.

FIGURE 12.8 Standardized positive and negative relative displacement SRS of a half-sine pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.9 Standardized positive and negative absolute acceleration SRS of a half-sine pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.3.5.2.1 Half-Sine Pulse

Figure 12.8 and Figure 12.9 show the standardized SRS curves in this case.

12.3.5.2.2 Versed Sine Pulse

Figure 12.10 shows the standardized SRS curves in this case.

12.3.5.2.3 Terminal Peak Sawtooth Pulse

Figure 12.11 and Figure 12.12 show the standardized SRS curves for terminal peak sawtooth (TPS) pulse.

12.3.5.2.4 Rectangular Pulse

Figure 12.13 gives the standardized SRS curves for a rectangular pulse shock.

12.3.5.2.5 Trapezoidal Pulse

Figure 12.14 presents the standardized SRS curve for a trapezoidal pulse. A comparison of various SRS curves is given in Figure 12.15.

FIGURE 12.11 Standardized positive and negative relative displacement SRS of a TPS pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.3.6 Choice of Damping

The choice of damping should be carried out according to the structure subjected to the shock. When this is not known, or studies are being carried out with a view to comparison with other already calculated spectra, the outcome is that one plots the shock response spectra with a damping ratio equal to 0.05 (i.e., $Q = 10$; see Chapter 19). It is an approximately average value for the majority of structures. Unless otherwise specified, as noted on the curve, it is the value chosen conventionally. With the spectra varying relatively little with damping, this choice is often not very important. To limit possible errors, the selected value should, however, be systematically noted on the diagram.

12.3.7 Shock Response Spectra Domains

Three domains can be schematically distinguished for shock spectra.

1. An *impulse domain* at low frequencies, in which the amplitude of the spectrum (and thus of the response) is lower than the amplitude of the shock: The system reduces the effects of the shock. It is thus

FIGURE 12.12 Standardized positive and negative relative displacement SRS of a TPS pulse with nonzero decay time. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.13 Standardized positive and negative relative displacement SRS of a rectangular pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

in this impulse region that it would be advisable to choose the natural frequency of an isolation system to the shock, from which we can deduce the stiffness envisaged of the insulating material:

$$k = m\omega_0^2 = 4\pi^2 f_0^2 m \quad (12.10)$$

with m being the mass of the material to be protected.

The shock here is of very short duration with respect to the natural period of the system. In this impulse region ($0 \leq f_0 \tau \leq 0.2$):

- The form of the shock has little influence on the amplitude of the spectrum. Only (for a given damping value) the velocity change ΔV associated with the shock, equal to the algebraic surface under the curve $\ddot{x}(t)$ is important.
- The slope p at the origin of the spectrum plotted for zero damping in linear scales is proportional to the velocity change ΔV corresponding to the shock pulse (Lalanne, 2002b):

$$p = \frac{d(\omega_0^2 z_{sup})}{df_0} = 2\pi\Delta V \quad (12.11)$$

This relation is approximate if damping is small.

FIGURE 12.14 Standardized positive and negative relative displacement SRS of a trapezoidal pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.15 Comparison between the SRS of the three main simple shock waveforms.

- The positive and negative spectra are in general the residual spectra (it is sometimes necessary that the frequency of spectrum is very small, and there can be exceptions for certain long shocks in particular). They are nearly symmetrical so long as damping is small.

2. A *static domain* in the range of the high frequencies, where the positive spectrum tends towards the amplitude of the shock whatever the damping: All occurs here as if the excitation were a static acceleration (or a very slowly varying acceleration), as the natural period of the system is small compared with the duration of the shock. This does not apply to rectangular shocks or to the shocks with zero rise time. Real shocks having necessarily a rise time different from zero, this restriction remains theoretical.

3. An *intermediate domain* in which there is dynamic amplification of the effects of the shock, the natural period of the system being close to the duration of the shock: This amplification, which is more or less significant depending on the shape of the shock and the damping of the system, does not exceed 1.77 for shocks of traditional simple shape (half-sine, versed sine, TPS). Much larger values are reached in the case of oscillatory shocks, made up, for example, by a few periods of a sinusoid.

Various domains of an SRS are illustrated in Figure 12.16.

Example

Consider a half-sine shock pulse, amplitude $\ddot{x}_m = 50 \text{ m/sec}^2$, duration $\tau = 11 \text{ msec}$, positive SRS (relative displacement) for a damping ratio $\xi = 0.05$.

The slope p of the SRS (Figure 12.16) at the origin is equal to $p = 30.6/15 = 2.04 \text{ m/sec}$, yielding

$$\Delta V \approx \frac{p}{2\pi} = \frac{2.04}{2\pi} \approx 0.325 \text{ m/sec}$$

a value to be compared with the surface under the half-sine shock pulse (Table 12.1):

$$\Delta V = \frac{2}{\pi} \ddot{x}_m \tau = \frac{2}{\pi} \times 50 \times 11 \times 10^{-3} \approx 0.35 \text{ m/sec}$$

12.3.8 Algorithms for Calculation of the Shock Response Spectra

Various algorithms have been developed to solve the second-order differential equation (Equation 12.7; O'Hara, 1962; Gaberson, 1980; Smallwood, 1981; Cox, 1983; Hughes and Belytschko, 1983; Irvine, 1986;

FIGURE 12.16 Shock response spectra domains.

Dokainish and Subbaraj, 1989; Colvin and Morris, 1990; Hale and Adhami, 1991; Mercer and Lincoln, 1991; Seipel, 1991; Merritt, 1993; Grivelet, 1996). Very reliable results are obtained in particular with those of Cox (1983) and Smallwood (1986, 2002).

12.3.9 Choice of the Digitization Frequency of the Signal

The SRS is obtained by considering the largest peak of the response of a one-DoF system. This response is in general calculated by the algorithms with the same temporal step as that of the shock signal.

First of all, the digitization (sampling) frequency must be sufficient to correctly represent the signal itself and in particular not to truncate its peaks. Two cases are shown in Figure 12.17 and Figure 12.18.

When the natural frequency of the one-DoF system is lower than the smallest shock frequency, the detection of peaks of the response can be carried out accurately even if the signal digitization (sampling) frequency is insufficient for correctly describing the shock (Figure 12.17). The error on the SRS is then only related to the poor digitization (sampling) of shock and results in an inaccuracy on the velocity change associated with the shock, i.e., on the SRS slope at low frequency.

Even if the sampling frequency allows a good representation of the shock, it can be insufficient for the response when the natural frequency of the system is higher than the maximum frequency of

FIGURE 12.17 Sampling frequency sufficient for the response and too low for the shock pulse (error on the slope of SRS at low frequency).

FIGURE 12.18 Sampling frequency sufficient for the shock pulse and too low for the response (error on the SRS at high frequency).

the signal (Figure 12.18). The error is here related to the detection of the largest peak of the response, which occurs throughout shock (primary spectrum).

Figure 12.19 shows the error made in the more stringent case when the points surrounding the peak are symmetrical with respect to the peak.

If we set

$$S_F = \frac{\text{Sample frequency}}{\text{SRS maximum frequency}}$$

it can be shown that, in this case, the error made according to the sampling factor, S_F , is equal to (Sinn and Bosin, 1981; Wise, 1983)

$$e_s = 100 \left[1 - \cos \left(\frac{\pi}{S_F} \right) \right] \tag{12.12}$$

The sampling frequency must be higher than 16 times the maximum frequency of the spectrum so that the error made at high frequency is lower than 2% (23 times the maximum frequency for an error lower than 1%). The rule of thumb often used to specify a sampling factor equal to ten can lead to an error of about 5%. Percentage error as a function of the sampling factor is plotted in Figure 12.20. Also see Table 12.2.

Algorithms use generally the same sampling frequency for the shock input and the response of the one-DoF system. This choice led to define the sampling frequency according to the highest SRS frequency. In order to decrease the computing time, it could be interesting to determine a sampling frequency varying with each natural frequency (Smallwood, 2002).

FIGURE 12.19 Error made in measuring the amplitude of the peak. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.20 Error made in measuring the amplitude of the peak plotted against sampling factor. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

Note: The sampling frequency must be higher than 16 times the maximum frequency of the spectrum so that the error made at high frequency is lower than 2%.

12.3.10 Use of Shock Response Spectra for the Study of Systems with Several Degrees of Freedom

By definition, the response spectrum gives the largest value of the response of a linear single-DoF system subjected to a shock. If the real structure is comparable to such a system, the SRS can be used to evaluate this response directly. This approximation is often possible, with the displacement response being mainly due to the first mode. In general, however, the structure comprises several modes, which are simultaneously excited by the shock. The response of the structure consists of the algebraic sum of the responses of each excited mode.

The maximum response of each one of these modes can be read on the SRS, but the following apply.

- One does not have any information concerning the moment of occurrence of these maxima. The phase relationships between the various modes are not preserved and the exact way in which the modes are combined cannot be known simply.
- The SRS is plotted for a given constant damping over all the frequency range, whereas this damping varies from one mode to another in the structure.

It thus appears difficult to use an SRS to evaluate the response of a system presenting more than one mode. However, it happens that this is the only possible means. The problem is to know how to combine these “elementary” responses so as to obtain the total response and to determine, if need be, any suitable participation factors dependent on the distribution of the masses of the structure, of the shapes of the modes, etc.

When there are several modes, several proposals have been made to limit the value of the total response of the mass j of the one of the DoF starting from the values read on the SRS, as follows.

- Add the values with the maxima of the responses of each mode, without regard to the phase (Benioff, 1934).
- Sum the absolute values of the maximum modal responses (Biot, 1932). As it is not probable that the values of the maximum responses take place all at the same moment with the same sign, the real maximum response is lower than the sum of the absolute values. This method gives an upper limit of the response and thus has a practical advantage: the errors are always on the side of safety. However, it sometimes leads to excessive safety factors (Shell, 1966).
- Perform an algebraic sum of the maximum responses of the individual modes. A study showed that, in the majority of the practical problems, the distribution of the modal frequencies and the shape of the excitation are such that the possible error remains probably lower than 10% (Rubin, 1958; Fung and Barton, 1958).
- Add to the response of the first mode a fixed percentage of the responses of the other modes, or increase in the response of the first mode by a constant percentage (Clough, 1955).
- Combine the responses of the modes by taking the square root of the sum of the squares to obtain an estimate of the most probable value (Merchant and Hudson, 1962). This criterion gives values of the total response lower than the sum of the absolute values and provides a more realistic evaluation of the average conditions (Ostrem and Rumerman, 1965; Ridler and Blader, 1969).
- Average the sum of the absolute values and the square root of the sum of the squares (Jennings, 1958). One can also choose to define positive and negative limiting values starting from a system of weighted averages. For example, the relative displacement response of the mass j is estimated by

$$\max_{t \geq 0} |z_j(t)| = \frac{\sqrt{\sum_{i=1}^n (z_m^2)_i} + p \sum_{i=1}^n |z_m|_i}{p + 1} \quad (12.13)$$

where the terms $|z_m|_i$ are the absolute values of the maximum responses of each mode and p is a weighting factor (Merchant and Hudson, 1962).

12.4 Pyroshocks

The aerospace industry uses many pyrotechnic devices such as explosive bolts, squib valves, jet cord, and pin pushers. During their operation, these devices generate shocks which are characterized by very strong acceleration levels at very high frequencies that can be sometimes dangerous for the structures, but especially for the electric and electronic components involved. An example of a pyroshock is given in Figure 12.21.

Pyroshock intensity is often classified according to the distance from the point of detonation of the device. Agreement on classifying intensity according to this criterion is not unanimous. Two fields are generally considered (Table 12.3):

- The near-field, close to the source (material within about 15 cm of point of detonation of the device, or about 7.5 cm for less intense pyrotechnic devices), in which the effects of the shocks are primarily related to the propagation of a stress wave in the material.
- The far-field (material beyond about 15 cm for intense pyrotechnic devices, or beyond 7.5 cm for less intense devices) in which the shock is then propagated whilst attenuating in the structure and from which the effects of this wave combine with a damped oscillatory response of the structure at its frequencies of resonance (or the structural response only).

Three fields are sometimes suggested: the near-field, the mid-field (same definition as the far-field above, between 15 and 60 cm, or 7.5 and 15 cm for the less intense shocks), and the far-field, where only the structural response effect persists.

An investigation by Moening (1986) showed that the causes of observed failures on the American launchers between 1960 and 1986 (63 due to pyroshocks) are mainly the difficulty in evaluating these shocks *a priori*, especially the lack of consideration of these excitations during design and the absence of rigorous test specifications.

Such shocks have the following general characteristics.

- The levels of acceleration are very important; the shock amplitude is not simply related to the quantity of explosive used (Hughes, 1983). The quantity of metal cut by a jet cord is, for example, a more significant factor than the mass of the explosive.

FIGURE 12.21 Example of a pyroshock. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

TABLE 12.3 Characteristics of Each Pyroshock Intensity Domain

Field	Distance from the Source (cm)	Intense Pyrotechnic Devices (cm)	Shock Amplitude Frequency Content
Near field (stress wave propagation effect)	< 7.5	< 15	> 5000g, up to 300,000g above 100,000 Hz
Far-field (stress wave propagation effect + structural response effect)	> 7.5	> 15	1000 to 5000g above 10,000 Hz

Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.

- The signals assume an oscillatory shape.
- The shocks have very close components according to three axes; their positive and negative response spectra are curves that are roughly symmetrical with respect to the axis of the frequencies. They begin at zero frequency with a very small slope at the origin, grow with the frequency until a maximum located at some kHz, even a few tens of kHz, is reached, and then tend according to the rule towards the amplitude of the temporal signal. Due to their contents at high frequencies, such shocks can damage electric or electronic components.
- The *a priori* estimate of the shock levels is neither easy nor precise.

These characteristics make pyroshocks difficult to measure, requiring sensors that are able to accept amplitudes of 100,000g, frequencies being able to exceed 100 kHz, with important transverse components. They are also difficult to simulate.

The dispersions observed in the response spectra of shocks measured under comparable conditions are often important, 3 dB with more than 8 dB compared with the average value, according to the authors (Smith, 1984, 1986). The reasons for this dispersion are in general related to inadequate instrumentation and the conditions of measurement (Smith, 1986):

- The fixing of the sensors on the structure using insulated studs or wedge which act like mechanical filters.
- Zero shift, due to the fact that high accelerations make the crystal of the accelerometer work in a temporarily nonlinear field (this shift can affect the calculation of the SRS).
- Saturation of the amplifiers.
- Resonance of the sensors.

With correct instrumentation, the results of measurements carried out under the same conditions are actually very close. The spectrum does not vary with the tolerances of manufacture and the assembly tolerances.

12.5 Use of Shock Response Spectra

12.5.1 Severity Comparison of Several Shocks

A shock, A, is regarded as more severe than a shock, B, if it induces in each resonator a larger stress. One then carries out an extrapolation, which is certainly open to criticism, by supposing that, if shock A is more severe than shock B when it is applied to all the standard resonators, it is also more severe with respect to an arbitrary real structure (which cannot be linear nor have a single DoF).

12.5.2 Test Specification Development from Real Environment Data

12.5.2.1 Synthesis of Spectra

Let us consider the most complex case where the real environment, described by curves of acceleration against time, is supposed to be composed of p different events (handling shock, inter-stage cutting shock on a satellite launcher, etc.), with each one of these events itself characterized by r_i successive measurements.

These r_i measurements allow a statistical description of each event. The following procedure holds for each one (Lalanne, 2002b; see Figure 12.22).

- Calculate the SRS of each signal recorded with the damping ratio of the principal mode of the structure if this value is known, if not, use the conventional value 0.05. In the same way, the

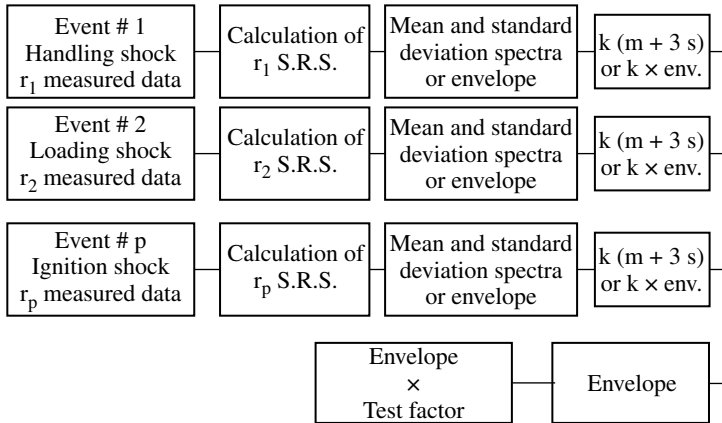

FIGURE 12.22 Process of developing a specification from real shocks measurements.

frequency band of analysis will have to envelop the principal resonant frequencies of the structure (known or foreseeable frequencies).

- If the number of measurements is sufficient, calculate the mean spectrum, m (mean of the points at each frequency) as well as the standard deviation spectrum (s), then the mean spectrum + α standard deviations, according to the frequency; if it is insufficient, make the envelope of the spectra.

The value of α can be either arbitrary (for example 2.5 or 3) or the result of a statistical calculation. It is often considered that the SRS amplitudes obey to a log-normal distribution. If y_i is the logarithm of the SRS amplitude, $y_j = \log_{10} \text{SRS}_j$, the real environment envelope (for a given probability P_0 of not exceeding at the confidence level π_0) can be defined by

$$\text{SRS}_{\text{Env}} = 10^{m_y + \alpha s_y} \quad (12.14)$$

where m_y and s_y are, respectively, the mean and the standard deviation of the y_j values:

$$m_y = \frac{1}{r_i} \sum_{j=1}^{r_i} y_j \quad (12.15)$$

$$s_y = \sqrt{\frac{\sum_{j=1}^{r_i} (y_j - m_y)^2}{r_i - 1}} \quad (12.16)$$

The number of standard deviations, α , is given in Table 12.4 for different values of r_i , P_0 , and π_0 . SRS_{Env} can also be defined as the upper one-sided normal tolerance interval for which 100 $P_0\%$ of the values will lie below the limit with 100 $\pi_0\%$ confidence.

- Apply the mean spectrum or the mean spectrum + α standard deviations a statistical uncertainty coefficient (Lalanne, 2002d), calculated for a probability of tolerated maximum failure (taking into account the uncertainties related to the dispersion of the real environment and of the mechanical strength), or contractual (if one uses the envelope).

TABLE 12.4 Number of Standard Deviations Corresponding to a Given Probability of not Exceeding, P_0 , at the Confidence Level, π_0

Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.

Each event thus being synthesized in only one spectrum, one proceeds to an envelope of all the spectra obtained to deduce from it an SRS covering the totality of the shocks of the life profile. After multiplication by a test factor, which takes account of the number of tests performed to demonstrate the resistance of the equipment (Lalanne, 2002d), this spectrum will be used as reference “real environment” for the determination of the specification.

The reference spectrum can consist of the positive and negative spectra or the envelope of their absolute value (maximax spectrum). In this last case, the specification will have to be applied according to the two corresponding half-axes of the test item.

12.5.2.2 Nature of the Specification

There is an infinity of shocks having a given response spectrum. This property is related to the very great loss of information in computing the SRS, since one retains only the largest value of the response according to the time to constitute the SRS at each natural frequency.

According to the characteristics of the spectrum and available means, the specification can be expressed in the forms given below.

- It can be a simple shape signal according to the time realizable on the usual shock machines (half-sine, TPS, rectangular pulse).

One can thus try to find a shock of simple form, in which the spectrum is closed to the reference spectrum, characterized by its form, its amplitude, and its duration. It is in general desirable that the positive and negative spectra of the specification, respectively, cover the positive and negative spectra of the field environment. If this condition cannot be obtained by application of only one shock (owing to the particular shape of the spectra, and the limitations of the facilities), the specification will be made up of two shocks, one on each half-axis. The envelope must be approaching the reference SRS as well as possible, if possible on all the spectrum in the frequency band retained for the analysis, if not in a frequency band surrounding the resonant frequencies of the test item (if they are known).

- It can be a SRS. In this case, the specification is directly the reference SRS.

12.5.2.3 Choice of Shape

The choice of the shape of a shock is carried out by a comparison of the shapes of the positive and negative spectra of the real environment with those of the spectra of the usual shocks of simple shape (half-sine, TPS, rectangle; [Figure 12.23](#)).

12.5.2.4 Amplitude

The amplitude of a shock is obtained by plotting the horizontal straight line that closely envelops the positive reference SRS at high frequency (Figure 12.24). This line cuts the y -axis at a point which gives the amplitude sought (here, one uses the property of the spectrum at high frequencies, which tends in this zone towards the amplitude of the signal in the time domain).

12.5.2.5 Duration

The shock duration is given by the coincidence of a particular point of the reference spectrum (Figure 12.24) and the reduced spectrum of the simple shock selected above.

One in general considers the abscissa, f_{01} , of the first point which reaches the value of the asymptote at the high frequencies (amplitude of shock) as shown in Figure 12.25. Table 12.5 joins together some values of this abscissa for the most usual simple shocks according to the Q factor (Lalanne, 2002b). Another possibility is to use the coordinates of the first (higher) peak of the SRS, as given in Table 12.6.

Notes:

1. If the calculated duration must be rounded (in milliseconds), the higher value should always be considered, so that the spectrum of the specified shock remains always higher or equal to the reference spectrum.

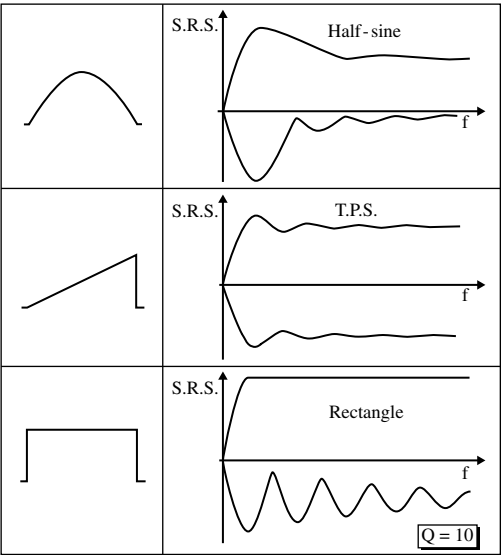

FIGURE 12.23 Shapes of the SRS of the realizable shocks on the usual machines. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.24 Determination of the amplitude and duration of the specification. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

- 2. It is in general difficult to carry out shocks of duration lower than 2 msec on standard shock machines (except for very light equipment).

One will validate the specification by checking that the positive and negative spectra of the shock thus determined will envelop the respective reference spectra and one will verify, if the resonant frequencies of the test item are known, that one does not overtest exaggeratedly at these frequencies.

Example

As an example, let us consider the positive and negative spectra characterizing the real environment plotted in Figure 12.24, which is a result of a true synthesis. It is noted that the negative spectrum preserves a significant level throughout the entire frequency domain (the beginning of the spectrum being excluded).

The most suitable simple shock shape is the TPS. The shock amplitude, whatever its waveform, is equal to 340 m/sec². The abscissa, f_{01} , of the first point that reaches the value of the asymptote is equal to 0.415. From this value, $f_0 = 49.5$ Hz, the duration is given by $\tau = 0.415/49.5 = 0.0084$ sec.

The duration of the shock will thus be (rounding up) $\tau = 9$ msec, which slightly moves the spectrum towards the left and makes it possible to better cover the low frequencies. Figure 12.26 shows the spectra of the environment and those of the TPS pulse thus determined.

The main steps of deriving a shock test specification from the SRS of a real environment are outlined in Table 12.7.

FIGURE 12.25 Determination of the shock duration. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.5.2.6 Difficulties

The response spectra of shocks measured in the real environment often have a complicated shape which is impossible to envelop by the spectrum of a shock of simple shape realizable with the usual test facilities of the drop table type. This problem arises in particular when the spectrum presents an important peak (Smallwood and Witte, 1972). The spectrum of a shock of simple shape will be (see Figure 12.27): either an envelope of the peak, which will lead to significant overtesting compared with the other frequencies, or envelope of the spectrum except the peak, consequently leading to undertesting at the frequencies close to the peak, if one knows that the material does not have any resonance in the frequency band around the peak. The simulation of shocks of pyrotechnic origin leads to this kind of situation.

TABLE 12.7 Deriving a Shock Test Specification from the SRS of the Real Environment

Specification	Determined by
Shock waveform	Comparing the shape of the SRS of the real environment (reference) to that of the SRS of the simple shape shocks (half-sine, TPS or rectangular waveform)
Shock amplitude	The SRS amplitude at high frequency
Shock duration	Writing that the abscissa of the first point which reaches the value of the asymptote at high frequencies (amplitude of shock) is the same for the reduced SRS of the chosen simple shock and the reference SRS

FIGURE 12.27 Examples of SRS that are difficult to envelop with the SRS of a simple shock. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

Shock pulses of simple shape (half-sine, TPS) have, in logarithmic scales, a slope of 6 dB/octave (i.e., 45°) at low frequencies incompatible with those larger ones, of spectra of pyrotechnic shocks (>9 dB/octave). When the levels of acceleration do not exceed the possibilities of the shakers, simulation with control using spectra is of interest (Section 12.10).

Note: In general, it is not advisable to choose a simple shock shape as a specification when the real shock is oscillatory in nature. In addition to overtesting at low frequencies (the oscillatory shock is with very small velocity change), the amplitude of the simple shock thus calculated is more sensitive to the value of the *Q* factor in the intermediate frequency range.

12.6 Standards

12.6.1 Types of Standards

There are two types of standards: (1) those which specify *arbitrary shock pulses* (IEC, ISO, MIL STD 810 C, ...), and (2) those which require *test tailoring* (GAM EG 13, 1986; DEF STAN, 1999; MIL STD 810 F, 2000; NATO, 2000).

For the first case, the most frequently specified shock shapes are the half-sine, the TPS, and the rectangular (or trapezoidal) waveforms. In these standards, a table proposes several values of levels and durations, with preferred combinations (for example, 30g, 18 msec or 50g, 11 msec).

To take account of the limitations of test facilities and unavoidable signal distortions, the shock carried out is regarded as acceptable if the time acceleration signal lies between two tolerance limits. Two shocks included within these limits can, however, have very different effects (which can be evaluated with the SRS; Lalanne, 2002b).

Some examples of standards are given in Figure 12.28 and Figure 12.29.

In the second case, the test specification is preferably written from real measurements corresponding to the life profile of the material. The data to be used can be any of the following, in the preferential order:

- Functional real environment time history measurements of the material.
- Data measured under similar conditions and estimated to be representative.
- Data issued from prediction or calculation.
- *Default* values (fallback levels), obviously more arbitrary in character, to be used if measured data not available (classical pulse shock or SRS).

Derivation of the test specification and subsequent test should be carried out, in the preferential order as follows:

- For measured data of the same event, if the measured pulse shapes are very similar, use direct reproduction of the measured data under shaker waveform control (if possible). If the measured shock shapes are very different, use the following method.
- For measured data of different shock events use a synthesis of measurements using SRS (see Section 12.5.2). Test on shaker with SRS control if possible. If not possible, test on shock machine with a classical pulse having the same SRS.
- If there is no measured data of the real shock, but measured data under similar conditions, use the method as above.
- If there are no measured data, fallback levels and provisional values are to be replaced by results of measurement as soon as possible.

The transformation shock spectrum-signal has an infinite number of solutions, and very different signals can have identical response spectra. Standards often require specifying in addition to the spectrum other complementary data such as the duration of the signal time, the velocity change during the shock or the number of cycles (less easy), in order to deal with the spectrum and the couple amplitude/duration of the signal at the same time (see Section 12.10.4).

It is not correct to decompose a SRS into two separate domains in order to be able to meet a shock requirement (a low frequency component and a high frequency component). If the specimen has no significant low natural frequency, it is permissible to allow the low frequency domain of the SRS to fall out of tolerance in order to satisfy the high frequency part of the requirement.

The tolerance on the SRS amplitude should be, for example (MIL STD 810 F), -1.5 dB, $+3$ dB over the specified frequency range; a tolerance of $+3$ dB, $+6$ dB being permissible over a limited frequency range.

It is generally required to determine the positive and negative spectra (absolute acceleration or relative displacement) at $Q = 10$, at at least $1/12$ -octave frequency intervals.

FIGURE 12.28 Half-sine pulse (NATO Stanag 4370, AECTP 403). T_1 : minimum time during which the pulse shall be monitored for shocks produced using a conventional shock-testing machine; T_2 : minimum time during which the pulse shall be monitored for shocks produced using a vibration generator.

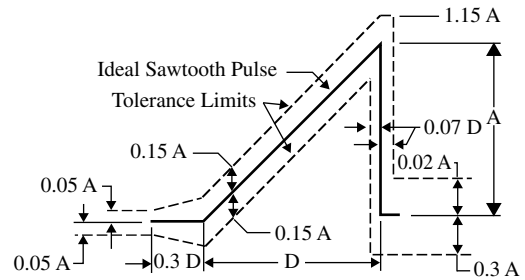

FIGURE 12.29 TPS pulse (MIL STD 810 F). D : duration of nominal pulse; A : peak acceleration of nominal pulse.

In the absence of accurate information on the number of shocks which the material will undergo in its service life, a minimum is often required of three shocks in both directions along each of the three orthogonal axes, a total of 18 shocks.

12.6.2 Installation Conditions of Test Item

- The test item should be mechanically fastened to the shock machine, directly by its normal means of attachment or by means of a fixture.
- The mounting configuration should enable the test item to be subjected to shocks along the various axes and directions as specified.
- External connections necessary for measuring purposes should add minimum restraint and mass.
- The fixture should not modify the dynamic behavior of the test item.
- Material intended for use with isolators should be tested with its isolators.
- The direction of gravity or any loading factors (mechanisms, shock isolators, etc.) must be taken into account by compensation or by suitable simulation.

12.6.3 Uncertainty Factor

An uncertainty factor may be added to the resulting envelope if confidence in the data is low or in order to take account of the dispersion of levels in the real environment when the data set is small. This factor can be arbitrary, of the order of 3 to 6 dB, for example, or determined from a reliability computation, taking account of the statistical distributions of the real environment and of the material strength (Lalanne, 2002d).

It is important that all uncertainties be clearly defined and that uncertainties are not superimposed upon estimates that already account for uncertainties.

Note: The purpose of the test is to demonstrate that the equipment has at least the specified strength at the time of its design. However, for obvious reasons of cost, this demonstration is generally conducted only on one specimen. To take into account the variability of the strength of the material, it is possible to increase the test severity by applying a “test factor.” This second factor depends on the number of tests to be conducted and on the coefficient of variation of the material strength (Lalanne, 2002d).

12.6.4 Bump Test

A *bump test* is a test in which a simple shock is repeated many times (DEF STAN, 1999; IEC, 1987b; AFNOR, 1993). Standardized severities are proposed. For example, half-sine, 10 g, 16 ms, 3000 bumps (shock) per axis, 3 bumps a second.

The purpose of this test is not to simulate any specific service condition. It is simply considered that it could be useful as a general ruggedness test to provide some confidence in the suitability of equipment for transportation in wheeled vehicles. It is intended to produce in the specimen effects similar of those resulting from repetitive shocks likely those encountered during transportation.

In this test, the equipment is always fastened (with its isolators if it is normally used with isolators) to the bump machine during conditioning.

12.7 Damage Boundary Curve

12.7.1 Definition

Products are placed in a package to be protected from possible free-fall drops and impacts onto a floor or a shipping platform during transport or handling. This packaging is often made up of a cushioning material (for example, honeycomb or foam) which absorbs the impact energy (related to the impact velocity) either by inelastic deformation, and which generates a shock at the entry of the material, whose

FIGURE 12.30 Shock transmitted to product during the crushing of package.

shape is often comparable to a rectangular or a trapezoid pulse (Figure 12.30). Alternatively, it can be made of an elastic material, which produces at the material entry a shock with a near half-sine waveform.

After determination of the shock environment, a statistical analysis allows one to specify the design drop height, with a given percentage of loss tolerated.

To choose the characteristics of the cushioning material constituting the package, it is first of all necessary to determine the shock fragility of the product that would be subjected to a shock with one of these two forms.

It can be considered that the severity of a shock is related to its amplitude and to its associated velocity change (we saw that these two parameters intervene in the SRS). We thus determine the largest acceleration and the largest velocity change that the unpackaged product subjected to these shocks can support.

At the time of two series of tests carried out on a shock machine, we note, for a given acceleration, the *critical velocity change* or, for a given velocity change, the *critical maximum shock acceleration* that leads to a damage on the material (deformation, fracture, faulty operation after the shock, etc.).

Results are expressed on a diagram of the acceleration–velocity change by a curve defined as the *damage boundary curve* (DBC; ASTM D3332), as shown in Figure 12.31.

Variable velocity change tests begin with a short-duration shock, then the duration is increased (by preserving constant acceleration) until the appearance of damage (functional or physical). The critical velocity change is equal to the velocity change just lower than that producing damage (ASTM, 1994).

The variable acceleration tests are performed on a new material, starting with a small acceleration level and with a rather large velocity change (at least 1.5 times the critical velocity change previously determined).

The tests should be carried out in the more penalizing impact configuration (unit orientation).

12.7.2 Analysis of Test Results

Damage can occur if the acceleration and the velocity change are together higher than the critical acceleration and the critical velocity change.

From the critical velocity change, the critical drop height can be calculated. If V_i is the impact velocity, V_R is the rebound velocity, and α is the

FIGURE 12.31 Damage boundary curve (rectangular shock pulse).

rate of rebound ($V_R = -\alpha V_i$), the velocity change ΔV is equal to

$$\begin{aligned}\Delta V &= V_R - V_i = -(V_i + \alpha V_i) \\ &= -(1 + \alpha)V_i\end{aligned}\quad (12.17)$$

and the free-fall drop height H_{cr} to

$$H_{cr} = \frac{V_i^2}{2g} = \frac{\Delta V^2}{2g(1 + \alpha)^2} \quad (12.18)$$

If this critical height is lower than the design height defined from the real use conditions of the product, it is necessary to use a package with a medium cushioning and then to define its characteristics (crush stress, thickness) so that maximum acceleration at the time of impact is lower than the critical acceleration. If not, no protection is necessary.

Tests are in general carried out with a rectangular shock waveform, for two reasons.

- As the rectangular shock is most severe (see SRSs), the result is conservative, as seen in Figure 12.32.
- The DBC is made up only of two lines, which makes it possible to determine the curve from only two set of tests (saving time) by destroying only two specimens. A much more significant number of sets of tests would be necessary to determine the curve from a half-sine shock waveform.

Note: If, for cost reasons, the same product is used to determine the critical velocity change or the critical acceleration, it undergoes several shocks before failure. The test result is usable only if the product fails in a brittle mode. If the material is ductile, each shock damages the product by an effect of fatigue, which should be taken into account (Burgess, 1996, 2000).

FIGURE 12.32 DBC comparison of half-sine and rectangular shock pulses.

12.8 Shock Machines

12.8.1 Main Types

A shock machine, whatever its standard, is primarily a device allowing modification over a short time period of the velocity of the material to be tested (also, see Chapter 15). Two principal categories are usually distinguished (Lalanne, 2002b):

- The first category is that of *impulse* machines, which increase the velocity of the test item during the shock. The initial velocity is in general zero. The air gun, which creates the shock during the setting of the velocity in the tube, is an example.
- The second category is that of *impact* machines, which decrease the velocity of the test item throughout the shock and/or which change its direction.

The test facilities now used are classified as follows:

- In free fall machines, the impact is made on a shock simulator (in American literature these devices are termed “shock programmers”) adapted to the shape of the specified shock (elastomer discs, conical or cylindrical lead pellets, pneumatic shock simulators, etc.). To increase the impact velocity, which is limited by the drop height, that is, by the height of the guide columns, the fall can be accelerated by the use of bungee cords.
- In pneumatic machines, the velocity is derived from a pneumatic actuator.
- In electrodynamic exciters, the shock is specified either by the shape of a temporal signal, its amplitude and its duration, or by a SRS.

- Exotic machines are designed to carry out shocks that are nonrealizable by the preceding methods, generally because their amplitude and duration characteristics are not compatible with the performances from these means. The desired shapes, not being normal, are not possible with the shock simulators delivered by the manufacturers.

We will try to show in the following sections how mechanical shocks could be simulated on materials in the laboratory. The facilities described are the most current, but the list is far from being exhaustive. Many other processes were or are still used to satisfy particular needs (Nelson and Prasthofer, 1974; Powers, 1974, 1976; Conway et al., 1976).

12.8.2 Impact Shock Machines

Most machines with free or accelerated drop testing belong to the category of impact shock machines. The machine itself allows the setting of velocity of the test item.

The shock is carried out by impact, with the help of the shock simulator (programmer), which formats the acceleration of braking according to the desired shape. The impact can be without rebound when the velocity is zero at the end of the shock, or with rebound when the velocity changes sign during the movement. Laboratory machines of this type consist of two vertical guide rods on which the table carrying the test item slides (Figure 12.33).

The impact velocity is obtained by gravity, after the dropping of the table from a certain height or using bungee cords allowing one to obtain a larger impact velocity.

Let us consider a free fall shock machine for which the friction of the shock table on the guidance system can be neglected. The necessary drop height, H , to obtain the desired impact velocity, v_i , is given by

$$H = \frac{v_i^2}{2g} \quad (12.19)$$

where g is the acceleration of gravity (9.81 m/sec^2).

These machines are limited by the possible drop height, that is, by the height of the columns and the height of the test item when the machine is provided with a gantry. It is difficult to increase the height of the machine due to overcrowding and problems with guiding the table.

However, the impact velocity can be increased using a force complementary to gravity by means of bungee cords tended before the test and exerting a force generally directed downwards. The acceleration produced by the cords is in general much higher than gravity, which then becomes negligible. This idea was used to design horizontal (Lonborg, 1963) and vertical machines (Marshall et al., 1965; La Verne Root and Bohs, 1969), this last configuration being less cumbersome.

During impact, the velocity of the table changes quickly and forces of great amplitude appear between the table and machine bases. To generate a shock of a given shape, it is necessary to control the amplitude of the force throughout the stroke during its velocity change. This is carried out using a shock simulator (programmer).

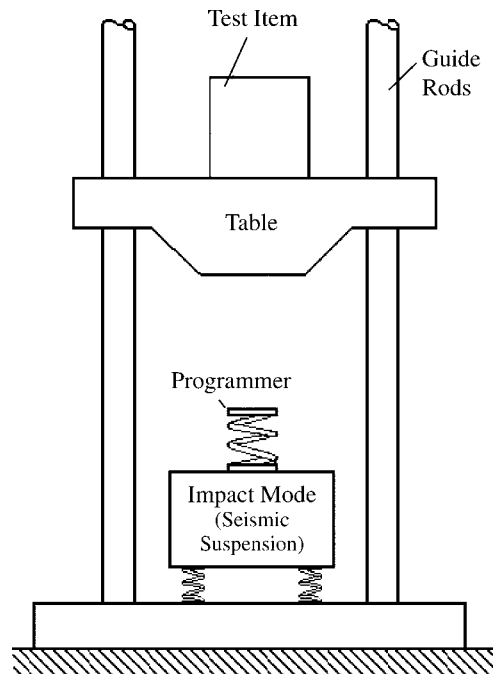

FIGURE 12.33 Elements of a shock-test machine. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.8.2.1 Universal Shock-Test Machines

12.8.2.1.1 Impact Mode

As an example, the MRL[®] Company (Monterey Research Laboratory) has marketed a machine allowing the carrying out of shocks according to two modes: impulse and impact (Bresk and Beal, 1966). In the two test configurations, the test item is installed on the upper face of the table. The table is guided by two rods that are fixed at a vertical frame.

To carry out a test according to the impact mode (the general case), one raises the table by the height required by means of a hoist attached to the top of the frame, using the intermediary assembly for raising and dropping (see Figure 12.34). By opening the blocking system in a high position, the table falls under the effect of gravity or owing to the relaxation of elastic cords if the fall is accelerated. After rebound, as seen on the shock simulator (programmer), the table is again blocked to avoid a second impact.

12.8.2.1.2 Impulse Mode

The impulse mode shocks (see Figure 12.35) are obtained while placing the table on the piston of the shock simulator (used for the realization of initial peak sawtooth shock pulses). The piston of this hydropneumatic shock simulator (programmer) propels the table upward according to an appropriate force profile to produce the specified acceleration signal. The table is stopped in its stroke to prevent its falling down for a second time on the shock simulator (programmer).

12.8.3 Shock Simulators (Programmiers)

We will describe only the most frequently used shock simulators to carry out half-sine, TPS and trapezoid shock pulses.

12.8.3.1 Half-Sine Pulse

These shocks are obtained using an elastic material interposed between the table and the solid mass reaction.

12.8.3.1.1 Shock Duration

The shock duration is calculated by supposing that the table and the shock simulator (programmer), for this length of time, constitute a linear mass–spring system with only one DoF. From the differential equation of the movement (valid only during the elastomeric material compression and its relaxation, so long as there is contact between the table and the shock simulator, i.e., during a half-period)

$$m \frac{d^2x}{dt^2} + kx = 0 \quad (12.20)$$

FIGURE 12.34 MRL universal shock-test machine (impact mode). (Source: Lalanne, *Chocs Mécaniques*, Hermes Science Publications. With permission.)

the shock duration τ can be deduced:

$$\tau = \pi \sqrt{\frac{m}{k}} \quad (12.21)$$

where m is the mass of the moving assembly (table + fixture + test item) and k is the stiffness constant of the shock simulator (programmer).

This expression shows that, theoretically, the duration can be regarded as a function alone of the mass, m , and of the stiffness of the target. It is, in particular, independent of the impact velocity. The mass, m , and the duration, τ , being known, we deduce from it the stiffness constant, k , of the target:

$$k = m \frac{\pi^2}{\tau^2} \quad (12.22)$$

12.8.3.1.2 Impact Velocity

Let us set v_i as the impact velocity of the table and v_R as the velocity of rebound. The elastomeric shock simulators often have a coefficient of restitution, α ($v_R = -\alpha v_i$), of about 50%. In a first approximation, we will consider that the rebound is perfect ($\alpha = 1$). The impact velocity is then equal to $\Delta V/2$, where ΔV is the velocity change given by Table 12.1:

$$\Delta V = \frac{2}{\pi} \ddot{x}_m \tau$$

12.8.3.1.3 Maximum Deformation of the Shock Simulator (Programmer)

If x_m is the maximum deformation of the shock simulator (programmer) during the shock, it becomes, by equalizing the kinetic loss of energy and the deformation energy during the compression of the shock simulator (programmer)

$$\frac{1}{2} m v_i^2 = \frac{1}{2} k x_m^2 \quad (12.23)$$

yielding

$$x_m = v_i \sqrt{\frac{m}{k}} \quad (12.24)$$

12.8.3.1.4 Shock Amplitude

From Equation 12.20, one has, in absolute terms, $m \ddot{x}_m = k x_m$, yielding $\ddot{x}_m = x_m (k/m)$ and, according to Equation 12.24

$$\ddot{x}_m = v_i \sqrt{\frac{k}{m}} \quad (12.25)$$

FIGURE 12.35 MRL universal shock-test machine (impulse mode). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

where the impact velocity, v_i is equal to

$$v_i = \sqrt{2gH} \quad (12.26)$$

where g is the acceleration of gravity ($1g = 9.81 \text{ m/sec}^2$) and H is the drop height.

This relation, established theoretically for perfect rebound, remains usable in practice as long as the rebound velocity remains higher than approximately 50% of the impact velocity. Having determined k from m and τ , it is enough to act on the impact velocity, that is, on the drop height, to obtain the required shock amplitude.

12.8.3.1.5 Characteristics of the Target

For a cylindrical shock simulator (programmer), we have

$$k = \frac{ES}{L} \quad (12.27)$$

where S and L are, respectively, the cross section and the height of the shock simulator (programmer) and where E is Young's modulus of material in compression.

Depending on the materials available, that is the possible values of E , one chooses the values of L and S that lead to a realizable shock simulator (by avoiding too large a height-to-diameter ratio to eliminate the risks from buckling). When the table has a large surface, it is possible to place four shock simulators to distribute the effort. The cross section of each shock simulator (programmer) is then calculated starting from the value of S determined above and divided by four.

If the surface of impact is planar, a wave created at the time of the impact is propagated in the cylinder and makes several up and down excursions (Figure 12.36). From it, at the beginning of the signal the appearance of a high frequency oscillation that distorts the desired half-sine pulse results.

To avoid this phenomenon, the front face of the shock simulator (programmer) is designed to be slightly conical (Figure 12.37) in order to insert the load material gradually (open module). The shock thus created is between a half-sine and a versed-sine pulse. In addition, a good empirical rule is to limit the maximum dynamic deformation of the shock simulator (programmer) from 10 to 15% of its initial thickness to avoid distortion of the half-sine due to damping of the material. If this limit is exceeded, the shape obtained risks nonlinear tendencies.

Example

Consider the realization of a half-sine shock 340 m/sec^2 , 9 msec. It is supposed that the mass of the moving assembly (table + fixture + test item) is equal to 470 kg (test item + fixture mass: 150 kg). From Equation 12.22

$$k = m \frac{\pi^2}{\tau^2} = 470 \frac{\pi^2}{(0.009)^2} \approx 5.727 \times 10^7 \text{ N/m}$$

FIGURE 12.36 High frequencies at impact. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.37 Impact module with conical impact face (open module). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

The impact velocity is calculated from Equation 12.25:

$$v_i = \ddot{x}_m \sqrt{\frac{m}{k}} = \ddot{x}_m \frac{\tau}{\pi} = 340 \frac{0.009}{\pi} \approx 0.974 \text{ m/sec}$$

which leads to the drop height, $H = (v_i^2/2g) \approx 48 \times 10^{-3} \text{ m}$. During the impact, the elastomeric target will be deformed to a height equal to Equation 12.24:

$$x_m = v_i \sqrt{\frac{m}{k}} = \ddot{x}_m \left(\frac{\tau}{\pi} \right)^2 = 300 \left(\frac{0.009}{\pi} \right)^2 \approx 2.79 \times 10^{-3} \text{ m}$$

The velocity change during the shock is equal to $\Delta V = (2/\pi)\ddot{x}_m\tau = (2/\pi)340 \times 0.009 \approx 1.91 \text{ m/sec}$. It is checked that $\Delta V = 2v_i$.

With L being the height of the target, its diameter D is calculated from $k = ES/L$:

$$D^2 = \frac{4}{\pi} \frac{k}{E} L$$

If the target is an elastomer of Young's modulus, $E = 5 \times 10^7 \text{ N/m}^2$ yielding, if $L = 0.015 \text{ m}$, $D \approx 0.148 \text{ m}$. It remains to check that the stress in the material does not exceed the acceptable value.

The manufacturers provide cylindrical modules made up of an elastomer sandwiched between two metal plates. The shock simulator (programmer) is composed of stacked modules of various stiffnesses (Figure 12.38). A relatively low number of different modules allows the covering of a broad range of shock durations by combinations of these elements (Brooks, 1966; Brooks and Mathews, 1966; Gray, 1966; Bresk, 1967).

The modules are in general distributed between the bottom of the table and the top of the solid mass of reaction to regularly distribute the load at the time of the shock in the lower part of the table. One thus avoids exciting its bending mode at lower frequency and amplifying the vibrations due to resonance of the table.

The shock simulators for very short duration shock are made up of a high strength and high Young's modulus thermoplastic material. The selected plastic is highly resilient and very hard. It is used within its yield stress and can thus be useful almost indefinitely. Reproducibility is very good.

The shock simulator (programmer) is composed of a cylinder of this material attached to a planar circular plate screwed to the lower part of the table of the shock machine.

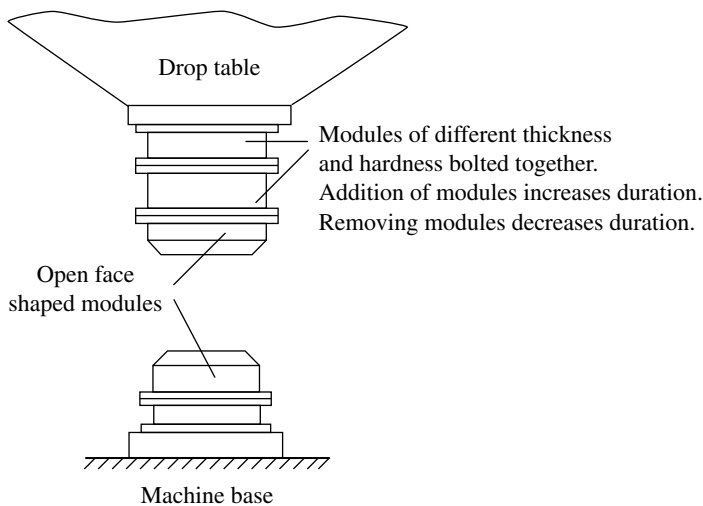

FIGURE 12.38 Distribution of the modules (half-sine shock pulse). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.8.3.2 Terminal Peak Sawtooth Shock Pulse

To generate a TPS shock pulse, any target made up of an inelastic material (crushable material) with a curve dynamic deflection-load which follows a cubic law is thus appropriate (McWhirter, 1961). This curve is approximated by using shock simulators of conical shape.

The material generally used is lead or honeycomb. The cones can be calculated as follows:

- Crushed length:

$$x_m = \frac{\ddot{x}_m \tau^2}{3} \quad (12.28)$$

yielding the height of the cone, $h > 1.2 x_m$ (to allow material to become deformed to the necessary height).

- Force maximum:

$$F_m = S_m \sigma_{cr} = m \ddot{x}_m \quad (12.29)$$

where S_m is the cross section of the cone at height x_m and σ_{cr} is the crush stress of material constituting the target yielding:

$$S_m = \frac{m \ddot{x}_m}{\sigma_{cr}} \quad (12.30)$$

When all the kinetic energy of the table is dissipated by the crushing of the lead, acceleration decreases to zero. The shock machine must have a very rigid solid mass of reaction, so that the time of decay to zero is not too long and satisfies the specification. The speed of this decay to zero is a function of the mass of reaction and of the mass of the table: if the solid mass of reaction has a nonnegligible elasticity, the time, already nonzero because of the imperfections inherent in the shock simulator (programmer), can become too long and unacceptable.

For lead, the order of magnitude of σ_{cr} is 760 kg/cm^2 ($7.6 \times 10^7 \text{ N/m}^2 = 76 \text{ MPa}$). The range of possible durations lies between approximately 2 and 20 msec.

For each machine and each shock, it is necessary to carry out preliminary tests to check that the shock simulator (programmer) is well calculated. The shock simulators are destroyed with each test. It is thus a relatively expensive method. One prefers to use, if possible, a *Universal Programmer* (Section 12.8.3.4).

Example

TPS shock pulse, 340 m/sec^2 , 9 msec (example of Section 12.5.2.5)

Unit table mass: 320 kg

Fixture + test item mass: 150 kg

Conical lead shock simulator ($\sigma_{cr} = 760 \text{ kg/cm}^2 = 7.6 \times 10^7 \text{ N/m}^2$)

The impact velocity is calculated from Table 12.1:

$$\Delta V = v_i = \frac{\ddot{x}_m \tau}{2} = \frac{340 \times 0.009}{2} \approx 1.53 \text{ m/sec}$$

which leads to the theoretical drop height $H = (v_i^2/2g) \approx 0.119 \text{ m}$. During the impact, the target will be deformed to a height equal to Equation 12.28:

$$x_m = \frac{\ddot{x}_m \tau^2}{3} = \frac{340 \times 0.009^2}{3} \approx 9.18 \times 10^{-3} \text{ m}$$

yielding the height of the target $h \geq 1.2 x_m \approx 1.2 \times 9.18 \times 10^{-3} \approx 0.011 \text{ m}$.

The cross section of the cone at height x_m is equal to Equation 12.30

$$S_m = \frac{m\ddot{x}_m}{\sigma_{cr}} = \frac{470 \times 340}{7.6 \times 10^7} \approx 2.1 \times 10^{-3} \text{ m}^2$$

corresponding to a diameter (at height x_m) $D \approx 0.052 \text{ m}$.

12.8.3.3 Rectangular Pulse – Trapezoidal Pulse

This test is carried out by impact. A cylindrical shock simulator (programmer) consists of a material which is crushed with constant force (lead, honeycomb) or using the Universal Shock simulator (programmer). In the first case, the characteristics of the shock simulator (programmer) can be calculated as follows:

- The cross section is given according to the shock amplitude to be realized using the relation

$$F_m = m\ddot{x}_m = S\sigma_{cr} \quad (12.31)$$

yielding

$$S = \frac{m\ddot{x}_m}{\sigma_{cr}} \quad (12.32)$$

- Starting from the dynamics of the impact without rebound, the length of crushing is equal to

$$x_m = \frac{\ddot{x}_m \tau^2}{2} \quad (12.33)$$

and that of the shock simulator (programmer) must be at least equal to $1.4x_m$ in order to allow a correct crushing of the matter with constant force.

The shock amplitude is controlled by the cross section of the shock simulator (programmer), the crush stress of material, and the mass of the total carriage mass. The duration is affected only by the impact velocity.

This method produces relatively disturbed signals, because of the impact between two plane surfaces. They are adapted only for shocks of short duration, because of the limits of deformation. A long duration requires a plastic deformation over a big length, but it is difficult to maintain the constant force of resistance on such a stroke. The honeycombs lend themselves better to the realization of a long duration shock (Gray, 1966).

Example

Rectangular shock pulse, 340 m/sec², 9 msec

Unit table mass: 320 kg

Fixture + test item mass: 150 kg

Cylindrical lead shock simulator ($\sigma_{cr} = 760 \text{ kg/cm}^2 = 7.6 \times 10^7 \text{ N/m}^2$)

The impact velocity is calculated from Table 12.1:

$$\Delta V = v_i = \ddot{x}_m \tau = 340 \times 0.009 = 3.06 \text{ m/sec}$$

which leads to the theoretical drop height $H = (v_i^2/2g) \approx 0.477 \text{ m}$. During the impact, the target will be deformed to a height equal to Equation 12.33:

$$x_m = \frac{\ddot{x}_m \tau^2}{2} = \frac{340 \times 0.009^2}{2} \approx 13.8 \times 10^{-3} \text{ m}$$

yielding the height of the target $h \geq 1.4x_m \approx 1.4 \times 13.8 \times 10^{-3} \approx 0.019 \text{ m}$.

TABLE 12.8 Characteristics of the Target for the Half-Sine, Sawtooth, and Rectangular Pulses

	Half-Sine	TPS	Rectangle
Maximum deformation of the shock simulator (programmer)	$x_m = \frac{\ddot{x}_m \tau^2}{\pi^2}$	$x_m = \frac{\ddot{x}_m \tau^2}{3}$	$x_m = \frac{\ddot{x}_m \tau^2}{2}$
Shock simulator (programmer) cross section at height x_m	$\frac{S}{h} = \frac{\pi^2 m}{E \tau^2}$	$S_m = \frac{m \ddot{x}_m}{\sigma_{cr}}$	$S = \frac{m \ddot{x}_m}{\sigma_{cr}}$
Shock simulator (programmer) height		$h \geq 1.2 \frac{\ddot{x}_m \tau^2}{3}$	$h \geq 1.4 \frac{\ddot{x}_m \tau^2}{2}$
Impact velocity	$v_i = \frac{\ddot{x}_m \tau}{\pi}$	$v_i = \frac{\ddot{x}_m \tau}{2}$	$v_i = \ddot{x}_m \tau$
Free fall height	$H = \frac{v_i^2}{2g}$		

The cross section of the cylinder is equal to Equation 12.32

$$S_m = \frac{m \ddot{x}_m}{\sigma_{cr}} = \frac{470 \times 340}{7.6 \times 10^7} \approx 2.1 \times 10^{-3} \text{ m}^2$$

corresponding to a diameter $D \approx 0.052 \text{ m}$.

Table 12.8 recapitulates the main relations allowing the predimensioning of targets for generating half-sine, sawtooth and rectangular shock pulses.

12.8.3.4 Universal Shock Simulator (Programmer)

MTS^{®1} has manufactured a shock simulator (programmer), known as *Universal*, still used in many laboratories, to produce half-sine, TPS, and trapezoidal shock pulses after various adjustments.

This shock simulator (programmer) consists of a cylinder fixed under the table of the machine, filled with a gas under pressure, and, in the lower part of a piston, a rod and a head (Figure 12.39).

12.8.3.4.1 Generating a Half-Sine Shock Pulse

The chamber is put under sufficient pressure so that, during the shock, the piston cannot move (Figure 12.39). The shock pulse is thus formatted only by the compression of the stacking of elastomeric cylinders (modular shock simulators), placed under the piston head. One is thus brought back to the case of Section 12.8.3.1.

12.8.3.4.2 Generating a Terminal Peak Sawtooth Shock Pulse

The gas pressure (nitrogen) in the cylinder is selected so that, after compression of elastomer during duration, τ , the piston, assembled in the cylinder as indicated in Figure 12.40, is suddenly released for a force corresponding to the required maximum acceleration, \ddot{x}_m .

The pressure that was exerted before separation over the whole area of the piston applies only after separation to one area equal to that of the rod, producing a negligible resistant force.

Acceleration thus passes very quickly from \ddot{x}_m to zero, as shown in Figure 12.41. The rise phase is not perfectly linear, but corresponds rather to an arc of versed-sine (since if the pressure were sufficiently strong, one would obtain a versed-sine by compression of the elastomer alone).

¹Registered trademark of MTS Systems Corporation.

FIGURE 12.39 MTS® *Universal* shock simulator (half-sine and rectangle pulse configuration). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.8.3.4.3 Trapezoidal Shock Pulse

The assembly here is the same as that of the half-sine pulse (Figure 12.39). At the time of the impact, there is:

- Compression of the elastomer until the force exerted on the piston balances the compressive force produced by nitrogen (this phase gives the first part [rise] of the trapezoid).
- Up and down displacement of the piston in the part of the cylinder of smaller diameter, approximately with constant force, since volume varies little (this phase corresponds to the horizontal part of the trapezoid).
- Relaxation of elastomer: decay to zero acceleration.

The rise and decay parts are not perfectly linear for the same reason as in the case of the TPS pulse.

12.8.4 Limitations

12.8.4.1 Limitations of the Shock Machines

The limitations are often represented graphically by straight lines plotted in logarithmic scales, delimiting the domain of realizable shocks (amplitude, duration). The shock machine is

FIGURE 12.40 MTS® Universal shock simulator (TPS pulse configuration). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

limited by (IMPAC 6060F Operating Manual; Figure 12.42):

- The allowable maximum force on the table. To carry out a shock of amplitude \ddot{x}_m , the force generated on the table, given by

$$F = [m_{\text{table}} + m_{\text{programmer}} + m_{\text{fixture}} + m_{\text{test item}}]\ddot{x}_m \tag{12.34}$$

must be lower than or equal to the acceptable maximum force, F_{max} . Knowing the total carriage mass, the relation (Equation 12.34) allows calculation of the possible maximum acceleration under the test conditions

$$(\ddot{x}_m)_{\text{max}} = F_{\text{max}}/[m_{\text{table}} + m_{\text{programmer}} + m_{\text{fixture}} + m_{\text{test item}}] \tag{12.35}$$

FIGURE 12.41 Realization of a TPS shock pulse. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

This limitation is represented on the abacus by a horizontal line constant, \ddot{x}_m .

- This emphasizes maximum free fall height, H , or the maximum impact velocity, that is the velocity change, ΔV of the shock pulse. If v_R is the rebound velocity, equal to a percentage α of the impact velocity, we have

$$\begin{aligned}\Delta V &= v_R - v_i = -(1 + \alpha)v_i \\ &= -(1 + \alpha)\sqrt{2gH} \\ &= \int_0^\tau \ddot{x}(t)dt\end{aligned}\tag{12.36}$$

yielding

$$H = \frac{\Delta V^2}{2g(1 + \alpha)^2}\tag{12.37}$$

where α is a function of the shape of the shock and of the type of shock simulator (programmer) used. In practice, there are losses of energy by friction during the fall and especially in the shock simulator (programmer) during the realization of the shock. Taking account of these losses is difficult to calculate analytically and so one can set:

$$H = \beta \frac{\Delta V^2}{2g}\tag{12.38}$$

where β takes into account at the same time losses of energy and rebound. As an example, the manufacturer of machine IMPAC 60 × 60 (MRL) gives Table 12.9, according to the type of shock simulators (*IMPAC 6060F Operating Manual*).

The limitation related to the drop height can be represented by parallel straight lines on a diagram giving the velocity change, ΔV , as a function of the drop height in logarithmic scales. The velocity change being, for all simple shocks, proportional to the product $\ddot{x}_m \tau$, we have

$$\Delta V = \lambda \ddot{x}_m \tau = \sqrt{2gH/\beta}\tag{12.39}$$

Some typical values for the amplitude × duration product are given in Table 12.10.

On logarithmic scales (\ddot{x}_m, τ), the limitation relating to the velocity change is represented by parallel, inclined straight lines (Figure 12.42).

12.8.4.2 Limitations of Shock Simulators

Elastomeric materials are used to generate shocks of:

- Half-sine shape (or versed-sine with a conical frontal module to avoid the presence of high frequencies).
- TPS and rectangular shapes, in association with a *Universal* shock simulator.

Elastomer shock simulators are limited by the allowable maximum force, a function of Young’s modulus, and their dimensions (Figure 12.42). This limitation is in fact related to the need to maintain the stress lower than the yield stress of the material, so that the target can be regarded as a pure stiffness. The maximum stress, σ_{\max} , developed in the target at the time of the shock can be expressed according to Young’s modulus, E , to the maximum deformation, x_m , and to the thickness, h , of the target according to

$$\sigma_{\max} = E \frac{x_m}{h} \tag{12.40}$$

with, for an impact with perfect rebound, $x_m = \ddot{x}_m \tau^2 / \pi^2$. It is necessary that, if R_e is the elastic ultimate stress

$$\frac{E \ddot{x}_m \tau^2}{h \pi^2} < R_e \tag{12.41}$$

that is

$$h > \frac{E \ddot{x}_m \tau^2}{R_e \pi^2} \tag{12.42}$$

Taking into account the mass of the carriage assembly, this limitation can be transformed into maximum acceleration ($F_m = m \ddot{x}_m$). With four shock simulators used simultaneously, the maximum acceleration is naturally multiplied by four. This limitation is represented on the abacus of Figure 12.42 by the straight lines of greater slope.

The *Universal* shock simulator is limited (*MRL 2680 Operating Manual*):

- By the acceptable maximum force.
- By the stroke of the piston: for each waveform, the displacement during the shock is always proportional to the product $\ddot{x}_m \tau^2$.

This limitation is provided by the manufacturer.

In short, the domain of the realizable shock pulses is limited on this diagram by straight lines representative of the conditions given in Table 12.11.

TABLE 12.11 Summary of Limitations on the Domain of Realizable Shock Pulses

$\ddot{x}_m = \text{constant}$	Acceptable force on the table or on the <i>Universal</i> shock simulator
$\ddot{x}_m \tau = \text{constant}$	Drop height (ΔV)
$\ddot{x}_m \tau^2 = \text{constant}$	Piston stroke of the <i>Universal</i> shock simulator
$\ddot{x}_m \tau^4 = \text{constant}$	Acceptable force for elastomers

12.8.5 Pneumatic Machines

Pneumatic machines in general consist of a cylinder separated into two parts by a plate bored to let pass the rod of a piston located lower down (Figure 12.43). The rod crosses the higher cylinder, comes out of the cylinder, and supports a table receiving the test item.

The surface of the piston subjected to the pressure is different according to whether it is on the higher face or the lower face, as long as it is supported in the higher position on the Teflon^{®2} seat (Thorne, 1964).

Initially, the moving piston, rod, and table rose by filling the lower cylinder (reference pressure). The higher chamber is then inflated to a pressure of approximately five times the reference pressure. When the force exerted on the higher face of the piston exceeds the force induced by the pressure of reference, the piston releases. The useful surface area of the higher face increases quickly and the piston is subjected in a very short time to a significant force exerted towards the bottom. It involves the table, which compresses the shock simulators (elastomers, lead cones, etc.) placed on the top of the body of the jack.

This machine is assembled on four rubber bladders filled with air to uncouple it from the floor of the building. The body of the machine is used as a solid mass of reaction. The interest behind this lies in its performance and its compactness. An industrial pneumatic shock machine is shown in Figure 12.44.

FIGURE 12.43 The principle of pneumatic machines. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.8.6 High Impact Shock Machines

The first machine was developed in 1939 to simulate the effects of underwater explosions (mines) on the equipment onboard military ships. Such explosions, which generally occur at large distances from the ships, create shocks that are propagated in all the structures.

The procedure consisted of specifying the machine to be used, the method of assembly, the adjustment of the machine and so on, and not of a SRS or a simple shape shock.

Two models of machines of this type were built to test lightweight and medium weight equipment.

12.8.6.1 Lightweight High Impact Shock Machine

The lightweight high impact shock machine, the first built, consists of a welded frame of standard steel sections and two hammers, one sliding vertically, the other describing an arc of a circle in a vertical plane, according to a pendular motion (Figure 12.45).

²Registered trademark of E.I. du Pont de Nemours & Company, Inc., Wilmington, DE.

A target plate carrying the test item can be placed to receive one or the other of the hammers. The combination of the two movements and the two positions of the target makes it possible to deliver shocks according to three perpendicular directions without disassembling the test item. Each hammer weighs approximately 200 kg and can fall a maximum height of 1.50 m (Conrad, 1952). The target is a plate of steel of 86 cm × 122 cm × 1.6 cm, reinforced and stiffened on its back face by I-beams.

In each of the three impact positions of the hammer, the target plate is assembled on springs in order to absorb the energy of the hammer with a limited displacement (38 mm to the maximum). Rebound of the hammer is prevented.

Several intermediate standardized plates simulate various conditions of assembly of the equipment on board. These plates are inserted between the target and the equipment tested to provide certain insulation at the time of impact and to restore a shock considered comparable with the real shock.

The mass of the equipment tested on this machine should not exceed 100 kg. For fixed test conditions (direction of impact, equipment mass, intermediate plate), the shape of the shock obtained is not very sensitive to the drop height. The duration of the produced shocks is about 1 msec and the amplitudes range between 5000 and 10,000 m/sec².

12.8.6.2 Medium Weight High Impact Shock Machine

This machine was designed to test equipment whose mass, including the fixture, is less than 2500 kg (Figure 12.46). It consists of a hammer weighing 1360 kg that swings through an arc of a circle at an angle greater than 180° and comes to strike an anvil at its lower face. Under the impact, this anvil, fixed under the table carrying the test item, moves vertically upwards. The movement of this unit is limited to approximately 8 cm at the top and 4 cm at the bottom (Vigness, 1947, 1961a; Conrad, 1951; Lazarus, 1967) by stops that halt it and reverse its movement. The equipment being tested is fixed on the table via a group of steel channel beams (and not directly to the rigid anvil structure), so that the natural frequency of the test item on this support metal structure is about 60 Hz.

FIGURE 12.44 Benchmark® SM 105 pneumatic shock machine. SM 105 and Benchmark are registered trademarks owned by Benchmark Electronics, Hunstville, Inc. (courtesy Benchmark Electronics).

FIGURE 12.45 High impact shock machine for lightweight equipment. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

The shocks obtained are similar to those produced with the machine for light equipment (Lazarus, 1967).

The shocks carried out on all these facilities are not very reproducible and are sensitive to the ageing of the machine and the assembly (the results can differ after dismantling and reassembling the equipment on the machine under identical conditions, in particular at high frequencies; Vigness, 1961b).

These machines can also be used to generate simple shape shocks such as half-sine or TPS pulses (Vigness, 1963), while inserting either an elastic or a plastic material between the hammer and the anvil carrying the test item. One thus obtains durations of about 10 msec at 20 msec for the half-sine pulse and 10 msec for the TPS pulse.

FIGURE 12.46 High impact machine for medium weight equipment. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.8.7 Specific Test Facilities

When the impact velocity of standard machines is insufficient, one can use other means to obtain the desired velocity. For example:

- One can use drop testers, equipped with two vertical (or inclined) guide cables (McWhirter, 1963; Lalanne, 1975). The drop height can reach a few tens of meters. It is wise to make sure that the guidance is correct and, in particular, and that friction is negligible. It is also desirable to measure the impact velocity (using photoelectric cells or any other device).
- One can also use gas guns, which initially use the expansion of a gas (often air) under pressure in a tank to propel a projectile carrying the test item towards a target equipped with a shock simulator fixed at the extremity of a gun on a solid reaction mass (McWhirter, 1961; McWhirter, 1963; Yarnold, 1965; Lazarus, 1967; Lalanne, 1975). One finds the impact mode to be as above. It is necessary that the shock created at the time of the velocity setting in the gun is of low amplitude with regard to the specified shock carried out at the time of the impact. Another operating mode consists of using the phase of the velocity setting to program the specified shock, the projectile then being braked at the end of the gun by a pneumatic device, with a small acceleration with respect to the principal shock. A major disadvantage of guns is related to the difficulty of handling cables instrumentation, which must be wound or unreel in the gun, in order to follow the movement of the projectile.
- Alternatively, one can use inclined-plane impact testers (Vigness, 1961a; Lazarus, 1967). These were especially conceived to simulate shocks undergone during too severe handling operations or in trains. They are made up primarily of a carriage on which the test item is fixed, traveling on an inclined rail and coming to run up against a wooden barrier (Figure 12.47).

FIGURE 12.47 Inclined plane impact tester (CONBUR tester). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

The shape of the shock can be modified by using elastomeric “bumpers” or springs. Tests of this type are often named “CONBUR tests.”

12.9 Generation of Shock Using Shakers

In about the mid-1950s, with the development of electrodynamic exciters for the realization of vibration tests, the need for a realization of shocks on this facility was quickly felt. This simulation on a shaker, when possible, indeed presents a certain number of advantages (Coty and Sannier, 1966).

12.9.1 Principle Behind the Generation of a Simple Shape Signal versus Time

The objective is to carry out on the shaker a shock of simple shape (half-sine, triangle, rectangle, etc.) of given amplitude and duration similar to that made on the classical shock machines. This technique was mainly developed during the years 1955 to 1965 (Wells and Mauer, 1961).

The transfer function between the electric signal of the control applied to the coil and acceleration to the input of the test item is not constant. It is thus necessary to calculate the signal of control according to this transfer function and the signal to be realized.

The process is as follows (Favour et al., 1969; Magne, 1971):

- Measurement of the transfer function of the installation (including the fixture and the test item) using a calibration signal; the measurement of the transfer function of the installation can be made using a calibration signal of the shock type, random vibration or sometimes by fast swept sine (Favour, 1974; Lalanne, 2002a).
- Calculation of the Fourier transform of the signal specified at the input of the test item.
- By division of this transform by the transfer function, calculation of the Fourier transform of the signal of control.
- Calculation of the control signal vs. time by inverse transformation.

In all cases, the procedure consists of measurement and calculation of the signal of control to $-n$ dB (-12 , -9 , -6 , and/or -3). The specified level is applied only after several adjustments on a lower level. These adjustments are necessary because of the sensitivity of the transfer function to the amplitude of the signal (nonlinearities). The development can be carried out using a dummy item representative of the mass of the specimen. However, particularly if the mass of the test specimen is significant (with respect to that of the moving element), it is definitely preferable to use the real test item or a model with dynamic behavior very near to it.

If random vibration is used as the calibration signal, its root-mean-square (rms) value is calculated in order to be lower than the amplitude of the shock (but not too distant in order to avoid the effects of any nonlinearities). This type of signal can result in application to the test item of many substantial peaks of acceleration compared with the shock itself.

12.9.2 Main Advantages

The realization of the shocks on shakers has very interesting advantages:

- Possibility of obtaining very diverse shocks shapes.
- Use of the same means for the tests with vibrations and shocks, without disassembly (saving time) and with the same fixtures (Wells and Mauer, 1961; Hay and Oliva, 1963).
- Possibility of a better simulation of the real environment, in particular by direct reproduction of a signal of measured acceleration (or of a given shock spectrum).
- Better reproducibility than on the traditional shock machines.
- Very easy realization of the test on two directions of an axis.
- No need to use a shock machine.

In practice, however, one is rather quickly limited by the possibilities of the exciters, which therefore do not make it possible to generalize their use for shock simulation.

12.9.3 Pre- and Postshocks

12.9.3.1 Requirements

The velocity change, $\Delta V = \int_0^\tau \ddot{x}(t)dt$ (τ = shock duration), associated with shocks of simple shape (half-sine, rectangle, TPS, etc.) is different from zero. At the end of the shock, the velocity of the table of the shaker must, however, be zero. It is thus necessary to devise a method to satisfy this need.

12.9.3.2 Solutions

One way of bringing back the variation of velocity associated with the shock to zero can be the addition of a negative acceleration to the principal signal so that the area under the pulse has the same value on the

FIGURE 12.48 Possibilities for pre- and postshock positioning. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.49 Kinematics of the movement with preshock alone [1], symmetrical pre and postshocks [2] and postshock alone [3]. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

side of positive accelerations and on the side of negative accelerations (Lalanne, 2002b). Various solutions are possible *a priori* (Figure 12.48):

- A preshock alone.
- A postshock alone.
- Pre- and postshocks, possibly of equal durations.

Preshock alone [1], which requires a less powerful power amplifier, thus seems preferable to postshock alone [3]. The use of symmetrical pre- and postshocks is however better, because of a certain number of additional advantages (Magne and Leguay, 1972; Figure 12.49).

- The final displacement is minimal. If the specified shock is symmetrical (with respect to the vertical line $\pi/2$), this residual displacement is zero (Young, 1964).
- For the same duration, τ , of the specified shock and for the same value of maximum velocity, the possible maximum level of acceleration is twice as big.
- The maximum force is provided at the moment when acceleration is maximum, that is, when the velocity is zero (one will be able to thus have the maximum current). The solution with symmetrical pre- and postshocks requires minimal electric power.

Another parameter is the shape of these pre- and postshocks, the most used shapes being the triangle, the half-sine, and the rectangle (Figure 12.50).

FIGURE 12.50 Shapes of pre- and postshock pulses. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

Owing to discontinuities at the ends of the pulse, the rectangular compensation is seldom satisfactory (Smallwood, 1985). One often prefers a versed-sine applied to the entire signal (Hanning window), which has the advantages of being zero and smoothed at the ends (first zero derivative) and presenting symmetrical pre- and postshocks.

In all the cases, the amplitude of pre- and postshocks must remain small with respect to that of the principal shock (preferably lower than approximately 10%), in order not to deform too much the temporal signal and consequently, the shock spectrum. For a given shape of pre- and postshock, this choice thus imposes the duration.

12.9.3.2.1 Optimized Pre- and Postpulses

Another method was developed (Fandrich, 1981) in order to take into account the tolerances on the shape of the signal allowed by the standards (R.T. Fandrich refers to standard MIL-STD 810 C) and to best use the possibilities of the shaker.

The solution suggested consists of defining the following:

1. One must define a preshock made up of the first two terms of the development in a Fourier series of a rectangular pulse (with coefficients modified after a parametric analysis). The table being in equilibrium in a median position before the test, the objective of this preshock is twofold:
 - To give to a velocity, just before the principal shock, having a value close to one of the two limits of the shaker so that, during the shock, the velocity can use the entire range of variation permitted by the machine.
 - To place, in the same way, the table as close as possible to one of the thrusts so that the moving element can move during the shock in the entire space between the two thrusts (limitation in displacement equal, according to the machines, to 2.54 or 5.08 cm).
2. One must also define a postshock composed of one period of a signal of the shape, $Kt^\gamma \sin(2\pi f_1 t)$, where the constants K , γ , and f_1 are evaluated in order to cancel the acceleration, the velocity, and the displacement at the end of the movement of the table.

The frequency and the exponent are selected in order to respect the ratio of the velocity to the displacement at the end of the principal shock. The amplitude of the postshock is adjusted to obtain the desired velocity change.

Figure 12.51 shows the total signal obtained in the case of a principal shock half-sine 30g, 11 msec. This methodology has been improved to provide a more general solution (Lax, 2001).

Note: The realization of shocks on free or accelerated fall machines imposes *de facto* preshocks and/or postshocks, the existence of which the user is not always aware, but that can modify the shock severity at

FIGURE 12.51 Overall movement in a half-sine shock. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

low frequencies. The movement of shock starts with dropping the table from the necessary height to produce the specified shock and finishes with stopping the table after rebound on the shock simulator (Lalanne, 2002b). The preshock takes place during the fall of the table, the postshock during its rebound (Figure 12.52). These pre- and postshocks modify the SRS low frequency and can lead to an unexpected behavior of material when its natural frequency is low.

FIGURE 12.52 Shock performed. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

12.9.3.3 Incidence on the Shock Response Spectra

Figure 12.53 shows the response, $\omega_0^2 z(t)$, of a one-DoF system ($f_0 = 4$ Hz, $\xi = 0.05$) to a TPS shock (the example of Section 12.5.2.5):

- For $z_0 = \dot{z}_0 = 0$ (conditions of the response spectrum).
- In the case of a shock with impact (free fall).
- In the case of a shock on shaker (half-sine symmetrical pre and postshocks with amplitude equal to 34 m/sec^2).

We observed in this example the differences between the theoretical response at 4 Hz and the responses actually obtained on the shaker and shock machine. According to the test facility used, the shock applied can underest or overtest the material. For the estimate of shock severity, one must take account of the whole of the signal of acceleration.

In Figure 12.54, for $\xi = 0.05$, is the SRS of:

- The nominal shock, calculated under the usual conditions of the spectra ($z_0 = \dot{z}_0 = 0$).
- The realizable shock on shaker, with its pre- and postshocks.
- The realizable shock by impact, taking of account of the fall and rebound phases.

One notes in this example that for:

- $f_0 \leq 6$ Hz, the spectrum of the shock by impact is lower than the nominal spectrum, but higher than the spectrum of the shock on the shaker.
- $6 \text{ Hz} < f_0 < 30$ Hz, the spectrum of the shock on the shaker is much overestimated.
- $f_0 < 30$ Hz, all the spectra are superimposed.

FIGURE 12.53 Influence of the realization mode of a TPS shock on the response of a one-DoF system. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.54 Influence of the realization mode of a TPS shock on the SRS. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

This result appears logical when we remember that the slope of the shock spectrum at the origin is, for zero damping, proportional to the velocity change associated with the shock. The compensation signal, added to bring the velocity change back to zero, thus makes the slope of the spectrum at the origin zero. In addition, the response spectrum of the compensated signal can be larger than the spectrum of the theoretical signal close to the frequency corresponding to the inverse of the duration of the compensation signal. It is thus advisable to make sure that the variations observed are not in a range that includes the resonant frequencies of the test item.

It is necessary to add pre- and/or postshock to the specified shock in order to bring back the velocity of the shaker table to zero at the end of the shock pulse. The use of pre- and postshocks is best. Their amplitude must remain small with respect to that of the principal shock (lower than approximately 10%).

The realization of shocks on free or accelerated fall machines also imposes pre- and postshocks.

These pre- and postshocks lead to differences at low frequency between the spectrum of the specified shock and the spectrum of the shock actually carried out on the test facility.

12.9.4 Limitations of Electrodynamic Shakers

12.9.4.1 Mechanical Limitations

Performances of electrodynamic shakers (see Chapter 15) are limited in the following fields (Miller, 1964; Magne and Leguay, 1972).

- They are limited in terms of the maximum stroke of the coil-table unit (according to the machines being used, 25.4 to 75 mm peak-to-peak). At the time of the realization of a usual simple shock on shaker, the displacement starts from the equilibrium position (rest) of the coil, passes through a maximum, then returns to the initial position. In fact only half of the available stroke is used. For better use of the capacities of the machine, it is possible to shift the rest position from the central value towards one of the extreme values (Figure 12.55; Miller, 1964; McClanahan and Fagan, 1966; Smallwood and Witte, 1972).

FIGURE 12.55 Displacement of the coil of the shaker. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

- The maximum velocity is also limited (Young, 1964): 1.5 to 3 m/sec in sine mode (in shock, one can admit a larger velocity with nontransistorized amplifiers (electronic tubes), because these amplifiers can generally accept a very short overvoltage). During the movement of the moving element in the air-gap of the magnetic coils, there is an electromotive force (emf) produced which is opposed to the voltage supply. The velocity must thus have a value such that this emf is lower than the acceptable maximum output voltage of the amplifier. The velocity must in addition be zero at the end of the shock movement (Smallwood and Witte, 1972; Galef, 1973).
- There is a limit to maximum acceleration, related to the maximum force. McClanahan and Fagan (1965) consider that the realizable maxima shock levels are approximately 20% below the vibratory limit levels in velocity and in displacement. The majority of authors agree that the limits in force are, for the shocks, larger than those indicated by the manufacturer (in sine mode). The determination of the maximum force and the maximum velocity is based, in vibration, on considerations of the fatigue of the shaker mechanical assembly. Since the number of shocks that the shaker will carry out is very much lower than the number of cycles of vibrations that it will undergo during its life, the parameter maximum force can be, for the shock applications, increased considerably.

Another reasoning consists of considering the acceptable maximum force, given by the manufacturer in random vibration mode, expressed by its rms value. Knowing that one can observe random peaks being able to reach 4.5 times this value (limitation of control system), one can admit the same limitation in shock mode. One finds other values in the literature, such as:

- ≤ 4 times the maximum force in sine mode, with the *proviso* of not exceeding 300g on the armature assembly (Hug, 1972).
- > 8 times the maximum force in sine mode in certain cases (very short shocks; 0.4 msec, for example; Gallagher and Adkins, 1966). Dinicola (1964) and Keegan (1973) give a factor of about ten for the shocks of duration lower than 5 msec.

The limits of velocity, displacement, and force are not affected by the mass of the specimen.

12.9.4.1.1 Abacuses

For a given shock and for given pre- and postshocks shapes, the velocity and the displacement can be calculated as a function of time by integration of the expressions of the acceleration, as well as the maximum values of these parameters, in order to compare them with the characteristics of the facilities.

From these data, abacuses can be established allowing quick evaluation of the possibility of realization of a specified shock on a given test facility (characterized by its limits of velocity and

FIGURE 12.56 Abacus of the realization domain of a shock. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

of displacement). These abacuses are made up of straight-line segments on logarithmic scales (Figure 12.56).

- AA' corresponding to the limitation of velocity: the condition $v_m \leq v_L$ (v_L = acceptable maximum velocity on the facility considered) results in a relationship of the form $\ddot{x}_m \tau \leq \text{constant}$ (independent of p , the ratio of the absolute values of the pre- and postshocks amplitude and of the principal shock amplitude).
- CC, DD, and so on, the greater slope corresponding to the limitation in displacement for various values of p ($p = 0.05, 0.10, 0.25, 0.50$, and 1.00).

A particular shock will be thus realizable on the shaker only if the point of coordinates τ, \ddot{x}_m (duration and amplitude of the shock considered) is located under these lines, this useful domain increasing when p increases.

Example

TPS shock pulse, 340 m/sec^2 , 9 msec
 (example of Section 12.5.2.5)
 Unit table mass: 192 kg
 Shaker: 135 kN (maximum velocity:
 1.78 m/sec , maximum stroke: $\pm 12.7 \text{ mm}$; see
 Figure 12.57)
 Test item + fixture mass: 150 kg
 Maximum acceleration without load:
 $(135,000/192) \approx 703 \text{ m/sec}^2$
 Maximum acceleration with test item and
 fixture: $(135,000/(192 + 150)) \approx 395 \text{ m/sec}^2$

The TPS shock pulse (340 m/sec^2 , 9 msec) is realizable on this shaker with $p = 0.05$.

FIGURE 12.57 Shaker 135 kN , $\pm 12.7 \text{ mm}$ — TPS pulse with half-sine symmetrical pre- and postshocks.

The limitation can also be due to:

- The resonance of the moving element (a few thousands Hertz; although it is kept to the maximum by design, the resonance of this element can be excited in the presence of signals with very short rise time).
- The strength of the material (very great accelerations can involve a separation of the coil of the moving component).

Mechanical limitations of electrodynamic shakers for shocks:

- Maximum stroke of the coil-table unit: 25.4 to 75 mm peak-to-peak.
- Maximum acceleration, related to the maximum force: according to the author, ≤ 4 times the maximum force in sine mode, with the *proviso* of not exceeding 300g on the armature assembly, more than eight times the maximum force in sine mode in certain cases (very short shocks; 0.4 msec, for example).
- Maximum velocity: 1.5 to 3 m/sec in sine mode.

12.9.4.2 Electronic Limitations

1. Limitation of the output voltage of the amplifier (Smallwood, 1974), which limits coil velocity.
2. Limitation of the acceptable maximum current in the amplifier, related to the acceptable maximum force (i.e., with acceleration).
3. Limitation of the bandwidth of the amplifier.
4. Limitation in power, which relates to the shock duration (and the maximum displacement) for a given mass.

Current transistor amplifiers make it possible to increase the low frequency bandwidth but do not handle even short over tensions well, and thus are limited in mode shock (Miller, 1964).

12.9.5 The Use of Electrohydraulic Shakers

Shocks are realizable on the electrohydraulic exciters, but with additional stresses.

- Contrary to the case of the electrodynamic shakers, one cannot obtain via these means shocks of amplitude larger than realizable accelerations in the steady mode.
- The hydraulic vibration machines are in addition strongly nonlinear (Favour, 1974).

However, their long stroke, required for long duration shocks, is an advantage.

12.10 Control by a Shock Response Spectrum

12.10.1 Principle

The exciters are actually always controlled by a signal that is a function of time. An acceleration–time signal gives only one SRS. However, there is an infinity of acceleration–time signals with a given spectrum. The general principle thus consists in searching out one of the signals, $\ddot{x}(t)$, having the specified spectrum.

Historically, the simulation of shocks with spectrum control was first carried out using analog and then digital methods (Smallwood and Witte, 1973; Smallwood, 1974).

FIGURE 12.58 Elementary shock (a) and its SRS (b). (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

From the data of selected points on the shock spectrum to be simulated, the calculator of the control system uses an acceleration signal with a very tight spectrum. For that, the calculation software proceeds as follows (Lalanne, 2002b):

- At each frequency, f_0 , of the reference shock spectrum, the software generates an elementary acceleration signal, for example, a decaying sinusoid. Such a signal has the property of having a SRS presenting a peak of the frequency of the sinusoid whose amplitude is a function of the damping of the sinusoid (Figure 12.58). With an identical shock spectrum, this property makes it possible to realize shocks on the shaker that would be unrealizable with a control carried out by a temporal signal of simple shape. For high frequencies, the spectrum of the sinusoid tends roughly towards the amplitude of the signal.
- All the elementary signals are added by possibly introducing a given delay (and variable) between each one of them in order to control to a certain extent the total duration of the shock, which is primarily due to the lower frequency components (Figure 12.59).
- The total signal being thus made up, the software proceeds to processes correcting the amplitudes of each elementary signal so that the spectrum of the total signal converges towards the reference spectrum after some iterations.

FIGURE 12.59 SRS of the components of the required shock. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

The operator must provide to the software with, at each frequency of the reference spectrum:

- The frequency of the spectrum
- Its amplitude
- A delay
- The damping of sinusoids or other parameters characterizing the number of oscillations of the signal

When a satisfactory spectrum time signal has been obtained, it remains to be checked that the maximum velocity and displacement during the shock are within the authorized limits of the test facility (by integration of the acceleration signal). Lastly, after measurement of the transfer function of the facility, one calculates the electric excitation which will make it possible to reproduce on the table the acceleration pulse with the desired spectrum, as in the case of control from a signal according to the time (Powers, 1974).

12.10.2 Principal Shapes of Elementary Signals

12.10.2.1 Decaying Sinusoid

The shocks measured in the field environment are very often responses of structures to an excitation applied upstream, and are thus composed of the superposition of several modal responses of a damped sine type (Smallwood and Witte, 1973; Crimi, 1978; Boissin et al., 1981; Smallwood, 1985). Electrodynamical shakers are completely adapted to the reproduction of this type of signal. According to this, one should be able to reconstitute a given SRS from such signals of the form:

$$\left. \begin{aligned} a(t) &= A e^{-\eta\Omega t} \sin \Omega t & t \geq 0 \\ a(t) &= 0 & t < 0 \end{aligned} \right\} \quad (12.43)$$

where $\Omega = 2\pi f$, f = frequency of the sinusoid, and η = damping factor.

Velocity and displacement are not zero at the end of the shock with this type of signal. These nonzero values are very awkward for a test on a shaker. Compensation can be carried out in several ways:

1. By truncating the total signal until it is realizable on the shaker. This correction can, however, lead to an important degradation of the corresponding spectrum (Smallwood and Witte, 1972).
2. By adding to the total signal (sum of all the elementary signals) a highly damped decaying sinusoid at low frequency, shifted in time, defined to compensate for the velocity and the displacement (Smallwood and Nord, 1974; Smallwood 1975, 1985).
3. By adding to each component two exponential compensation functions, with a phase in the sinusoid (Nelson and Prasthofer, 1974; Smallwood, 1975).

FIGURE 12.60 Shock pulse generated from decaying sinusoids, compensated by a decaying sinusoid. (Source: Lalanne, *Chocs Mécaniques*, Hermes Science Publications. With permission.)

Example

The reference SRS is that of Figure 12.24 (Section 12.5.2.5). Examples of acceleration signals generated from decaying sinusoids and having approximately the same SRS are shown in Figure 12.60 and Figure 12.61 in the cases of a compensation by a decaying sinusoid and by two exponential functions.

12.10.2.2 ZERD Function

The use of a decaying sinusoid with its compensation waveform modifies the response spectrum at the low frequencies and, in certain cases, can harm the quality of simulation. Fisher and Posehn (1977) proposed using a waveform, which they named “ZERD” (Zero Residual Displacement), defined by the expression:

$$a(t) = A e^{-\eta\Omega t} \left[\frac{1}{\Omega} \sin \Omega t - t \cos(\Omega t + \phi) \right] \quad (12.44)$$

where $\phi = \arctan(2\eta/1 - \eta^2)$. This function resembles a damped sinusoid and has the advantage of leading to zero velocity and displacement at the end of the shock (Figure 12.62).

Example

The reference SRS is that of Figure 12.24 (Section 12.5.2.5). Figure 12.63 shows an example of acceleration signal generated from ZERD functions having approximately the same SRS.

12.10.2.3 WAVSIN Waveform

Yang (1970, 1972) and Smallwood (1974, 1975, 1985) proposed (initially for the simulation of the earthquakes) a signal of the form:

$$\left. \begin{aligned} a(t) &= a_m \sin 2\pi b t \sin 2\pi f t & 0 \leq t \leq \tau \\ a(t) &= 0 & \text{elsewhere} \end{aligned} \right\} \quad (12.45)$$

where

$$f = Nb \quad (12.46)$$

$$\tau = \frac{1}{2b} \quad (12.47)$$

FIGURE 12.61 Acceleration signal generated from decaying sinusoids, compensated by two exponential functions. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.62 ZERD waveform of D.K. Fisher and M.R. Posehn (example).

where N is an integer (which must be odd and higher than on 1). The first term of $a(t)$ is a window of half-sine form of half-period τ . The second describes N half-cycles of a sinusoid of greater frequency (f), modulated by the preceding window (Figure 12.64).

This function leads also to zero velocity and displacement at the end of the shock.

Example

Figure 12.65 shows an example of acceleration signal generated from WAVSIN functions having approximately the same SRS as the reference SRS of Figure 12.24 (Section 12.5.2.5).

12.10.3 Comparison of WAVSIN, SHOC Waveforms, and Decaying Sinusoid

The cases treated by Smallwood (1974) seem to show that these three methods give similar results. It is noted, however, in practice, that, according to the shape of the reference spectrum, one or other of these waveforms allows a better convergence. The ZERD waveform very often gives good results.

12.10.4 Criticism of Control by a Shock Response Spectrum

Whatever the method adopted, simulation on a test facility of shocks measured in the real world requires the calculation of their SRSs and the search for an equivalent shock.

If the specification must be presented in the form of a time-dependent shock pulse, the test requester must define the characteristics of shape, duration, and amplitude of the signal, with the already quoted difficulties.

If the specification is given in the form of an SRS, the operator inputs in the control system the given spectrum, but the shaker is always controlled by a signal according to the time calculated and according to procedures described in the preceding sections. It is known that the transformation shock spectrum signal has an infinite number of solutions, and that very different signals can have identical SRSs. This phenomenon is related to the loss of most of the information initially contained in the signal, $\ddot{x}(t)$, during the calculation of the spectrum (Metzgar, 1967).

FIGURE 12.63 Acceleration signal generated from ZERD functions.

FIGURE 12.64 Example of WAVSIN waveform. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

FIGURE 12.65 Acceleration signal generated from WAVSIN functions.

The oscillatory shock pulses have a spectrum that presents an important peak to the frequency of the signal. This peak can, according to choice of parameters, exceed by a factor of five the amplitude of the same spectrum at the high frequencies; that is, five times the amplitude of the signal itself. Being given a point of the specified spectrum of amplitude, S , it is thus enough to have a signal vs. time of amplitude $S/5$ to reproduce the point. For a simple shaped shock, this factor does not exceed two in the most extreme case. All these remarks show that the determination of a signal of the same spectrum can lead to very diverse solutions, the validity of which one can question.

If any particular precaution is not taken, the signals created by these methods have, in a general way, one duration much larger and an amplitude much smaller than the shocks that were used to calculate the reference SRS (a factor of about ten in both cases). Figure 12.66 and Figure 12.67 give an example.

In the face of such differences between the excitations, one can legitimately wonder whether the SRS is a sufficient condition to guarantee a representative test. It is necessary to remember that this equivalence is based on the behavior of a linear system that one chooses the Q factor *a priori*. One must be aware of the following.

FIGURE 12.66 Example of shocks having spectra near the SRS.

FIGURE 12.67 SRS of the shocks shown in Figure 12.66.

- The behavior of the structure is in practice far from linear and that the equivalence of the spectrum does not lead to stresses of the same amplitude. Another effect of these nonlinearities appears sometimes by the inaptitude of the system to correct the drive waveform to take account of the transfer function of the installation.
- Even if the amplitudes of the peaks of acceleration and the maximum stresses of the resonant parts of the tested structure are identical, the damage by the fatigue generated by accumulation of the stress cycles is rather different when the number of shocks to be applied is significant.
- The tests carried out by various laboratories do not have the same severity.

These questions did not receive a really satisfactory response. By prudence rather than by rigorous reasoning, many agree, however, on the need for placing parapets, while trying to supplement the specification defined by a spectrum with complementary data (ΔV , duration of the shock, require SRS at two different values of damping, etc.; Favour, 1974; Smallwood, 1974, 1975, 1985).

There is an infinity of acceleration–time signals with a given spectrum. Several elementary waveforms can be used to build a signal of acceleration having a given SRS. They give similar results.

Without particular precaution, the signals thus obtained generally have one duration much larger and an amplitude much smaller than the shocks which were used to calculate the reference SRS. A complementary parameter (shock duration, velocity change, etc.) is often specified with the SRS to limit this effect.

12.11 Pyrotechnic Shock Simulation

Many works have been published on the characterization, measurement, and simulation of shocks of pyrotechnic origin, generated by bolt cutters, explosive valves, separation nuts, and so on (Zimmerman, 1993). The test facilities suggested are many, ranging from traditional machines to very exotic means.

The tendency today is to consider that the best simulation of shocks measured in near-field can be obtained only by subjecting the material to the shock produced by the real device.

For shocks in the far-field, simulation can be carried out either using the real pyrotechnic source and a particular mechanical assembly, using specific equipment using explosives, or by impacting metal to metal if the structural response is more important. When the real shock is practically made up only of the response of the structures, a simulation on a shaker is possible (when performances by this means are allowed).

12.11.1 Simulation Using Pyrotechnic Facilities

The simplest solution consists of making functional, real pyrotechnic devices on real structures. The simulation is perfect but (Conway et al., 1976; Luhrs, 1976):

- It can be expensive and destructive.
- One cannot apply an uncertainty factor (Lalanne, 2002d) to cover the variability of this shock without being likely to create unrealistic local damage (a larger load, which requires an often expensive modification of the devices and can be much more destructive). To avoid this problem, an expensive solution consists of carrying out several tests in a statistical matter.

One often prefers to carry out a simulation on a reusable assembly, the excitation still being pyrotechnic in nature. Several devices have been designed, some examples of which are as follows:

- A test facility made up of a cylindrical structure (Ikola, 1964), which comprises a “consumable” sleeve cut out for the test by an explosive cord. Preliminary tests are carried out to calibrate the facility while acting on the linear charge of the explosive cord and/or the distance between the equipment to be tested (fixed on the structure as in the real case if possible) and the explosive cord.
- A greater number of small explosive charges near the equipment to be tested on the structure in “flowers pots.” The number of pots to be used on each axis depends on the amplitude of the shock, the size of the equipment, and the local geometry of the structure. The shape of the shock can be modified within certain limits by use of damping devices, placing the pot closer to or further from the equipment, or by putting suitable padding in the pot (Aerospace Systems pyrotechnic shock data, 1970).
- A test facility made up of a basic rectangular steel plate (Figure 12.68) suspended horizontally. This plate receives on its lower part, directly or by the intermediary of an “expendable” item, an explosive load (chalk line, explosive in plate or bread).

FIGURE 12.68 Plate with resonant system subjected to detonation. (Source: Lalanne, *Chocs Mecaniques*, Hermes Science Publications. With permission.)

A second plate supporting the test item rests on the base plate via four elastic supports (Thomas, 1973). The reproducibility of the shocks is better if the explosive charge is not in direct contact with the base plate.

12.11.2 Simulation Using Metal-to-Metal Impact

The shock obtained by a metal-to-metal impact has similar characteristics to those of a pyrotechnical shock in an intermediate field: great amplitude; short duration; high frequency content; SRS comparable with a low frequency slope of 12 dB per octave, etc. The simulation is in general satisfactory up to approximately 10 kHz.

The shock can be created by the impact of a hammer on the structure itself, a Hopkinson bar or a resonant plate (Bai and Thatcher, 1979; Luhrs, 1981; Davie, 1985; Dokainish and Subbaraj, 1989; Davie and Batemen, 1992).

With all these devices, the amplitude of the shock is controlled while acting on the velocity of impact. The frequency components are adjusted by modifying the resonant geometry of system (changing the length of the bar between two points of fixing, adding or removing runners, etc.) or by the addition of a deformable material between the hammer and the anvil.

12.11.3 Simulation Using Electrodynamic Shakers

The limitation relating to the stroke of the electrodynamic shaker is not very constraining for the pyrotechnical shocks since they are at high frequencies. The possibilities are limited especially by the acceptable maximum force and then concern the maximum acceleration of the shock

(Conway et al., 1976; Luhrs, 1976; Powers, 1976; Caruso, 1977). If one agrees to cover only part of the SRS where material has resonant frequencies, then when one makes a possible simulation on the shaker, which gives a better approach to matching the real spectrum.

Exciters have the advantage of allowing the realization of any signal shape such as shocks of simple shapes (Dinicola, 1964; Gallagher and Adkins, 1966), but also of reproducing a specified SRS (direct control from an SRS; see Section 12.10.1).

It is possible, in certain cases, to reproduce the real SRS up to 1000 Hz. If one is sufficiently far away from the source of the shock, the transient has a lower level of acceleration and the only limitation is the bandwidth of the shaker, which is about 2000 Hz. Certain facilities of this type were modified to make it possible to simulate the effects of pyrotechnical shocks up to 4000 Hz. One can thus manage to simulate shocks whose spectrum can reach 7000g (Moening, 1986).

12.11.4 Simulation Using Conventional Shock Machines

We saw that, generally, the method of development of a specification of a shock consists of replacing the transient of the real environment, whose shape is in general complex, with a simple shape shock, such as half-sine, triangle, trapezoid, and so on, starting from the SRS equivalence criterion, with the application of a given or calculated uncertainty factor (Lalanne, 2002d) to the shock amplitude (Luhrs, 1976).

With the examination of the shapes of the response spectra of standard simple shocks, it seems that the signal best adapted is the TPS pulse, whose spectra are also appreciably symmetrical. SRSs of the pyrotechnical shocks with, in general, averages close to zero have a very weak slope at low frequencies. The research of the characteristics of such a triangular pulse (amplitude, duration) having an SRS envelope of that of a pyrotechnical shock led often to a duration of about 1 msec and to an amplitude being able to reach several tens of thousands of msec⁻². Except in the case of very

TABLE 12.12 Advantages and Drawbacks of Various Test Facilities for the Pyroshock Simulation

Shock Facility	Field	Advantages	Drawbacks
Real pyrotechnic devices on real structures	Near	Very good simulation	Expensive, generally destructive, no uncertainty factor/test factor
Reusable assembly with pyrotechnic excitation	Near	Good simulation	Necessity of preliminary tests, no uncertainty factor/test factor, use of explosive (specific conditions to ensure safety), expensive
Metal to metal impact	Near	Good simulation, no explosive charge	Necessity of preliminary tests, limitations in acceleration and frequency (approximately 10 kHz)
Electrodynamic shaker	Far	Easy implementation, control using any time history signal or SRS, possibility of using an uncertainty factor or a test factor	Necessity of one test by axis, maximum frequency up to about 1 to 2 kHz
Conventional shock-test machine	Far	Easy implementation, possibility of using an uncertainty factor or a test factor	Use of a shock pulse with velocity change instead of an oscillatory shock pulse (over test at low frequency), necessity of one test by axis, shock duration higher than 2 msec (0.1 msec using a specific device for very light test item), limitation in amplitude, useable for very small test items only

small test items, it is in general not possible to carry out such shocks on the usual drop tables due to certain limitations:

- Limitation in amplitude (acceptable maximum force on the table).
- Duration limit: the pneumatic shock simulators do not allow it to go below 3 to 4 msec; even with the lead shock simulators, it is difficult to obtain a duration of less than 2 msec and a larger shock duration leads to a significant overttest at low frequency.
- The SRSs of the pyrotechnical shocks are much more sensitive to the choice of damping than simple shocks carried out on shock machines.

A comparison of some pyroshock-test facilities is given in [Table 12.12](#).

Summary

This chapter provides a concise guide to vibration theory, sources of dynamic loading and effects on structures, options for dynamic analyses, and methods of vibration control. Section 13.1 gives an introduction to

different types of dynamic loads. Section 13.2 covers the basic theory underlying earthquake engineering and seismic design. In this section, seismic codes and standards are reviewed including American, British, and European practices. Active and passive control systems for seismic mitigation are also discussed. This section contains analytical and design examples on seismic analysis and building response to earthquakes. Section 13.3 introduces the nature of wind loading, dynamic effects, and the basic principles of wind design. This section includes formulae, charts, graphs, and tables on both static and dynamic approaches for designing structures to resist wind loads. Types of dampers to reduce vibration in tall buildings under wind loads are also introduced. Section 13.4 gives a brief overview of vibration due to fluid–structure interaction. Section 13.5 extensively covers the effects of explosion on structures. An explanation of the nature of explosions and the mechanism of blast waves in free air is given. This section also introduces different methods to estimate blast loads and structural response. Section 13.6 deals with the impact loading. An analytical example of aircraft impact on a building is given. Section 13.7 looks in detail at the problems of floor vibration. Charts and tables are given for designing floor slabs to avoid excessive vibrations. A comprehensive list of references is provided.

13.1 Introduction

The different types of dynamic loading considered in this chapter include: earthquakes, wind, floor vibrations, blast effects, and impact- and wave-induced vibration. The effects of these loadings on different engineering structures are also discussed. It is standard practice to use equivalent static horizontal forces when designing buildings for earthquake and wind resistance. This is the simplest way of obtaining the dimensions of structural members. Dynamic calculations may follow to check, and perhaps modify, the design. However, vibrations caused by extreme loads such as blast and impact must be assessed by methods of dynamical analysis or by experiment.

Some examples of dynamic loading are shown in Figure 13.1. The first (a) is a record of fluctuating wind velocity. Corresponding fluctuating pressures will be applied to the structure. The random nature of the loading is evident, and it is clear that statistical methods are required for establishing an appropriate design loading. The next figure (b) shows a typical earthquake *accelerogram*. As shown, the maximum ground acceleration of the El-Centro earthquake was about 0.33g. The third figure (c) shows the characteristic shape of the air pressure impulse caused by a

FIGURE 13.1 Examples of dynamic loading. (a) Fluctuating wind velocity; (b) earthquake accelerogram; (c) pressure time history for bomb blasts.

bomb blast. The shapes of air-blast curves are usually quite similar, having an initial peak followed by an almost linear decay and often followed by some suction. The duration of the impulsive loads and their amplitudes depend on many factors, for example, distance from blast and charge weight.

Vibration of structures is undesirable for a number of reasons, as follows:

1. Overstressing and collapse of structures
2. Cracking and other damage requiring repair
3. Damage to safety-related equipment
4. Impaired performance of equipment or delicate apparatus
5. Adverse human response

With modern forms of construction, it is feasible to design structures to resist the forces arising from dynamic loadings such as major earthquakes. The essential requirement is to prevent total collapse and consequent loss of life. For economic reasons, however, it is the accepted practice to absorb the earthquake energy by ductile deformation, therefore accepting that repair might be required.

Some forms of loading are quite well defined and may be quantified by observation or experiment. Many forms of loading are not at all well defined and require judgment on the part of the engineer. London's Millennium Bridge, which is a 350-m pedestrian bridge, opened in June 2000. However, local authorities shut it down after two days due to vibration problems. Engineers found that the "synchronous lateral excitation" caused the problem and fitted 91 dampers to reduce the excessive movement. In January 2001, a 2000-strong crowd marched across the bridge to check the performance of the structure before it was reopened to the public.

Data on certain types of dynamic loading, such as earthquakes and wind, are readily available in many design codes. Other types of loading are less well covered, though much data may be available in published research papers. One of the aims of this chapter is to discuss the nature of the most important types of dynamic loading and to direct the reader to relevant literature for further information.

13.2 Earthquake-Induced Vibration of Structures

13.2.1 Seismicity and Ground Motions

The most common cause of earthquakes is thought to be the violent slipping of rock masses along major geological fault lines in the Earth's crust, or lithosphere. These fault lines divide the global crust into about 12 tectonic plates, which are rigid, relatively cool slabs about 100 km thick. Tectonic plates float on the molten mantle of the Earth and move relative to one another at the rate of 10 to 100 mm/year.

The basic mechanism causing earthquakes in the plate boundary regions appears to be that the continuing deformation of the crustal structure eventually leads to stresses/strains which exceed the material strength. A rupture will then initiate at some critical point along the fault line and will propagate rapidly through the highly stressed material at the plate boundary. In some cases, the plate margins are moving away from one another. In those cases, molten rock appears from deep in the Earth to fill the gap, often manifesting itself as volcanoes. If the plates are pushing together, one plate tends to dive under the other and, depending on the density of the material, it may resurface in the form of volcanoes. In both these scenarios, there may be volcanoes and earthquakes at the plate boundaries, both being caused by the same mechanism of movement in the Earth's crust. Another possibility is that the plate boundaries will slide sideways past each other, essentially retaining the local surface area of the plate. It is believed that approximately three quarters of the world's earthquakes are accounted for by this rubbing–sticking–slipping mechanism, with ruptures occurring on faults on boundaries between tectonic plates.

Earthquake occurrence maps tend to outline the plate boundaries. Such earthquakes are referred to as interplate earthquakes.

Earthquakes do occur at locations away from the plate boundaries. Such events are known as intraplate earthquakes and they are much less frequent than interplate earthquakes. They are also much less predictable than events at the plate margins and they have been observed to be far more severe. For example, the Eastern United States, which is located well away from the tectonic plate boundaries of California, has recorded the largest earthquakes in the history of European settlement in the country. These major intraplate earthquakes occurred in the middle of last century in South Carolina on the East Coast and Missouri in the interior. However, because of the low population density at the time, the damage caused was minimal. It is significant to note, however, that these intraplate earthquakes, although very infrequent, were considerably larger than the moderately sized interplate earthquakes that frequently occur along the plate boundaries in California. (It is thought that, because tectonic plates are not homogeneous or isotropic, areas of local high stress are developed as the plate attempts to move as a rigid body. Accordingly, rupture within the plate, and the consequent release of energy, are believed to give rise to these intraplate events.)

The point in the Earth's crustal system where an earthquake is initiated (the point of rupture) is called the hypocenter or focus of the earthquake. The point on the Earth's surface directly above the focus is called the epicenter and the depth of the focus is the focal depth. Earthquake-occurrence maps usually indicate the location of various epicenters of past earthquakes and these epicenters are located by seismological analysis of the effect of earthquake waves on strategically located receiving instruments called seismometers.

When an earthquake occurs, several types of seismic wave are radiated from the rupture. The most important of these are the body waves (primary (P) and secondary (S) waves). P waves are essentially sound waves traveling through the Earth, causing particles to move in the direction of wave propagation with alternate expansions and compressions. They tend to travel through the Earth with velocities of up to 8000 m/sec (up to 30 times faster than sound waves through air). S waves are shear waves with particle motion transverse to the direction of propagation. S waves tend to travel at about 60% of the velocity of P waves, so they always arrive at seismometers after the P waves. The time lag between arrivals often provides seismologists with useful information about the distance of the epicenter from the recorder.

The total strain energy released during an earthquake is known as the magnitude of the earthquake and it is measured on the Richter scale. It is defined quite simply as the amplitude of the recorded vibrations on a particular kind of seismometer located at a particular distance from the epicenter. The magnitude of an earthquake by itself, which reflects the size of an earthquake at its source, is not sufficient to indicate whether structural damage can be expected at a particular site. The distance of the structure from the source has an equally important effect on the response of a structure, as do the local ground conditions. The local intensity of a particular earthquake is measured on the subjective Modified Mercalli scale (Table 13.1) which ranges from 1 (barely felt) to 12 (total destruction). The Modified Mercalli scale is essentially a means by which damage may be assessed after an earthquake. In a given location, where there has been some experience of the damaging effects of earthquakes, albeit only subjective and qualitative, regions of varying seismic risk may be identified. The Modified Mercalli scale is sometimes used to assist in the delineation of these regions. A particular earthquake will be associated with a range of local intensities, which generally diminish with distance from the source, although anomalies due to local soil and geological conditions are quite common.

Modern seismometers (or seismographs) are sophisticated instruments utilizing, in part, electromagnetic principles. These instruments can provide digitized or graphical records of earthquake-induced accelerations in both the horizontal and vertical directions at a particular site. Accelerometers provide records of earthquake accelerations and the records may be appropriately integrated to provide velocity records and displacement records. Peak accelerations, velocities, and displacements are all in turn significant for structures of differing stiffness (Figure 13.2).

TABLE 13.1 Modified Mercalli Intensity Scale

- I. Not felt except by a very few under especially favorable circumstances
- II. Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing
- III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motor cars may rock slightly. Vibration like passing truck. Duration estimated
- IV. During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, and doors disturbed; walls make creaking sound. Sensation like heavy truck striking building. Standing motorcars rock noticeably
- V. Felt by nearly everyone; many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop
- VI. Felt by all; many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight
- VII. Everybody runs outdoors. Damage negligible in buildings of good design and construction, slight to moderate in well-built ordinary structures; considerable in poorly built or badly designed structures. Some chimneys broken. Noticed by persons driving motor cars
- VIII. Damage slight in specially designed structures; considerable in ordinary substantial buildings, with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motorcars disturbed
- IX. Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken
- X. Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from riverbanks and steep slopes. Shifted sand and mud. Water splashed over banks
- XI. Few, if any (masonry), structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly
- XII. Damage total. Waves seen on ground surfaces. Lines of sight and level distorted. Objects thrown upward into the air

13.2.2 Influence of Local Site Conditions

Local geological and soil conditions may have a significant influence on the amplitude and frequency content of ground motions. These conditions affect the earthquake motions experienced (and hence the structural response) in one, or more, of the following ways:

- Interaction between the bedrock earthquake motion and the soil column will modify the actual ground accelerations input to the structure. This manifests itself by an increase in the amplitude of the ground motion over and above that at the bedrock, and a filtering of the motion so that the range of frequencies present becomes narrow with the high-frequency components being eliminated. This condition particularly arises in areas where soft sediments and alluvial soil overly bedrock. The degree of amplification is dependent on the strength of shaking at the bedrock. Because of nonlinear effects in the soil, the amplification ratio is less in strong shaking than under base motions of lower amplitude.
- The soil properties in the proximity of the structure contribute significantly to the effective stiffness of the structural foundation. This may be a significant parameter in determining the overall structural response, especially for structures that would be characterized as stiff under other environmental loadings.
- The strength (and response) of the local soil under earthquake shaking may be critical to the overall stability of the structure.

It is also important that information on relevant geological features, such as faulting, be assessed. Geological information on suspected active faults near the site can assist in providing a basis for

FIGURE 13.2 El-Centro earthquake, north-south component. (A) Record of the ground acceleration; (B) ground velocity, obtained by integration of (A); (C) ground displacement, obtained by integration of (B).

evaluating the intensity of a likely earthquake. It is usual to use this information, together with the regional seismicity data, to determine the likely level of seismic activity.

13.2.3 Response of Structures to Ground Motions

The effect of ground motion on the various categories of structures is dictated almost entirely by the distribution of mass and stiffness in the structure. It is important to appreciate that, in an earthquake, loads are not applied to the structure. Rather, earthquake loading arises because of accelerations generated by the foundation level(s) of the structure intercepting and being influenced by transient ground motions. Specifically, the product of the structural mass and the total acceleration produces the inertia loading experienced by the structure. This is an expression of Newton's Second Law. It is important to appreciate that the total acceleration is the absolute acceleration of the structure, namely, the sum of the ground acceleration and that of the structure relative to the ground.

If the structure is stiff there is little, if any, additional acceleration relative to the ground motion and, therefore, the earthquake loading experienced is essentially proportional to the building mass, that is, $F_{eq} \propto M$.

For structures that are flexible, for example, those in the high-rise or long-span category, the absolute acceleration is low. This occurs because the ground acceleration and the acceleration of the building relative to the ground tend to oppose one another. In this case, the earthquake loading is approximately proportional to the square root of the mass, that is $F_{eq} \propto M^{0.5}$.

For structures in the cantilever category, which are essentially vertical, it is the horizontal accelerations that are significant; whereas for structures that are largely horizontal in extent, the effect of the vertical accelerations is dominant. Moreover, if the plan distributions of mass and stiffness are dissimilar in vertical structures, significant twisting motions may arise.

The peak ground acceleration is of importance in the response of stiff structures and peak ground displacements are of importance in the response of flexible structures, with peak ground velocity being of importance for structures of intermediate stiffness. Stiff structures tend to move in unison with the ground while flexible structures, such as high-rise buildings, experience the ground moving beneath them, their upper floors tending to remain motionless.

13.2.4 Dynamic Analysis

13.2.4.1 Equations of Motion for Linear Single-Degree-of-Freedom Systems

Consider the linear single-degree-of-freedom (single-DoF) system shown in Figure 13.3 subjected to a time varying ground displacement, $z(t)$. Let the relative displacement of the system to the ground be, $y(t)$; y is then the extension of the spring and dashpot. From the equation of motion, it follows that

$$m(\ddot{y} + \ddot{z}) = -ky - c\dot{y} \quad (13.1)$$

Rearranging Equation 13.1, and replacing m , k , and c by the system's radial frequency ω and damping ratio ξ , gives

$$\ddot{y} + 2\xi\omega\dot{y} + \omega^2y = -\ddot{z} \quad (13.2)$$

Given a description of the input motion, $z(t)$, (for example, from an accelerograph recording), the solution of Equation 13.2 provides a complete time history of the response of a structure with a given natural period and damping ratio, and can also be used to derive maximum responses for constructing a response spectrum (Figure 13.6). Owing to the random nature of earthquake ground motion, numerical solution techniques are needed for Equation 13.2, as described by Clough and Penzien (1993).

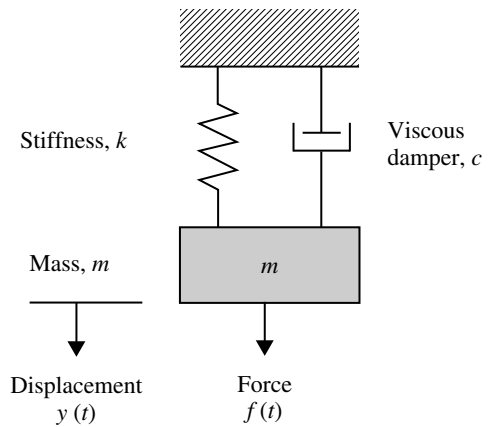

FIGURE 13.3 Single-DoF system.

13.2.4.2 Equations of Motion for Linear Multiple-Degree-of-Freedom Systems

The dynamic response of many linear multiple-degree-of-freedom (multi-DoF) systems can be split into decoupled natural modes of vibration (Figure 13.4), each mode effectively representing a single-DoF system. A modified form of Equation 13.2 then applies to each mode, which for mode i becomes

$$\ddot{Y}_i + 2\xi_i\omega_i\dot{Y}_i + \omega_i^2Y_i = \frac{L_i}{M_i}\ddot{z} \quad (13.3)$$

Here, Y_i is the generalized modal response in the i th mode. (L_i/M_i) is a participation factor, which depends on the mode shape and mass distribution, and describes the participation of the mode in overall response to a particular direction of ground motion. For a two-dimensional (2D) structure with n lumped masses, responding in one horizontal direction

FIGURE 13.4 Typical modes for multistory buildings.

$$\frac{L_i}{M_i} = \frac{\sum_{j=1}^n \phi_{ij}m_j}{\sum_{j=1}^n \phi_{ij}^2m_j} \quad (13.4)$$

In Equation 13.4, ϕ_{ij} , describes the modal displacement of the j th mass in the i th mode. The higher modes often have very low values of (L_i/M_i) , and their contribution can then be omitted. In this way, the computational effort is greatly reduced. In cases where only the first mode in each direction is significant (often the case for low- to medium-rise building structures), equivalent static analysis may be sufficient, as described later.

13.2.5 Earthquake Response Spectra

13.2.5.1 Elastic Response Spectra

For design purposes, it is generally sufficient to know only the maximum value of the response due to an earthquake. A plot of the maximum value of a response quantity as a function of the natural vibration frequency of the structure, or as a function of a quantity which is related to the frequency such as natural period, constitutes the *response spectrum* for that quantity (see Chapter 17 and Chapter 31).

The peak relative displacement is usually called S_d and the peak strain energy of the oscillator is

$$SE = \frac{1}{2}KS_d^2$$

$$SE = \frac{1}{2}M\frac{K}{M}S_d^2$$

or

$$SE = \frac{1}{2}MS_v^2$$

Hence, the pseudo-relative velocity and acceleration spectra are defined as

$$S_v = \omega S_d \quad (13.5)$$

$$S_a = \omega^2 S_d \quad (13.6)$$

Figure 13.5 shows that a record of peak relative displacement response of an single-DoF oscillator can be plotted for a given earthquake, given damping, and a range of periods, typical of structures.

The structure's natural period (T or $1/n$) is conventionally taken as the abscissa, and curves are drawn for various levels of damping (Figure 13.6). It should be noted that the response spectrum gives no information about the duration of response (and hence the number of damaging cycles) that the structure experiences, which can have a very significant influence on the damage sustained.

13.2.5.2 Smoothed Design Spectra

Owing to the highly random nature of earthquake ground motions, the response spectrum for a real earthquake record contains many sharp peaks and troughs, especially for low levels of damping. The peaks and troughs are determined by a number of uncertain factors, such as the precise location of the earthquake source, which are unlikely to be known precisely in advance. Therefore, spectra for design purposes are usually smoothed envelopes of spectra for a range of different earthquakes; indeed, one of the advantages of response spectrum analysis over time history analysis is that it can represent the envelope response to a number of different possible earthquake sources from a single analysis, and is not dependent on the precise characteristic of one particular ground motion record. Codes of practice such as UBC (2000) and Eurocode 8 (ENV 1998, 1994-8) provide smoothed spectra for design purposes.

13.2.5.3 Ductility-Modified Response Spectrum Analysis

In a ductile structure, or subassemblage, the resistance, R , may be sustained at displacements that are several times those at first yield, Δ_y , as represented in Figure 13.7.

For yielding single-DoF systems, ductility-modified acceleration response spectra can be drawn, representing the maximum acceleration response of a system as a function of its initial (elastic) period, T , damping ratio, ξ , and displacement ductility ratio, μ (μ is the ratio of maximum displacement,

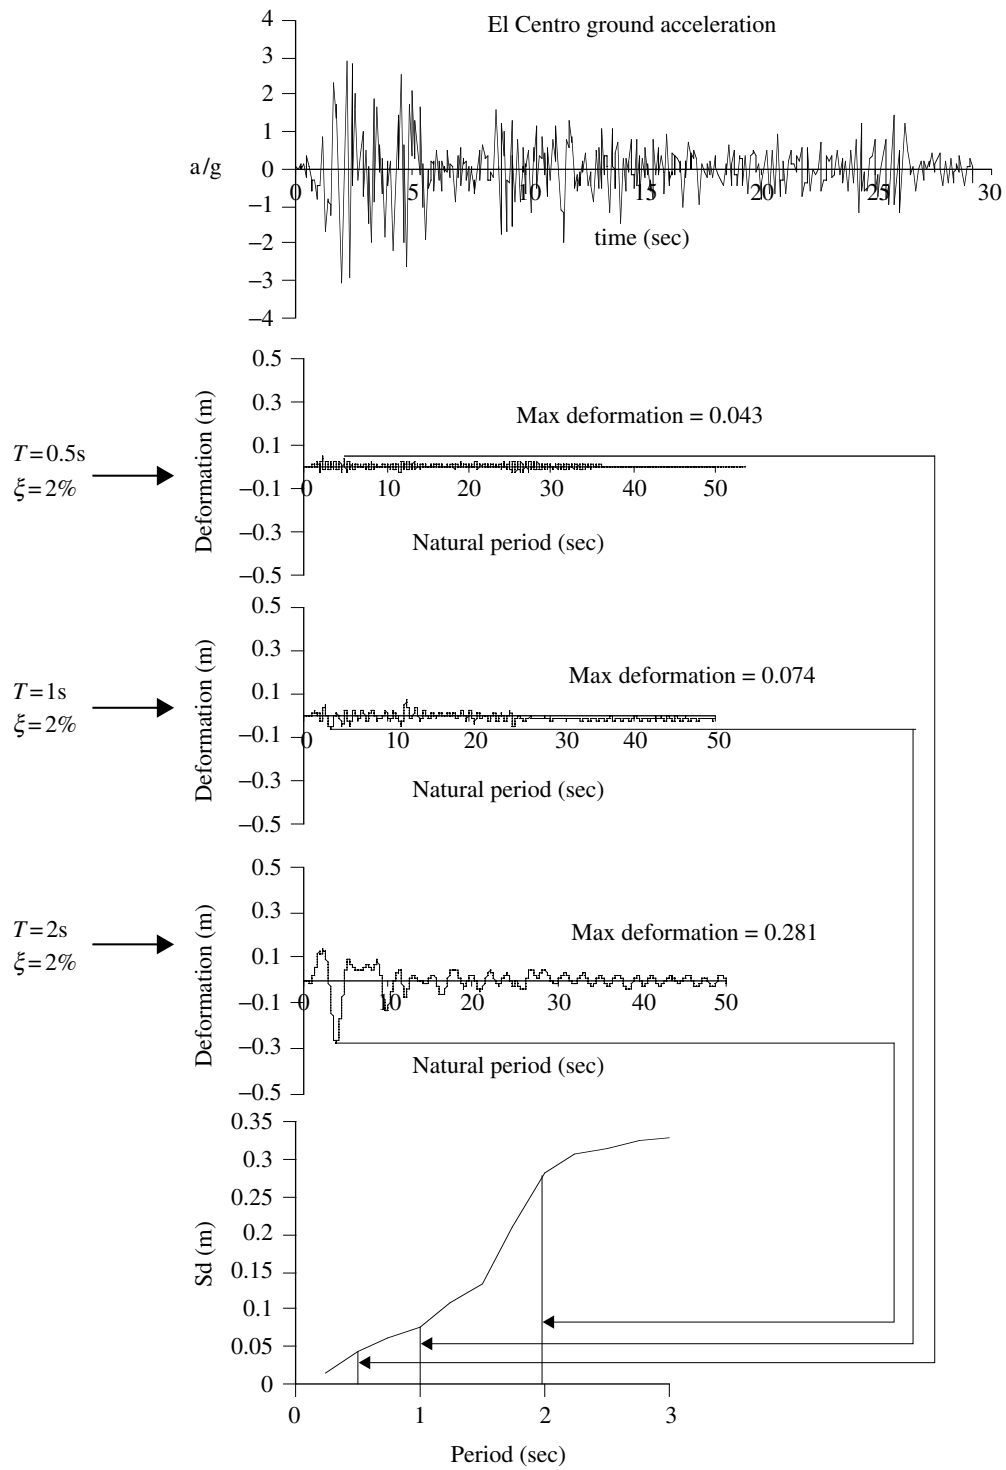

FIGURE 13.5 Compilation of (relative) displacement response spectra.

FIGURE 13.6 Acceleration response spectrum for El-Centro 1940 earthquake.

FIGURE 13.7 A simple bilinear elasto-plastic curve of response, representative of ductile performance.

Δ_{max} , to yield displacement, Δ_y). The reduction in acceleration response of the yielding system compared with the elastic one is period dependent; for structural periods greater than the predominant earthquake periods, the reduction is approximately $1/\mu$, for very stiff systems there is no reduction, while at intermediate periods a reduction factor between $1/\mu$ and 1 applies.

To derive peak accelerations and internal forces, the system can be treated as linear elastic and the ductility-modified spectrum used exactly like a normal elastic spectrum. However, deflections derived from this treatment must be multiplied by μ to allow for the plastic deformation.

It is now standard practice to analyze multi-DoF systems in the same way. That is, a yielding multi-DoF system is treated as elastic, and an appropriate ductility-modified spectrum is substituted for an elastic one. Acceleration and force responses are derived directly and deflections are multiplied by μ . However, this procedure is not (contrary to the case for single-DoF systems) rigorously correct. Although it gives satisfactory answers for regular structures, it can be seriously in error for structures (such as those with weak stories) where the plasticity demand is not evenly distributed. Nevertheless, most codes of practice allow the use of ductility-modified spectra for design, and give appropriate values for the reduction factors (called q , or behavior factors in Eurocode 8 and R factors in UBC) to apply to elastic response spectra.

13.2.6 Design Philosophy and the Code Approach

In areas of the world recognized as being prone to major earthquakes, the engineer is faced with the dilemma of being required to design for an event, the magnitude of which has only a small chance of

occurring during the life of the facility. If the designer adopts conservative performance criteria for the facility, the client (often society) is faced with costs which may be out of proportion to the risks involved. On the other hand, to ignore the possibility of a major earthquake could be construed as negligent in these circumstances.

To overcome this problem, a *dual design philosophy* has been developed, by which procedure:

1. A moderate earthquake, such as may reasonably be expected at the site, is used as a basis for the seismic design. The facility should be proportioned to resist such an earthquake without significant damage. This “damageability” limit state should ensure safety, limited nonstructural damage, and the continued performance of facilities and services, particularly in those with important postearthquake functions. The list includes hospitals, police, fire and civil defense facilities, water supply, telecommunications, electricity generation and distribution systems, and so on. Almost as important is the maintenance of road and rail communications, particularly for food distribution (including warehouses and their contents). Similarly, the protection of industrial complexes, in their own right, as well as the protection of individual items of equipment in other buildings and facilities, is a necessary consequence of adoption of this limit state.
2. The most severe, credible earthquake that may be expected to occur at the site is used to test safety. In this ultimate limit state, significant structural and nonstructural damage is expected but neither collapse nor loss of life should occur.

The main strategy for preventing collapse has traditionally been provision of ductility. This is the opposite quality to brittleness, and may be defined as the ability to sustain repeated excursions beyond the elastic limit without fracture. Owing to the cyclic, imposed displacement nature of earthquake loading, a ductile structure can absorb very large amounts of energy without collapse; the designer must think in terms of designing for maximum imposed displacements, rather than imposed loads.

Achieving ductility is partly a matter of choosing the right structural system, and partly a matter of detailing. In the former category comes the important concept of “capacity design,” as described by Paulay (1993). This involves ensuring a hierarchy of strengths within a structure to ensure that yielding occurs in ductile modes (such as flexure) rather than brittle modes (such as buckling or, for reinforced concrete, shear). There are other aspects of structural form which are important, particularly regularity in elevation (to avoid “soft” or weak stories) and regularity in plan (to minimize torsional response). These aspects are described in many textbooks and are quantified in some codes of practice (Park and Paulay, 1975).

Detailing of the structure is also important to ensure ductility. For concrete structures, this primarily involves reinforcement detailing and in steel structures connection detailing. The latter aspect has been particularly recognized following the failure of H-welded connections in the Northridge earthquake of 1994 (Burdekin, 1996). The primary reliance is on empirical solutions to these problems, as described in codes of practice, such as Eurocode 8 (ENV 1998, 1994-8) Part 1.3 and UBC/IBC (2000). Textbooks discussing these issues for concrete include Paulay and Priestley (1992), Booth (1994), Penelis and Kappos (1996), FEMA 273/274, FEMA 356/357 “NEHRP guidelines for seismic rehabilitation of buildings,” FEMA 368/369 “NEHRP recommended provisions for seismic regulations for new buildings and other structures,” and FEMA 306/307/308 “Evaluation and repair of earthquake damaged concrete and masonry buildings.” Textbooks covering failures of steel structures in recent earthquakes include Burdekin (1996) and FEMA 350-354 (2000).

Another important aspect of detailing is to allow for the maximum inelastic deflections caused by the design earthquake. Nonseismic-resisting elements of a structure such as cladding and infill walls must be able to accommodate these deflections safely, as must (crucially) the gravity load-bearing structure, which still suffers the seismic displacements even when not contributing to seismic resistance. In addition, adequate separation between adjacent structures must be provided. Codes of practice (e.g., Eurocode 8 and UBC) give guidance on suitable limits.

13.2.6.1 Performance-Based Design

In recent years, seismic design codes throughout the world have been shifting toward the adoption of performance-based design philosophy. The goal of a performance-based design procedure is to produce structures that have predictable seismic performance under multiple levels of earthquake intensity. In order to do so, it is important that the behavior of the structures is targeted in advance, both in the elastic as well as the inelastic ranges of deformation. The four important parameters in seismic design, strength, stiffness, ductility, and deformation, become the primary elements of a performance-based design procedure and have to be designed rationally. The next generation of codes is expected to be based on performance-based principles such as Asian Model Concrete Code (ACMC, 2001).

13.2.7 Analysis Options for Earthquake Effects

Analysis is only one part of the design process; conceptual design, detailing, and proper construction are the other vital components for ensuring good seismic performance. This section provides a brief theoretical review of the basis for seismic analysis, describing the main analytical techniques currently used by designers. More details are given by Clough and Penzien (1993), a standard general text for dynamic analysis, and Chopra (2001), which deals specifically with concerns for earthquake engineers.

Essentially, an earthquake engineer is faced with four possible methods of analysis/design for earthquake loading on a structure. In all methods, the dual damage criteria discussed above may be applied. The four analysis/design options available are:

- Dynamic time history analysis
- Response spectrum analysis
- Equivalent static approach (or force-based approach)
- Displacement-based approach

Equivalent static methods are usually adequate for conventional, regular building structures under about 75 m in height. A response spectrum analysis is required for taller buildings, because higher mode effects may become important, and also for buildings with plan or elevational eccentricities because torsional effects or nonstandard mode shapes may be significant. Codes of practice such as Eurocode 8 and UBC (2000) specify the degree of eccentricity at which such analysis is required. Unusual or very important structures may require nonlinear time history analysis, and this may also be required where the inaccuracies implicit in the use of ductility-modified response spectrum analysis become unacceptable. Displacement-based approach is a new method for seismic design, which is gaining popularity. The above four analysis options are discussed next.

13.2.7.1 Dynamic Time History Analysis

The most rigorous form of dynamic analysis involves stepping a nonlinear model of the structure through a complete time history of earthquake ground motions. The advantage of the method is that it can give direct information on nonlinear response, the duration of response (and hence the number of loading cycles), and the relative phasing of response between various parts. The method involves subjecting an appropriate finite element computer model of the building, or structural system, to a given, previously recorded, earthquake record and examining its response in real time. Response peaks are generally of most interest. The analysis must be performed for a number of different earthquake time histories to reduce dependence on the random characteristics of a particular record.

There are certain special circumstances where this procedure is useful but, for general seismic design, it is of little value as the actual earthquake that the structure may have to resist cannot be guaranteed to have sufficiently similar characteristics to the design earthquake. In particular, the intensity, duration, and frequency content of the earthquake may be unsuitable especially if, as often happens, the record comes from another country or continent. Moreover, the method is expensive and time-consuming, so that only for special structures can its use be justified. If, in addition, inelastic response calculations are involved, another level of complexity (and uncertainty) is introduced. Response then becomes

dependent, often heavily so, on the nonlinear models chosen and this is in addition to that inherent in choosing to use one particular record.

13.2.7.2 Response Spectrum Analysis

13.2.7.2.1 Response Spectrum Analysis of Single-Degree-of-Freedom Systems

With a knowledge of the natural period and damping of an single-DoF system, its peak (i.e., spectral) acceleration, S_a , can be determined directly from an appropriate response spectrum (see Chapter 17). In undamped systems, this peak response occurs when the equivalent spring is at its maximum extension point, so that the maximum force in the spring is given by

$$F = mS_a \quad (13.7)$$

From Equation 13.7, the peak (i.e., spectral) displacement, S_x , of the spring is given by

$$S_x = \frac{F}{k} = mS_a \frac{T^2}{4\pi^2 m} = \frac{S_a T^2}{4\pi^2} \quad (13.8)$$

For structures with relatively small viscous damping, the same relationships are still approximately true, because the maximum acceleration occurs when the velocity is low and hence the damping force (which is velocity proportional) is also low. Therefore, Equation 13.7 and hence also Equation 13.8 are still very good approximations for lightly damped systems.

Thus the two most important parameters of structural response — maximum force and displacement — can be determined for a linear single-DoF system directly from the acceleration response spectrum, provided only that the mass, natural period, and damping are known.

It is important to realize that the spectral acceleration, S_a , is an absolute value (the true acceleration of the structure in space) whereas the spectral displacement, S_x , is a relative value, measured in relation to the ground, which itself is moving in the earthquake. This at first sight may seem confusing, until it is remembered that the absolute acceleration of the mass is determined by the force on it (Equation 13.7), which itself is determined by the relative compression of the spring with respect to the ground (Equation 13.8).

13.2.7.2.2 Response Spectrum Analysis of Multi-Degree-of-Freedom Systems

By considering the response of each mode separately, a response spectrum analysis is also possible for an multi-DoF system, if generalized modal quantities are used (compare Equation 13.2 and Equation 13.3). For example, for a 2D structure with n lumped masses, responding in one horizontal direction, Equation 13.4 is modified to give the maximum base shear in the i th mode as

$$F_i = \frac{\left(\sum_{j=1}^n \phi_{ij} m_j \right)^2}{\sum_{j=1}^n \phi_{ij}^2 m_j} S_a = m_{\text{eff},i} S_a \quad (13.9)$$

where S_a is the spectral acceleration corresponding to the damping and frequency of mode i .

Higher modes with low effective masses, $m_{\text{eff},i}$, may contribute little to response and can usually be neglected. Since the sum of effective masses, $m_{\text{eff},i}$, of all modes equals the total mass, a good test of whether the first r modes are sufficient to capture response adequately is

$$\sum_{i=1}^r m_{\text{eff},i} \geq 0.9 \sum_{i=1}^n m_i = 0.9 \text{ (total mass)} \quad (13.10)$$

A response spectrum analysis gives the maximum response of the structure for each mode of vibration considered. Although it is rigorously correct to add the response in each mode at any time to obtain the total response, the maximum responses in each mode, calculated from response spectrum analysis, do

not occur simultaneously, and hence simple addition produces an overestimate of response. A common and usually adequate approximation is the square root of the sum of the squares (SRSS) rule, where the maximum total response is estimated as the SRSS combination of the individual modal responses. However, this may not be conservative enough for closely spaced or high-frequency modes, and other methods, such as the complete quadratic combination (CQC) method, are available (Gupta, 1990).

There are many commercially available computer programs which can perform response spectrum analysis, and it is now regarded as a standard rather than a specialist technique.

13.2.7.3 Equivalent Static Analysis (Force-Based Approach)

This is the type of analysis presented in most contemporary codes of practice, and it is conditional for its accuracy upon response being dominated by one mode of vibration in each direction. In the case of buildings, a quantity usually referred to as the “total base shear” is calculated from the product of the weight of the building and a coefficient. This coefficient takes into account the location and importance of the structure, its ductility or energy absorption capacity, its dynamic characteristics, and the local soil conditions and their effect on structural responses. Once the total base shear has been calculated, it is distributed up the structure as a series of horizontal loads at each floor level and the structure is analyzed with these equivalent horizontal loads applied.

The maximum lateral base shear is first calculated. Equation 13.11 gives the relevant formulae in UBC (2000). Other current codes follow similar formats

$$V = \frac{C_v IW}{RT} \text{ but } V \leq \frac{2.5C_a I}{R} W \text{ and } \geq 0.11C_a IW \quad (13.11)$$

In addition, $V \geq (0.8ZN_v I/R)W$ (high seismicity, Zone 4 only), where:

V = ultimate seismic base shear (force units, e.g., kN)

C_v, C_a = seismic coefficients, depending on the zone factor Z as given in UBC

I = importance factor = 1 to 1.25 in UBC

R = reduction coefficient depending on the ductility of structure = 2.8 to 8.5 in UBC

T = first mode period of the building (sec)

W = building weight (force units, e.g., kN)

Z = zone factor expressed as the peak ground acceleration on rock (in gravity units) for a 475-year return period = 0.075 to 0.4 in UBC

N_v = factor allowing for proximity to active faults = 1.0 to 2.0 in UBC

(V/W) represents the shape of a standard design response spectrum with a peak amplification on ground acceleration for 5% damping of 2.5, and a minimum value at long period to allow for the uncertainty in long-period motions and for proximity to active faults.

The base shear calculated by these methods is then applied to the structure as a set of horizontal forces, with a vertical distribution based on the first mode shape of regular vertical cantilever structures. Horizontal distribution follows the mass distribution, with some additional allowance for torsional effects.

13.2.7.4 Displacement-Based Approach

In the development of performance-based earthquake engineering, which stresses the inelastic behavior of structural system under severe earthquake ground motions (high seismic region), displacement rather than force has been recognized as the most suitable and direct performance or damage indicator. Deformation-controlled design can be achieved either by using the traditional force/strength-based design procedure together with a check on the displacement/drift limit, or by employing a direct displacement-based procedure. The idea of displacement-based design was introduced by Gulkan and Sozen (1974). They developed the concept of substitute structure to estimate the nonlinear structural response through an equivalent elastic model, assuming a linear behavior and a viscous

damping equivalent to the nonlinear response. This idea has been adopted recently by Priestley and Kowalsky (2000) for a direct displacement design of single-DoF and multi-DoF reinforced concrete structures. Another direct displacement-based design approach was proposed by Fajfar (2000) based on the capacity spectrum method (Chopra and Goel, 1999).

In all the above references, seismic demand is specified as either a displacement response spectrum (D-T format) or an acceleration displacement response spectrum (ADRS format). For a general-purpose spectrum, nonlinear elastic behavior of a structural system can be accounted for by either an equivalent elastic response spectrum or an inelastic response spectrum. The former is associated with effective viscous damping ξ_{eff} and the latter is directly constructed based on the relation between reduction factors and ductility. Although the elastic acceleration design spectrum is available from codes, it is not appropriate to be a basis for the determination of the elastic displacement design spectrum because the displacement increases with period even at longer periods.

13.2.8 Soil–Structure Interaction

Structural analyses usually assume that ground motions are applied *via* a rigid base, thus neglecting the effect of ground compliance on response. Although this rigid base assumption may lead to an underestimate of deflections, it is usually conservative as far as forces are concerned, because ground compliance reduces stiffness and usually moves structural periods farther from resonance with the ground motion. However, this conservatism may not always apply, and Eurocode 8 Part 5 lists the following cases where soil–structure interaction (SSI) should be investigated:

1. Structures where P-Delta (second order) effects need to be considered
2. Structures with massive or deep-seated foundations, such as bridge piers, offshore caissons, and silos
3. Slender, tall structures such as towers and chimneys
4. Structures supported on very soft soils with an average shear wave velocity less than 100 m/sec

Allowance for SSI effects is usually a specialist task. The simplest method is to present the soil flexibility by discrete springs connected to the foundation. These require a knowledge of the shear stiffness of the soil. Further information is given by Pappin (1991) and Wolf (1985, 1994).

13.2.9 Active and Passive Control Systems

Alternative strategies of designing for earthquake resistance involve modification of the dynamic characteristics of structure to improve seismic response. The systems can be classified as either passive or active. The basic role of these systems is to absorb a portion of the input energy, thereby reducing energy dissipation demand on primary structural members and minimizing possible structural damage.

The most common type of passive system involves lengthening the structure's fundamental period of vibration by mounting the superstructure on bearings with a low horizontal stiffness; this is known as base or seismic isolation. Where this increases, the fundamental period above the predominant periods of earthquake excitation, the acceleration (but not necessarily displacement) response is significantly reduced. Usually, additional damping is provided in the seismic isolation bearing to control deflections.

The principle of seismic isolation is illustrated by Figure 13.8. The reduction in response, often of the order of 50, has proved highly effective in recent earthquakes in reducing damage to both building structure and building contents. UBC (2000) provides codified guidance for seismic isolation of buildings while AASHTO (1991) and Eurocode 8 (ENV 1998, 1994-8) Part 2 treat bridge structures. Seismic isolation has been incorporated in many hundreds of recent structures, particularly in bridges, and also in buildings such as hospitals with contents that must remain functional after an earthquake. It has also been used to improve the seismic resistance of existing structures. Another form of passive

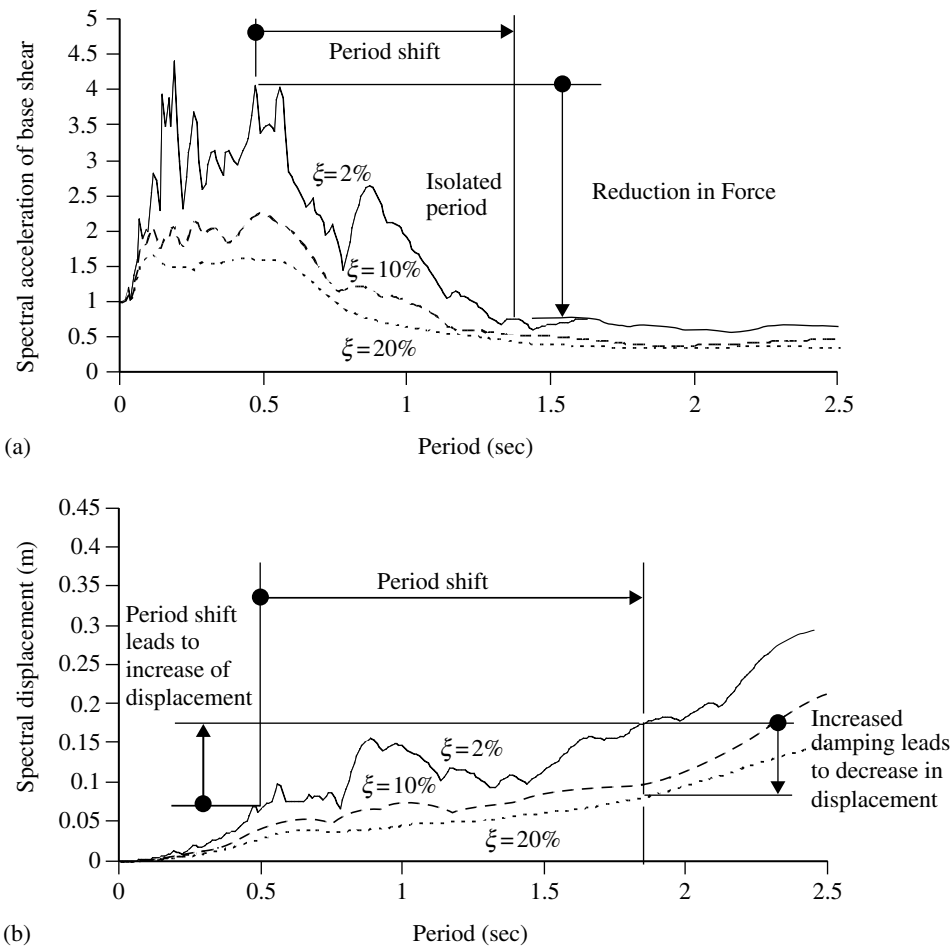

FIGURE 13.8 Effect of seismic isolation on forces and displacements for an earthquake with predominant period around 0.5 sec. (a) Effect of period shift on design forces; (b) Effect of period shift and damping on relative displacement between ground and structure.

system is the provision of additional structural damping in the form of discrete viscous, frictional, or hysteretic dampers.

Active systems modify the dynamic characteristics of a structure in real time during an earthquake, by computer-controlled devices such as active mass dampers. Presently, very few buildings are actually constructed in this way, but there has been a recent large international research effort (Casciati, 1996; Kabori, 1996; Soong, 1996). Owing to their adaptability, active systems are less dependent for their effectiveness on the precise nature of the input motion (a concern for passive systems, particularly where they are very close to the earthquake source) but they must have a very high degree of reliability to ensure they function during the crucial few seconds of an earthquake.

13.2.10 Worked Examples

Example 13.1 Seismic Analysis of a 30-Story Frame

A 30-story building has the effective stiffness, $K_e = 2.5 \times 10^3$ kN/m, together with a mass per unit height of $m = 30$ tons/m.

FIGURE 13.9 First mode shape of the 30-story frame.

The mass of the building is uniform over its height of 120 m. An appropriate first mode shape for the structure is the parabola, as shown in Figure 13.9.

For this frame, using the response spectrum for 2% damping (Figure 13.10), find:

1. The peak tip deflection
2. The peak base shear
3. The overturning moment
4. The peak interstory drift at the top of the frame
5. The peak acceleration at the top of the frame

The effective mass, M_e or M_i , (see Equation 13.4)

$$M_e = \phi^2 m = \int_0^H m(x) \left(\frac{x}{H} \right)^4 dx = \frac{m(x)}{5} \frac{x^5}{H^4} \Big|_0^H = \frac{mH}{5} = \frac{30 \times 120}{5} = 720 \text{ tons}$$

This is the effective mass tributary to one frame.

The effective earthquake mass, M_{eq} or L_i (see Equation 13.4)

$$M_{eq} = \phi m = \int_0^H m(x) \left(\frac{x}{H} \right)^2 dx = \frac{m(x)}{3} \frac{x^3}{H^2} \Big|_0^H = \frac{mH}{3} = \frac{30 \times 120}{3} = 1200 \text{ tons}$$

The natural period is 3.37 sec, a long-period structure, given:

$$K_{eq} = 2.5 \times 10^3 \text{ kN/m}$$

$$T = 2\pi(720/2500)^{0.5}$$

The participation factor is

$$PF = \frac{M_{eq}}{M_e} = \frac{1200}{720} = 1.667$$

(i) *Peak tip deflection*

From Figure 13.9

$$S_d = 0.32 \text{ m} = 320 \text{ mm} = PF \times S_d$$

$$\Delta_{tip} = 1.667 \times 320 = 533.44 \text{ mm}$$

(ii) *Peak base shear* = $PF \times F_{max}$

$$V_0 = PF(\Delta_{tip} K_e) = 1.667(0.53344 \times 2500) = 2.22 \text{ MN}$$

(iii) *Peak overturning moment*

$$M_{ot} = V_0 \bar{x}$$

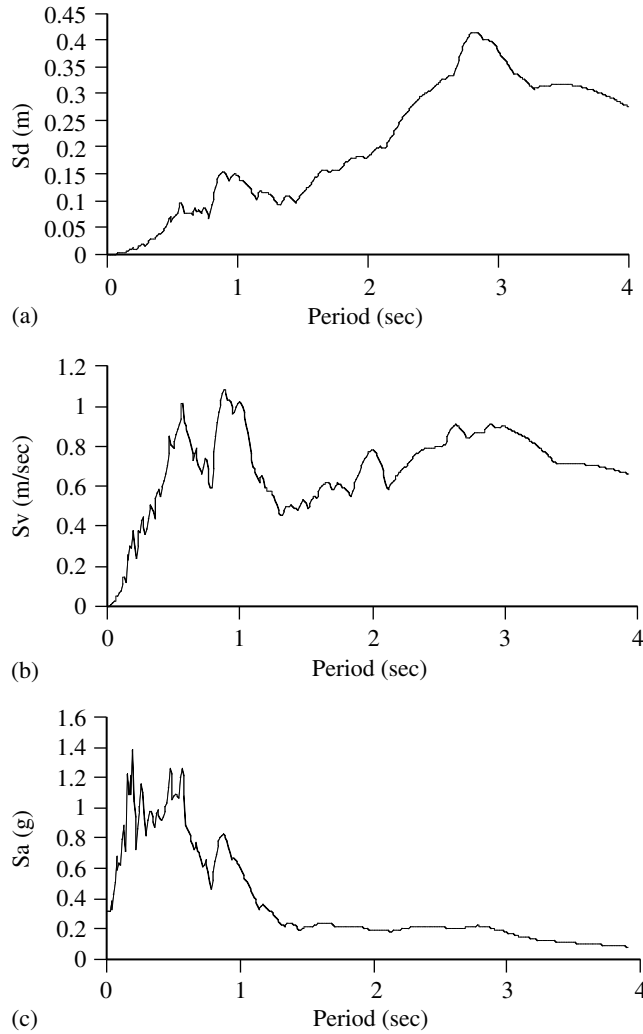

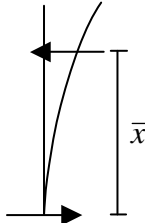

FIGURE 13.10 (a) Deformation (or displacement); (b) pseudo-velocity, and (c) pseudo-acceleration response spectra. El-Centro ground motion. Damping ratio $\xi = 2\%$.

$$\bar{x} = \frac{\int_0^H xm(x) \left(\frac{x}{H} \right)^2 dx}{\int_0^H m(x) \left(\frac{x}{H} \right)^2 dx} = \frac{\int_0^H m(x) \frac{x^3}{H^2} dx}{\int_0^H m(x) \frac{x^2}{H^2} dx}$$

$$\bar{x} = \frac{3H}{4} = \frac{3 \times 120}{4} = 90 \text{ m}$$

$$M_{ot} = 2223.11 \times 90 = 2.0008 \times 10^5 \text{ kN m}$$

$$\text{Equivalent static loading} = m(t)\omega^2 \times \text{PF} \times S_d \left(\frac{x}{H} \right)^2$$

Distribution of lateral forces

UBC (2000) specifies the load at the top to be

$$F_t = 0.07TV = 19.778 \text{ MN}$$

Extracting calculation for level 48,

$$W_i H_i = 16.9 \times 192 = 3.245 \times 10^3 \text{ MN}$$

$$F_x = \frac{(V - F_t)(W_{48} H_{48})}{\sum_i^{52} W_i H_i} = \frac{(79.113 - 19.778)(3.245 \times 10^3)}{87.012 \times 10^3} = 2.21 \text{ MN}$$

$$\text{Shear force} = \text{Shear}_{49} + F_{48} = 24.9 + 2.21 = 27.1 \text{ MN}$$

$$\text{Moment} = \text{Moment}_{49} + (\text{Shear}_{49} \times \text{story height}) = 347.7 + (24.9 \times 4) = 447.3 \text{ MN m}$$

13.3 Dynamic Effects of Wind Loading on Structures

13.3.1 Introduction

The turbulent nature of the wind is characterized by sudden gusts superimposed upon a mean wind velocity. The wind vector at a point may be regarded as the sum of the mean wind vector (static component) and a dynamic component

$$V(z, t) = \bar{V}(z) + v(z, t) \quad (13.12)$$

Wind is a phenomenon of great complexity because of the many flow situations arising from the interaction of wind with structures. Wind is composed of a multitude of eddies of varying sizes and rotational characteristics carried along in a general stream of air moving relative to the Earth's surface. These eddies give wind its gusty or turbulent character. The gustiness of strong winds in the lower levels of the atmosphere largely arises from interaction with surface features. The average wind speed over a time period of the order of 10 min or more tends to increase with height, while the gustiness tends to decrease with height.

A further consequence of turbulence is that dynamic loading on a structure depends on the size of the eddies. Large eddies, whose dimensions are comparable with the structure, give rise to well-correlated pressures as they envelop the structure. On the other hand, small eddies result in pressures at various parts of the structure being practically uncorrelated. Eddies generated around a typical structure are shown in Figure 13.12.

FIGURE 13.12 Generation of eddies. (a) Elevation; (b) plan.

Some structures, particularly those that are tall or slender, respond dynamically to the wind. The best-known structural collapse due to wind was the Tacoma Narrows Bridge which occurred in 1940 at a wind speed of only about 19 m/sec. It failed after it had developed a joint torsional and flexural mode of oscillation.

There are several different phenomena giving rise to dynamic response of structures in wind. These include buffeting, vortex shedding, galloping, and flutter. Slender structures are likely to be sensitive to dynamic response in line with the wind direction as a consequence of turbulence buffeting. Transverse or crosswind response is more likely to arise from vortex shedding or galloping, but may be excited by turbulence buffeting also. Flutter is a coupled motion, often a combination of bending and torsion, and can result in instability.

An important problem associated with the wind-induced motion of buildings is concerned with the human response to vibration. At this point, it will suffice to note that humans are surprisingly sensitive to vibration, to the extent that motions may feel uncomfortable even if they correspond to relatively unimportant stresses. The next few sections give a brief introduction to the dynamic response of structures in wind. More details can be found in wind engineering texts (e.g., Sachs, 1978; Holmes, 2001).

13.3.2 Wind Speed

At great heights above the surface of the Earth, where frictional effects are negligible, air movements are driven by pressure gradients in the atmosphere, which in turn are the thermodynamic consequence of variable solar heating of the Earth. This upper level wind speed is known as the gradient wind velocity.

Different terrains can be categorized according to the roughness length. Table 13.3 shows the different categories specified in the Australian/New Zealand wind code, AS/NZS 1170.2 (2002). Closer to the surface, the wind speed is affected by frictional drag of the air over the terrain. There is a boundary layer within which the wind speed varies from almost zero, at the surface, to the gradient wind speed at a height known as the gradient height. The thickness of this boundary layer, which may vary from 500 to 3000 m, depends on the type of terrain, as depicted in Figure 13.13. As can be seen, the gradient height within a large city center is much higher than it is over the sea where the surface roughness is less.

In practice, it has been found useful to start with a reference wind speed based on statistical analysis of wind speed records obtained at meteorological stations throughout the country. The definition of the reference wind speed varies from one country to another. For example, in Australia/New Zealand, it is the 3-sec gust wind speed at a height of 10 m above the ground assuming terrain category 2. Maps of reference wind speeds applying to various countries are usually available.

An engineering wind model for Australia has been developed by Melbourne (1992) from the Deaves and Harris (1978) model. This model is based on extensive full-scale data and on the classic logarithmic law in which the mean velocity profile in strong winds applicable in noncyclonic regions (neutral stability conditions) is given by Equation 13.13

$$\bar{V}_z \approx \frac{u^*}{0.4} \left[\log_e \left(\frac{z}{z_0} \right) + 5.75 \left(\frac{z}{z_g} \right) - 1.88 \left(\frac{z}{z_g} \right)^2 - \left(\frac{z}{z_g} \right)^3 + 0.25 \left(\frac{z}{z_g} \right)^4 \right] \quad (13.13)$$

The numerical values are based on a mean gradient wind speed of 50 m/sec.

TABLE 13.3 Terrain Category and Roughness Length (z_0)

Terrain Category	Roughness Length (z_0)
Exposed open terrain with few or no obstructions and water surfaces at serviceability wind speeds	0.002
Water surfaces, open terrain, grassland with few, well-scattered obstructions having heights generally from 1.5 to 10 m	0.02
Terrain with numerous closely spaced obstructions 3 to 5 m high such as areas of suburban housing	0.2
Terrain with numerous large, high (10.0 to 30.0 m high) and closely spaced obstructions such as large city centers and well-developed industrial complexes	2

FIGURE 13.13 Mean wind profiles for different terrains.

For values of $z < 30.0$ m the z/z_g values become insignificant and the above equation simplifies to

$$\bar{V}_z \approx \frac{u^*}{0.4} \log_e \left(\frac{z}{z_0} \right) \tag{13.14}$$

where:

\bar{V}_z = the design hourly mean wind speed at height z , in m/sec

u^* = the friction velocity

$$u^* = \sqrt{\frac{\text{surface friction shear stress}}{\text{atmospheric density}}}$$

z = the distance or height above ground, in m

z_g = the gradient height in meters (the value ranges from 2700 to 4500 m), see Table 13.4 (derived by the authors)

$$z_g = \frac{u^*}{6 \times 10^{-4}}$$

As given in Table 13.3, there is an interaction between roughness length and terrain category, so it is necessary to define a terrain category to find the design hourly wind speeds and gust wind speeds. The link between hourly mean and gust wind speeds is as follows:

$$V = \bar{V} \left[1 + 3.7 \left(\frac{\sigma_v}{\bar{V}_z} \right) \right] \tag{13.15}$$

where

$$\sigma_v = 2.63 \eta u^* \left[0.538 + 0.09 \log_e \left(\frac{z}{z_0} \right) \right]^{\eta^{16}} \tag{13.16}$$

TABLE 13.4 Roughness Length, Friction Velocity, and Gradient Height

Terrain Category	z_0 (m)	u^*	z_g (m)
1	0.002	1.662	2769
2	0.02	1.910	3184
3	0.2	2.243	3738
4	2	2.708	4514

$$\eta = 1.0 - \left(\frac{z}{z_g} \right) \quad (13.17)$$

For design, the basic wind speed is classified into three different speeds as follows:

$V_s = V_{20 \text{ yr}}$ = serviceability limit state design speed having an estimated probability of exceedance of 5% in any one year, for the serviceability limit states

$V_p = V_{50 \text{ yr}}$ = permissible, or working, stress design wind speed and can be obtained directly from V_u using the relation $V_p = V_u/(1.5)^{0.5}$

$V_u = V_{1000 \text{ yr}}$ = ultimate limit state design wind speed having an estimated probability of exceedance of 5% in a lifetime of 50 years, for the ultimate limit states

Using rigorous analysis incorporating probability distribution of wind speed and direction, basic design wind speeds for different directions and different return periods can be derived. For example, AS/NZS 1170.2 provides a wind direction multiplier, which varies from 0.80 for wind from the east to 1.0 for wind from the west, and having wind speeds up to a 2000-year return period.

13.3.3 Design Structures for Wind Loading

The characteristics of wind pressures are a function of the characteristics of the approaching wind, the geometry of the structure, and the geometry and proximity of the upwind structures. The pressures are not steady, but highly fluctuating, partly as a result of the gustiness of the wind, but also because of local vortex shedding at the edges of the structures themselves. The fluctuating pressures result in fatigue damage to structures, and in dynamic excitation, if the structure happens to be dynamically wind sensitive. The pressures are also not uniformly distributed over the surface of the structure, but vary with position.

The complexities of wind loading should be kept in mind when designing a structure. Because of the many uncertainties involved, the maximum wind loads experienced by a structure during its lifetime may vary widely from those assumed in the design. Thus, the failure or nonfailure of a structure in a windstorm cannot necessarily be taken as an indication of the nonconservativeness, or conservativeness, of the wind-loading standard. The standards do not apply to buildings or structures that are of unusual shape or location. Wind loading governs the design of some types of structures, such as tall buildings and slender towers. Experimental wind tunnel data may be used in place of the coefficients given in the code for these structures.

13.3.3.1 Types of Wind Design

Typically, for wind-sensitive structures, three basic wind effects need to be considered:

- *Environmental wind studies* — to study the wind effects on the surrounding environment caused by erecting the structure (e.g., a tall building). This study is particularly important to assess the impact of wind on pedestrians and motor vehicles and so on, which utilize the public domain within the vicinity of the proposed structure.
- *Wind loads for facade* — to assess design wind pressures throughout the surface area of the structure to design the cladding system. Owing to the significant cost of typical facade systems in proportion to the overall cost of very tall buildings, engineers cannot afford the luxury of conservatism in assessing design wind loads. With due consideration to the complex building shapes and dynamic characteristics of the wind and building structure, even the most advanced wind codes generally cannot accurately assess design loads. Wind tunnel tests to assess design loads for cladding are now a normal industry practice, with the aim of minimizing initial capital costs, and more significantly, to avoid the expensive maintenance costs associated with malfunctions due to leakage and/or structural failure.

- *Wind loads for structure* — to determine the design wind load so as to design the lateral load-resisting structural system of a structure and therefore satisfy the various design criteria.

13.3.3.2 Design Criteria

In terms of designing a structure for lateral wind loads, the following design criteria need to be satisfied:

- *Stability* against overturning, uplift, and/or sliding of the structure as a whole.
- The *strength* of the structural components of the building, and stresses that must be withstood without failure during the life of the structure.
- *Serviceability*, for example for buildings, where interstory and overall deflections are within acceptable limits. The control of deflection and drift is imperative for tall buildings in order to limit damage and cracking to nonstructural members such as the facade, internal partitions, and ceilings.

As adopted by most international codes, to satisfy stability and strength limit state requirements, ultimate limit state wind speed is used. In many codes, such a speed has a 5% probability of being exceeded in a 1-year period.

An additional criterion that requires careful consideration in wind-sensitive structures such as tall buildings is the control of accelerations when subjected to wind loads under serviceability conditions. Acceptability criteria for vibrations in buildings are frequently expressed in terms of acceleration limits for a 1- or 5-year return period wind speed, and are based on human tolerance to vibration discomfort in the upper levels of buildings. Wind response is relatively sensitive to both mass and stiffness, and response accelerations can be reduced by increasing either or both of these parameters. However, this is in conflict with earthquake design optimization where loads are minimized in buildings by reducing both the mass and stiffness. Increasing the damping results in a reduction in both the wind and earthquake responses.

The detailed procedure described in wind codes is subdivided into static analysis and dynamic analysis methods. The static approach is based on a quasi-steady assumption. It assumes that the building is a fixed rigid body in the wind. The static method is not appropriate for tall or slender structures or structures susceptible to vibration in the wind. In practice, static analysis is normally appropriate for structures up to 50 m in height. The subsequently described dynamic method is for exceptionally tall, slender, or vibration-prone buildings. The codes not only provide some detailed design guidance with respect to dynamic response, but also state specifically that a dynamic analysis must be undertaken to determine overall forces on any structure with both a height (or length) to breadth ratio greater than five, and a first mode frequency less than one.

Wind-loading codes may give the impression that wind forces are relatively constant with time. In reality, wind forces vary significantly over short time intervals, with large amplitude fluctuations at high-frequency intervals. The magnitude and frequency of the fluctuations is dependent on many factors associated with the turbulence of the wind and local gusting effects caused by the structure and surrounding environment.

To simplify this complex wind characteristic, most international codes have adopted a simplified approach by utilizing a quasi-steady assumption. This approach simply uses a single value equivalent, static wind pressure, to represent the maximum peak pressure the structure would experience.

13.3.3.3 Static Analysis

This method assumes the quasi-steady approximation. It approximates the peak pressures on the building surfaces by the product of gust dynamic wind pressure and the mean pressure coefficients. The mean pressure coefficients are measured in a wind-tunnel or full-scale tests and are given by $p_{\text{bar}}/q_{z(\text{bar})}$. The implied assumption is that the pressures on the building surface (external and internal) faithfully follow the variations in upwind velocity. Thus, it is assumed that a peak value of wind speed is accompanied by a peak value of pressure or load on the structure. The quasi-steady model has been found to be fairly good for small structures.

In static analysis, gust wind speed, V_z , is used to calculate the forces, pressures, and moments on the structure.

The main advantages and disadvantages of the quasi-steady/peak gust format can be summarized as follows:

- Advantages:
 - Simplicity.
 - Continuity with previous practice.
 - Pressure coefficients should need little adjustment for different upwind terrain types.
 - Existing meteorological data on wind gusts are used directly.
- Disadvantages:
 - The approach is not suitable for very large structures, or for those with significant dynamic response.
 - The response characteristics of the gust anemometers and the natural variability of the peak gusts tend to be incorporated into the wind load estimates.
 - The quasi-steady assumption does not work well for cases where the mean pressure coefficient is near zero.

However, the advantages outweigh the disadvantages — certainly for smaller, stiff structures for which the code is mainly intended.

The philosophy used in specifying the peak loads in AS/NZS 1170.2 has been to approximate the real values of the extremes. In many cases, this has required the adjustment of the quasi-steady pressures with factors such as area reduction factors and local pressure factors.

The dynamic wind pressure at height z is given by

$$\bar{q}_z = 0.6 \bar{V}_z^2 \times 10^{-3} \quad (13.18)$$

where

\bar{V}_z = the design gust wind speed at height z , in meters per second = $VM_{(z,cat)}M_zM_tM_i$

V = the basic wind speed

The multiplying factors (M) take into account the type of terrain (M_t), height above ground level (M_z), topography, and the importance of the structure (M_i). The above derivation essentially forms the basis of most international codes.

The mean base overturning moment M_{bar} is determined by summing the moments resulting from the net effect of the mean pressure and leeward sides of the structure given by

$$\bar{F}_z = \sum c_{p,e} \bar{q}_z A_z$$

or for structures with discrete elements:

$$\bar{F}_d = \sum c_d \bar{q}_z A_z \quad (13.19)$$

where

\bar{F}_z = the hourly mean net horizontal force acting on a structure at height z

$C_{p,e}$ = the pressure coefficients for both windward and leeward surfaces

A_z = the area of a structure or a part of a structure, at height z , in square meters

\bar{F}_d = the hourly mean drag force acting on discrete elements

C_d = the drag force coefficient for an element of the structure

13.3.4 Along and Across-Wind Loading

Not only is the wind approaching a building a complex phenomenon, but the flow pattern generated around a building is complicated by the distortion of the mean flow, the flow

separation, the vortex formation, and the wake development. Large wind pressure fluctuations due to these effects occur on the surface of a building. As a result, large aerodynamic loads are imposed on the structural system and intense localized fluctuating forces act on the facade of such structures. Under the collective influence of these fluctuating forces, a building vibrates in rectilinear and torsional modes, as illustrated in Figure 13.14. The amplitude of such oscillations is dependant on the nature of aerodynamic forces and the dynamic characteristics of the building.

FIGURE 13.14 Wind response directions.

13.3.4.1 Along-Wind Loading

The along-wind loading or response of a building due to the gusting wind can be assumed to consist of a mean component due to the action of the mean wind speed (e.g., the mean hourly wind speed), and a fluctuating component due to wind speed variations from the mean. The fluctuating wind is a random mixture of gusts or eddies of various sizes, with the larger eddies occurring less often (i.e., with a lower average frequency) than smaller eddies. The natural frequency of vibration of most structures is sufficiently higher than the component of the fluctuating load effect imposed by the larger eddies. That is, the average frequency with which large gusts occur is usually much less than any of the structure's natural frequencies of vibration and so they do not force the structure to respond dynamically. The loading due to those larger gusts (which are sometimes referred to as "background turbulence") can therefore be treated in similar way to that due to the mean wind speed. The smaller eddies, however, because they occur more often, may induce the structure to vibrate at or near one of the structure's natural frequencies of vibration. This in turn induces a magnified dynamic load effect in the structure which can be significant.

The separation of wind loading into mean and fluctuating components is the basis of the so-called "gust factor" approach, which is the basis of many design codes. The mean load component is evaluated from the mean wind speed using pressure and load coefficients. The fluctuating loads are determined separately by a method which makes an allowance for the intensity of turbulence at the site, size reduction effects, and dynamic amplification (Davenport, 1967; Vickery, 1971).

The dynamic response of buildings in the along-wind direction can be predicted with reasonable accuracy by the gust factor approach, provided the wind flow is not significantly affected by the presence of neighboring tall buildings or surrounding terrain.

13.3.4.2 Across-Wind Loading

There are many examples of slender structures that are susceptible to dynamic motion perpendicular to the direction of the wind. Tall chimneys, street lighting standards, towers, and cables frequently exhibit this form of oscillation, which can be very significant, especially if the structural damping is small. Crosswind excitation of modern tall buildings and structures can be divided into three mechanisms (AS/NZS 1170.2, 2002). These and higher time derivatives are described as follows:

1. The most common source of crosswind excitation is that associated with "vortex shedding." Tall buildings are bluff (as opposed to streamlined) bodies that cause the flow to separate from the surface of the structure, rather than follow the body contour (Figure 13.15). For a

particular structure, the shed vortices have a dominant periodicity that is defined by the Strouhal number. Hence, the structure is subjected to a periodic pressure loading, which results in an alternating crosswind force. If the natural frequency of the structure coincides with the shedding frequency of the vortices, large amplitude displacement response may occur, and this

FIGURE 13.15 Vortex formation in the wake of a bluff object.

is often referred to as critical velocity effect. The asymmetric pressure distribution created by the vortices around the cross section results in an alternating transverse force as they are shed. If the structure is flexible, oscillation will occur transverse to the wind, and the conditions for resonance would exist if the vortex shedding frequency coincided with the natural frequency of the structure. This situation could give rise to very large oscillations and possibly failure.

In practice, vertical structures are exposed to a turbulent wind in which both the wind speed and the turbulence level vary with height, so that excitation due to vortex shedding is effectively broadband. Therefore, the term “wake excitation” is used to include all forms of excitation associated with the wake and not just those associated with the critical wind velocity.

2. The “incident turbulence” mechanism refers to the situation where the turbulence properties of the natural wind give rise to changing wind speeds and directions that directly induce varying lift and drag forces and pitching moments on the structure over a wide band of frequencies. The ability of incident turbulence to produce significant contributions to crosswind response depends very much on the ability to generate a crosswind (lift) force on the structure as a function of longitudinal wind speed and angle of attack. In general, this means that sections with a high lift curve slope or pitching moment curve slope, such as a streamlined bridge deck section or a flat deck roof, are possible candidates for this effect.
3. Higher derivatives of crosswind displacement: there are three commonly recognized displacement-dependent excitations (i.e., “galloping,” “flutter,” and “lock-in”), all of which are also dependent on the effects of turbulence (turbulence affects the wake development, and hence, the aerodynamic derivatives). Many formulae are available to calculate these effects (Holmes, 2001). Recently, computational fluid dynamics techniques have also been used (Tamura, 1999) to evaluate these effects.

13.3.5 Wind Tunnel Tests

There are many situations in which analytical methods cannot be used to estimate certain types of wind loads and the associated structural response. For example, when the aerodynamic shape of the building is rather uncommon, or the building is very flexible so that its motion affects the aerodynamic forces acting on the building. In such situations, more accurate estimates of wind effects on buildings are obtained through aeroelastic model tests in a boundary-layer wind tunnel.

Wind tunnel tests currently being conducted on buildings and other structures can be divided into two types. The first is concerned with the determination of wind-loading effects to enable the design of a wind-resistant structure. The second is concerned with the flow fields induced around the structure, such as its effects on pedestrian comfort and safety at ground level or air intake concentration levels of exhaust pollutants.

Wind tunnel studies involve blowing wind on the subject building model and its surrounding at various angles relative to the building orientation, representing the wind directions. This is typically achieved by placing the complete model on a rotating platform within the wind tunnel. Once testing is

FIGURE 13.16 Wind tunnel test.

complete for a select direction, the platform is simply rotated by a chosen increment to represent a new wind direction. A typical wind tunnel model is illustrated in Figure 13.16.

The design wind speed is based on meteorological data for the given city or area, which are analyzed to produce the required probability distribution of gust wind speeds. By appropriate integration processes and the application of necessary scaling factors, directional wind speeds for the wind tunnel can be determined.

Although wind tunnel testing attempts to duplicate a complex problem, the actual models are quite simple and are based on the premise that the fundamental mode of displacement for a structure such as a tall building can be approximated by a straight line. In general terms, it is not necessary to achieve a correct mass density distribution along the building height as long as the mass moment of inertia about the pivot point is the same as the prototype density distribution. The pivot point is typically chosen to obtain a mode shape which provides the best agreement with the calculated fundamental mode shapes of the prototype. Springs are located near the pivot points to achieve the correct frequencies of vibrations in the two fundamental sway modes corresponding to the orthogonal building axis. An electromagnet or oil dashpot provides the model with a damping corresponding to that of the full scale tower. In addition to the stiffness and damping compatibility, it is essential that structural length scale, timescale, and the inertial force are the same between the model and the full structure.

Buildings of similar size located in close proximity to the proposed building can cause large increases in across-wind responses. Fortunately, in wind tunnel studies, surroundings comprising existing and/or future buildings can easily be incorporated with relatively minor costs.

13.3.6 Comfort Criteria: Human Response to Building Motion

There are no generally accepted international standards for comfort criteria. A considerable amount of research has been carried out into the important physiological and psychological parameters that affect human perceptions of motion and vibration in the low-frequency range of 0 to 1 Hz encountered in tall buildings. These parameters include the occupant's expectations and experience, activity, body posture, and orientation; visual and acoustic cues; and the amplitude, frequency, and acceleration of both the translational and rotational motion to which the occupant is subjected. Table 13.5 gives some guidance on the general human perception levels.

TABLE 13.5 Human Perception Levels

Level	Acceleration (m/sec ²)	Effect
1	<0.05	Humans cannot perceive motion
2	0.05 to 0.1	Sensitive people can perceive motion; hanging objects may move slightly
3	0.1 to 0.25	The majority of people will perceive motion; the level of motion may affect desk work; long-term exposure may produce motion sickness
4	0.25 to 0.4	Desk work becomes difficult or almost impossible; ambulation still possible
5	0.4 to 0.5	People strongly perceive motion; it is difficult to walk naturally; standing people may lose their balance
6	0.5 to 0.6	Most people cannot tolerate the motion and are unable to walk naturally
7	0.6 to 0.7	People cannot walk or tolerate the motion
8	>0.85	Objects begin to fall and people may be injured

FIGURE 13.17 Horizontal acceleration criteria for occupancy comfort in buildings.

Acceleration limits are a function of the frequency of the vibration felt. Upper limits have been recommended for corresponding frequencies of vibration with the relationship suggested by Irwin (1978). Peak acceleration limits as suggested by Melbourne (1988) and Chen (1987) have been plotted along with the Irwin E2 curve in Figure 13.17. To obtain the peak acceleration, the root-mean-square (rms) value can be multiplied by a peak factor. The peak factor is generally between 3 and 4.

13.3.7 Dampers

The damping in a mechanical or structural system is a measure of the rate at which the energy of motion of the system is dissipated. All real systems have some damping. An example is friction in a bearing. Another example is the viscous damping created by the oil within an automotive shock absorber. In many systems, damping is not helpful and it has to be overcome by the system input. In the case of wind-sensitive structures such as tall buildings, however, it is beneficial, as damping reduces motion, making the building feel more stable to its occupants.

Controlling vibrations by increasing the effective damping can be a cost-effective solution. Occasionally, it is the only practical and economical solution.

The types of damping systems that can be implemented include:

- Tuned mass damper (TMD; an example is given in Figure 13.18)
- Distributed viscous dampers
- Tuned liquid column dampers (TLCD), also known as liquid column vibration absorbers (LCVA)
- Tuned sloshing water dampers (TSWD)
- Impact-type dampers
- Visco-elastic dampers
- Semiactive dampers
- Active dampers

While general design philosophy tends to favor passive damping systems due to their lower capital and maintenance costs, active or semiactive dampers may be the ideal solution for certain vibration problems. More details about passive and active systems to control vibrations are given by Soong and Constantinou (1994).

FIGURE 13.18 One of the TMDs designed for the skybridge legs of the Petronas Towers by RWDI Inc. (12 TMDs were installed, three in each of the four legs).

13.3.8 Comparison with Earthquake Loading

Extremes of wind loading, which may be as much as three or four times the loading associated with the mean result, are possible, and a significant contribution to this extreme is often supplied by the resonant component in the turbulence of the wind. Resonance refers to a condition in which the periodicity of forcing is identical to that of the structure, with a consequential amplification of response that is limited only by the level of damping of the structure. A typical wind contains a wide range of frequency components in its turbulence, so it is always possible that the peak response has a resonant component.

Earthquake ground motions are characterized by a series of rather random spikes, with the range of frequencies present (i.e., the range of intervals between zero crossings on the ground acceleration record) being somewhat narrower than for normal wind turbulence. Structures that are stiff will move essentially in unison with the ground motion. For more flexible structures, response is analogous to that from a series of impulses, with the dominant frequency in the response being that of the structure itself. This frequency, the natural frequency of the structure, is dependent on the mass and stiffness of the system.

Wind loading depends on exposed area; earthquake loading depends on the (hidden) mass of the structure. Structures attract wind loadings which increase steadily with the major dimension (height or span, say). The earthquake loading experienced by such structures increases much less rapidly, with the result that, for high-rise structures, wind loading is almost always the dominant lateral loading. This assumes elastic responses for both regimes of loading.

Wind loading depends on topography and, in urban areas, on the proximity of other buildings. Earthquake loading, on the other hand, depends to a marked degree on the foundation materials. It is universally observed that buildings founded on soft soils perform much worse than those founded on rock.

The most important differences between wind and earthquake loading are summarized in Table 13.6.

TABLE 13.6 Main Differences between Wind and Earthquake Loading

Characteristic	Wind	Earthquake
Source of loading	External force due to wind pressures	Applied base motion from ground vibration
Type and duration of loading	Wind storm of several hours duration. Loads fluctuate, but are predominantly in one direction	Transient cyclic loads of at most a few minutes total duration. Loads change repeatedly in direction
Predictability	Good statistical basis is generally available	Poor
Sensitivity of loading to return period	Moderate; +15% typical for $\times 10$ on return period	High; maximum credible earthquake often greatly in excess of "design" values
Influence of local soil conditions	Little effect on dynamic sensitivity	Soil conditions can be very important
Spectral peak input range	Gust: <0.1 Hz	Usually 1 to 5 Hz
Main factors affecting building response	External shape of building or structure. Generally only global dynamic properties are important. Dynamic considerations affect only a small fraction of building structures	Response is governed by global dynamic properties (fundamental period, damping, and mass) but plan and vertical regularity of structure also important. All structures are affected dynamically
Normal design basis	Elastic response is required	Inelastic response is usually permitted, but ductility must be provided
Design of nonstructural elements	Applied loading is concentrated on external cladding	Entire building contents are shaken and must be appropriately designed

13.4 Vibrations Due to Fluid–Structure Interaction

The principles of vibration due to fluids such as water are very similar to those of wind action presented in the previous section. The fluid flow can significantly affect the vibrational characteristics of a structure. The presence of a quiescent fluid decreases the natural frequencies and increases the damping of the structure. Similar to wind, a turbulent fluid flow exerts random pressures on a structure, and these random pressures induce a random response leading to large structural deformations or failure. More details on fluid–structure interaction can be found in text books (e.g., Tiejens and Prandtl, 1957; Milne-Thompson, 1968).

13.4.1 Added Mass and Inertial Coupling

A real fluid is viscous and compressible. In contrast, a perfect fluid is nonviscous and incompressible. Fluid damping is absent in perfect fluids, and therefore, for a structure oscillating in a quiescent perfect fluid, the fluid-force component is associated with the fluid inertia called the added mass. This is of practical importance when the fluid density is comparable to the density of the structure, because then the added mass becomes a significant fraction of the total mass in dynamic motion. Added mass and fluid damping associated with single and multiple cylindrical structures are discussed in detail by Chen (1987). For example, the added mass for a circular cylinder of radius a and height h is equal to $\pi a^2 h$. Added masses for different cross-sectional shapes are presented by Milne-Thompson (1968).

13.4.2 Wave-Induced Vibration of Structure

This effect is similar to wind; however, the density is very much larger than wind, thus making the structural damping less effective. Therefore, it is essential to ensure that resonance does not occur.

The fluid forces which act in line with the direction of wave propagation (Figure 13.19) can be found using a generalized form of Morrison's equation comprising both drag (proportional to area times velocity squared) and inertia forces (proportional to immersed volume times acceleration). More details can be found in Muga and Wilson (1970).

Flexible structures will resonate with the wave if the structural natural period equals the wave period or a harmonic of the wave period. Since the wave frequencies of importance are ordinarily less than 0.2 Hz, such a resonance occurs only for exceptionally flexible structures such as offshore platforms. The amplitude of structural response at resonance is a balance between the wave force and the structural stiffness times the damping.

The above discussion considers only the in-line forces. These in-line forces produce an in-line response. However, substantial transverse vibrations also occur for ocean flows around circular cylinders. These vibrations are associated with periodic vortex shedding, which was discussed under wind-induced vibration.

FIGURE 13.19 A circular cylindrical structure exposed to ocean waves.

13.5 Blast Loading and Blast Effects on Structures

The use of vehicle bombs to attack city centers has been a feature of campaigns by terrorist organizations around the world. A bomb explosion within or very near a building can have catastrophic effects, destroying or severely damaging portions of the building's external and internal structural frames, collapsing walls, blowing out large expanses of windows, and shutting down critical life-safety systems, such as fire detection and suppression, ventilation, light, water, sewage, and power systems. Loss of life and injuries to occupants can result from many causes, including direct blast effects, structural collapse, debris impact, fire, and smoke. The indirect effects can combine to inhibit or prevent timely evacuation, thereby contributing to additional casualties. In addition, major catastrophes resulting from gas-chemical explosions or nuclear leakage result in large dynamic loads, greater than the original design loads, of many structures. Owing to the threat of such extreme loading conditions, efforts have been made during the past three decades to develop methods of structural analysis and design to resist blast loads. The analysis and design of structures subjected to blast loads requires a detailed understanding of blast phenomena and the dynamic response of various structural elements.

13.5.1 Explosions and Blast Phenomenon

An explosion is defined as a large-scale, rapid, and sudden release of energy. Explosions can be categorized on the basis of their nature as physical, nuclear, or chemical events. In physical explosions, energy may be released from the catastrophic failure of a cylinder of compressed gas, volcanic eruptions, or even the mixing of two liquids at different temperatures. In a nuclear explosion, energy is released from the formation of different atomic nuclei by the redistribution of the protons and neutrons within the interacting nuclei; whereas the rapid oxidation of fuel elements (carbon and hydrogen atoms) is the main source of energy in the case of chemical explosions.

Explosive materials can be classified according to their physical state as solids, liquids, or gases. Solid explosives are mainly high explosives, for which blast effects are best known. They can also be classified on the basis of their sensitivity to ignition as secondary or primary explosive. The latter is one that can be easily detonated by simple ignition from a spark, flame, or impact. Materials such as mercury fulminate and lead azide are primary explosives. Secondary explosives detonate creating blast (shock) waves, which

FIGURE 13.20 Blast wave propagation.

result in damage to the surroundings. Examples include trinitrotoluene (TNT) and ammonium nitrate and fuel oil (ANFO).

The detonation of a condensed high explosive generates hot gases under pressure of up to 300 kbar and a temperature of about 3000 to 4000°C. The hot gas expands, forcing out the volume it occupies. As a consequence, a layer of compressed air (blast wave) forms in front of this gas volume, containing most of the energy released by the explosion. The blast wave instantaneously increases to a value of pressure above the ambient atmospheric pressure. This is referred to as the side-on overpressure, and decays as the shock wave expands outward from the explosion source. After a short time, the pressure behind the front may drop below the ambient pressure (see Figure 13.20 and Figure 13.21). During such a negative phase, a partial vacuum is created and air is sucked in. This is also accompanied by high suction winds that carry the debris for long distances away from the explosion source.

FIGURE 13.21 Blast wave pressure — time history.

13.5.2 Explosive Air-Blast Loading

The threat for a conventional bomb is defined by two equally important elements, the bomb size, or charge weight, W , and the standoff distance, R , between the blast source and the target (Figure 13.22). For example, the blast that occurred at the basement of the World Trade Center in 1993 had the charge weight of 816.5 kg TNT. The Oklahoma City bomb in 1995 had a charge weight of 1814 kg at a stand off of 4.5 m (Longinow and Mniszewski, 1996). As terrorist attacks may range from a small letter bomb to a gigantic truck bomb, as experienced in Oklahoma City, the mechanics of a conventional explosion and their effects on the target must be addressed.

The observed characteristics of air-blast waves are found to be affected by the physical properties of the explosion source. Figure 13.21 shows a typical blast pressure profile. At an arrival time of t_A after the explosion, pressure at that position suddenly increases to a peak value of overpressure, P_{so} , over the ambient pressure, P_0 . The pressure then decays to the ambient pressure at time t_d until it reaches a partial vacuum of peak underpressure P_{so}^- , and eventually returns to the ambient pressure at time $t_d + t_d^-$. The quantity P_{so} is usually referred to as the peak side-on overpressure, incident peak overpressure, or merely the peak overpressure (TM 5-1300, 1990).

FIGURE 13.22 Blast loads on a building.

The incident peak overpressure, P_{so} , is amplified by a reflection factor as the shock wave encounters an object or structure in its path. Except for the specific focusing of high-intensity shock waves at near 45° incidence, these reflection factors are typically greatest for normal incidence (a surface adjacent and perpendicular to the source) and diminish with the angle of obliquity or angular position relative to the source. Reflection factors depend on the intensity of the shock wave. For large explosions at normal incidence these reflection factors may enhance the incident pressures by as much as an order of magnitude.

Throughout the pressure–time profile, two main phases can be observed; the portion above ambient pressure is called positive phase of duration t_d , while that below ambient is called negative phase of duration, t_d^- . The negative phase is of a longer duration and a lower intensity than the positive duration. The duration of the positive-phase blast wave increases with range, resulting in a lower amplitude, longer duration shock pulse the further a target structure is situated from the burst. Charges situated extremely close to a target structure impose a highly impulsive, high-intensity pressure load over a localized region of the structure; charges situated further away produce a lower-intensity, longer-duration uniform pressure distribution over the entire structure. Eventually, the entire structure is engulfed in the shock wave, with reflection and diffraction effects creating focusing and shadow zones in a complex pattern around the structure. During the negative phase, the weakened structure may be subjected to impact by debris that may cause additional damage.

If the exterior building walls are capable of resisting the blast load, the shock front penetrates through window and door openings, subjecting the floors, ceilings, walls, contents, and people within to sudden pressures and fragments from shattered windows, doors, and other fixtures. Building components not capable of resisting the blast wave will fracture and be further fragmented and moved by the dynamic pressure that immediately follows the shock front. Building contents and people will be displaced and tumbled in the direction of blast wave propagation. In this manner the blast will propagate through the building.

13.5.2.1 Blast Wave Scaling Laws

All blast parameters are primarily dependent on the amount of energy released by a detonation in the form of a blast wave and the distance from the explosion. A universal normalized description of the blast effects can be given by scaling distance relative to $(E/P_0)^{1/3}$, and pressure relative to P_0 , where E is the energy release (kJ) and P_0 the ambient pressure (typically 100 kN/m^2). For convenience, however, it is general practice to express the basic explosive input or charge weight W as an equivalent mass of TNT. Results are then given as a function of the dimensional distance parameter (scaled distance)

$Z = R/W^{1/3}$, where R is the actual effective distance from the explosion. W is generally expressed in kilograms. Scaling laws provide parametric correlations between a particular explosion and a standard charge of the same substance.

13.5.2.2 Prediction of Blast Pressure

Blast wave parameters for conventional high-explosive materials have been the focus of a number of studies during the 1950s and 1960s. Estimations of peak overpressure due to a spherical blast based on the scaled distance $Z = R/W^{1/3}$ were introduced by Brode (1955) as

$$P_{so} = \frac{6.7}{Z^3} + 1 \text{ bar } (P_{so} > 10 \text{ bar})$$

$$P_{so} = \frac{0.975}{Z} + \frac{1.455}{Z^2} + \frac{5.85}{Z^3} - 0.019 \text{ bar } (0.1 \text{ bar} < P_{so} < 10 \text{ bar})$$
(13.20)

Newmark and Hansen (1961) introduced a relationship to calculate the maximum blast overpressure, P_{so} , in bars, for a high-explosive charge detonated at the ground surface as

$$P_{so} = 6784 \frac{W}{R^3} + 93 \left(\frac{W}{R^3} \right)^{\frac{1}{2}}$$
(13.21)

Another expression of the peak overpressure in kPa was introduced by Mills (1987), in which W is expressed as the equivalent charge weight in kg of TNT, and Z is the scaled distance

$$P_{so} = \frac{1772}{Z^3} - \frac{114}{Z^2} + \frac{108}{Z}$$
(13.22)

As the blast wave propagates through the atmosphere, the air behind the shock front is moving outward at a lower velocity. The velocity of the air particles, and hence the wind pressure, depends on the peak overpressure of the blast wave. This later velocity of the air is associated with the dynamic pressure, $q(t)$. The maximum value, q_s , say, is given by

$$q_s = 5P_{so}^2/2(P_{so} + 7P_0)$$
(13.23)

If the blast wave encounters an obstacle perpendicular to the direction of propagation, reflection increases the overpressure to a maximum reflected pressure P_r as

$$P_r = 2P_{so} \left\{ \frac{7P_0 + 4P_{so}}{7P_0 + P_{so}} \right\}$$
(13.24)

A full discussion and extensive charts for predicting blast pressures and blast durations are given by TM 5-1300 (1990) and Mays and Smith (1995). Some representative numerical values of peak-reflected overpressure are given in Table 13.7.

TABLE 13.7 Peak-Reflected Overpressures P_r (in MPa) with Different W – R Combinations

R (m)	W			
	100 kg TNT	500 kg TNT	1000 kg TNT	2000 kg TNT
1	165.8	354.5	464.5	602.9
2.5	34.2	89.4	130.8	188.4
5	6.65	24.8	39.5	60.19
10	0.85	4.25	8.15	14.7
15	0.27	1.25	2.53	5.01
20	0.14	0.54	1.06	2.13
25	0.09	0.29	0.55	1.08
30	0.06	0.19	0.33	0.63

For design purposes, reflected overpressure can be idealized by an equivalent triangular pulse of maximum peak pressure P_r and time duration t_d , which yields the reflected impulse i_r :

$$i_r = \frac{1}{2} P_r t_d \quad (13.25)$$

The reflection effect dissipates as the perturbation propagates to the edges of the obstacle at a velocity related to the speed of sound (U_s) in the compressed and heated air behind the wave front. Denoting the maximum distance from an edge as S (for example, the lesser of the height or half the width of a conventional building), the additional pressure due to reflection is considered to reduce from $P_r - P_{so}$ to 0 in time $3S/U_s$. Conservatively, U_s can be taken as the normal speed of sound, about 340 m/sec, and the additional impulse to the structure evaluated on the assumption of a linear decay.

After the blast wave has passed the rear corner of a prismatic obstacle, the pressure similarly propagates on to the rear face; linear build-up over duration $5S/U_s$ has been suggested. For skeletal structures, the effective duration of the net overpressure load is thus small, and the drag loading based on the dynamic pressure is then likely to be dominant. Conventional wind-loading pressure coefficients may be used, with the conservative assumption of instantaneous build-up when the wave passes the plane of the relevant face of the building, the loads on the front and rear faces being numerically cumulative for the overall load effect on the structure. Various formulations have been put forward for the rate of decay of the dynamic pressure loading; a parabolic decay (i.e., corresponding to a linear decay of equivalent wind velocity) over a time equal to the total duration of positive overpressure is a practical approximation.

13.5.3 Gas Explosion Loading and Effect of Internal Explosions

In the circumstances of a progressive build-up of fuel in a low-turbulence environment, typical of domestic gas explosions, flame propagation on ignition is slow and the resulting pressure pulse is correspondingly extended. The specific energy of combustion of a hydrocarbon fuel is very high (46,000 kJ/kg for propane, compared with 4520 kJ/kg for TNT) but widely differing effects are possible according to the conditions at ignition.

Internal explosions often produce complex pressure loading profiles as a consequence of having two loading phases. The first results from the blast overpressure reflection and, due to the confinement provided by the structure, re-reflection will occur. Depending on the degree of confinement of the structure, the confined effects of the resulting pressures may cause different degrees of damage to the structure. On the basis of the confinement effect, target structures can be described as either vented or unvented. The latter must be stronger to resist a specific explosion yield than a vented structure where some of the explosion energy would be dissipated by the breaking of window glass or fragile partitions.

Generally, venting following the failure of windows (typically at 7 kN/m²) greatly reduces the peak values of internal pressures. A study of this problem at the Building Research Establishment (Ellis and Crowhurst, 1991) showed that an explosion fuelled by a 200 ml aerosol canister in a typical domestic room produced a peak pressure of 9 kN/m² with a pulse duration over 0.1 sec. This is long by comparison with the natural frequency of wall panels in conventional building construction, and a quasi-static design pressure is commonly advocated. Much higher pressures with a shorter timescale are generated in turbulent conditions. Suitable conditions arise in buildings in multiroom explosions on the passage of the blast through doorways, but can also be created by obstacles closer to the release of the gas. These may be presumed to occur on a release of gas due to a failure of industrial pressure vessels or pipelines.

13.5.4 Structural Response to Blast Loading

Complexity in analyzing the dynamic response of blast-loaded structures involves the effect of high strain-rates, nonlinear inelastic material behavior, uncertainties of blast-load calculations, and time-dependent deformations. Therefore, to simplify the analysis, a number of assumptions related to the response of structures and loads have been proposed and widely accepted. To establish the principles of

this analysis, the structure is idealized as an single-DoF system and the link between the positive duration of the blast load and the natural period of vibration of the structure is established. This leads to blast-load idealization and simplifies the classification of the blast-loading regimes.

13.5.4.1 Elastic Single-Degree-of-Freedom Systems

The simplest discretization of transient problems is by means of the single-DoF approach. The actual structure can be replaced by an equivalent system of one concentrated mass and one weightless spring, representing the resistance of the structure against deformation. Such an idealized system is illustrated in Figure 13.23. The structural mass, M , is under the effect of an external force, $F(t)$, and the structural resistance, R , is expressed in terms of the vertical displacement, y , and the spring constant, K .

The blast load can also be idealized as a triangular pulse having a peak force F_m and positive-phase duration t_d (see Figure 13.23). The forcing function is given as

$$F(t) = F_m \left(1 - \frac{t}{t_d}\right) \quad (13.26)$$

The blast impulse is approximated as the area under the force–time curve, and is given by

$$I = \frac{1}{2} F_m t_d \quad (13.27)$$

The equation of motion of the undamped elastic single-DoF system for a time ranging from 0 to the positive-phase duration, t_d , is given by Biggs (1964) as

$$M\ddot{y} + Ky = F_m \left(1 - \frac{t}{t_d}\right) \quad (13.28)$$

The general solution can be expressed as

$$\begin{aligned} \text{Displacement } y(t) &= \frac{F_m}{K} (1 - \cos \omega t) + \frac{F_m}{K t_d} \left(\frac{\sin \omega t}{\omega} - t \right) \\ \text{Velocity } \dot{y}(t) &= \frac{dy}{dt} = \frac{F_m}{K} \left[\omega \sin \omega t + \frac{1}{t_d} (\cos \omega t - 1) \right] \end{aligned} \quad (13.29)$$

in which ω is the natural circular frequency of vibration of the structure and T is the natural period of vibration of the structure given as

$$\omega = \frac{2\pi}{T} = \sqrt{\frac{K}{M}} \quad (13.30)$$

The maximum response is defined by the maximum dynamic deflection y_m , which occurs at time t_m . The maximum dynamic deflection y_m can be evaluated by setting dy/dt in Equation 13.29 equal to zero, that is, when the structural velocity is zero. The dynamic load factor (DLF) is defined as the ratio of the maximum dynamic deflection y_m to the static deflection y_{st} which would have resulted from the static

FIGURE 13.23 (a) Single-DoF system and (b) blast loading.

application of the peak load F_m , as follows:

$$DLF = \frac{y_{\max}}{y_{st}} = \frac{y_{\max}}{F_m/K} = \psi(\omega t_d) = \Psi\left(\frac{t_d}{T}\right) \quad (13.31)$$

The structural response to blast loading is significantly influenced by the ratio t_d/T or ωt_d ($t_d/T = \omega t_d/2\pi$). Three loading regimes are categorized as follows:

1. $\omega t_d < 0.4$: impulsive loading regime
2. $\omega t_d < 0.4$: quasi-static loading regime
3. $0.4 < \omega t_d < 40$: dynamic loading regime

13.5.4.2 Elasto-Plastic Single-Degree-of-Freedom Systems

Structural elements are expected to undergo large inelastic deformation under a blast load or high-velocity impact. The exact analysis of dynamic response is then only possible by a step-by-step numerical solution requiring non-linear dynamic finite-element software. However, the degree of uncertainty in both the determination of the loading, and the interpretation of acceptability of the resulting deformation, is such that the solution of a postulated equivalent ideal elasto-plastic single-DoF system (Biggs, 1964) is commonly used. Interpretation is based on the required ductility factor $\mu = y_m/y_e$ (Figure 13.24).

FIGURE 13.24 Simplified resistance function of an elasto-plastic single-DoF system.

For example, a uniform simply supported beam has first mode shape $\phi(x) = \sin \pi x/L$ and the equivalent mass is $M = (1/2)mL$, where L is the span of the beam and m is mass per unit length. The equivalent force corresponding to a uniformly distributed load of intensity p is $F = (2/\pi)pL$. The response of the ideal bilinear elasto-plastic system can be evaluated in closed form for the triangular load pulse comprising rapid rise and linear decay, with maximum value F_m and duration t_d . The result for the maximum displacement is generally presented in chart form (TM 5-1300) as a family of curves for

FIGURE 13.25 Maximum response of an elasto-plastic single-DoF system to a triangular load (TM 5-1300).

selected values of R_u/F_m showing the required ductility μ as a function of t_d/T , in which R_u is the structural resistance of the beam and T is the natural period (Figure 13.25).

13.5.5 Material Behaviors at High Strain Rate

Blast loads typically produce very high strain-rates in the range of 100 to 10,000 sec^{-1} . This high straining (loading) rate would alter the dynamic mechanical properties of target structures and, accordingly, the expected damage mechanisms for various structural elements. For reinforced concrete structures subjected to blast effects, the strength of concrete and steel reinforcing bars can increase significantly due to the strain-rate effect. Figure 13.26 shows approximate ranges of the expected strain rates for different loading conditions. It can be seen that the ordinary static strain rate is located in the range of 10^{-6} to 10^{-5} sec^{-1} , while blast pressures normally yield loads associated with strain rates in the range of 100 to 10,000 sec^{-1} .

13.5.5.1 Dynamic Properties of Concrete under High Strain Rates

The mechanical properties of concrete under dynamic loading conditions can be quite different from that under static loads. While the dynamic stiffness does not change very much compared with the static stiffness, the stresses that are sustained for a certain period under dynamic conditions may gain values that are remarkably higher than the static compressive strength (Figure 13.27). Strength magnification factors as high as four in compression and up to six in tension for strain rates in the range of 100 to 1000 sec^{-1} have been reported (Grote et al., 2001).

FIGURE 13.26 Strain rates associated with different types of loading.

FIGURE 13.27 Stress–strain curves of concrete at different strain rates. (Source: Data from Ngo, T. et al., *Proc. 18th Australasian Conf. on Mechanics of Structures and Materials*, Perth, Australia. With permission.)

For the increase in peak compressive stress (f'_c), a dynamic increase factor (DIF) is introduced in the Comité Euro-International du Béton (CEB-FIP; 1990) model (Figure 13.28) for strain-rate enhancement of concrete as follows:

$$\text{DIF} = \left(\frac{\dot{\epsilon}}{\dot{\epsilon}_s} \right)^{1.026\alpha} \quad \text{for } \dot{\epsilon} \leq 30 \text{ sec}^{-1} \quad (13.32)$$

$$\text{DIF} = \gamma \left(\frac{\dot{\epsilon}}{\dot{\epsilon}_s} \right)^{1/3} \quad \text{for } \dot{\epsilon} > 30 \text{ sec}^{-1} \quad (13.33)$$

where

$\dot{\epsilon}$ = strain rate

$\dot{\epsilon}_s = 30 \times 10^{-6} \text{ sec}^{-1}$ (quasi-static strain rate)

$\log \gamma = 6.156\alpha - 2$

$\alpha = 1/(5 + 9f'_c/f_{co})$

$f_{co} = 10 \text{ MPa} = 1450 \text{ psi}$

FIGURE 13.28 Dynamic increase factor for peak stress of concrete (CEB-FIP model).

13.5.5.2 Dynamic Properties of Reinforcing Steel under High Strain Rates

Owing to the isotropic properties of metallic materials, their elastic and inelastic response to dynamic loading can easily be monitored and assessed. Norris et al. (1959) tested steel with two different static yield strengths (330 and 278 MPa) under tension at strain rates ranging from 10^{-5} to 0.1 sec^{-1} . Strength increases of 9–21% and 10–23% were observed for the two steel types, respectively. Dowling and Harding (1967) conducted tensile experiments using the tensile version of the Split Hopkinson's Pressure Bar (SHPB) on mild steel using strain rates varying between 10^{-3} and 2000 sec^{-1} . It was concluded from this test series that materials of body-centered cubic (BCC) structure (such as mild steel) showed the greatest strain rate sensitivity, the lower yield tensile strength of mild steel was almost doubled, the ultimate tensile stress was increased by about 50%, the upper yield tensile strength considerably increased, and the ultimate tensile strain decreased by different percentages, depending on the strain rate.

Malvar (1998) also studied the strength enhancement of steel reinforcing bars under the effect of high strain rates. This was described in terms of the DIF, which can be evaluated for different steel grades and for yield stresses, f_y , ranging from 290 to 710 MPa as

$$\text{DIF} = \left(\frac{\dot{\epsilon}}{10^{-4}} \right)^{\alpha} \quad (13.34)$$

where for calculating yield stress $\alpha = \alpha_{fy}$,

$$\alpha_{fy} = 0.074 - 0.04 (f_y/414) \quad (13.35)$$

and for ultimate stress calculation $\alpha = \alpha_{fu}$

$$\alpha_{fu} = 0.019 - 0.009 (f_y/414) \quad (13.36)$$

13.5.6 Failure Modes of Blast-Loaded Structures

Blast-loading effects on structural members may produce both local and global responses associated with different failure modes. The type of structural response depends mainly on the loading rate, the orientation of the target with respect to the direction of the blast wave propagation, and boundary conditions. The general failure modes associated with blast loading can be flexure, direct shear, or punching shear. Local responses are characterized by localized breaching and spalling, and generally

result from the close-in effects of explosions, while global responses are typically manifested as flexural failure.

13.5.6.1 Global Structural Behavior

The global response of structural elements is generally a consequence of transverse (out of plane) loads with long exposure time (quasi-static loading), and is usually associated with global membrane (bending) and shear responses. Therefore, the global response of above-ground reinforced concrete structures subjected to blast loading is referred to as membrane/bending failure.

The second global failure mode to be considered is shear failure. It has been found that under the effect of both static and dynamic loads, four types of shear failure can be identified: diagonal tension, diagonal compression, punching shear, and direct (dynamic) shear (Woodson, 1993). The first two types are common in reinforced concrete elements under static loads, while punching shear is associated with local shear failure; for example, the familiar case is column punching through flat slabs. These shear response mechanisms have relatively minor structural effect in case of blast loading and can be neglected. The fourth type of shear failure is direct (dynamic) shear. This failure mode is primarily associated with transient short duration dynamic loads that result from blast effects, and it depends mainly on the intensity of the pressure waves. The associated shear force is many times higher than the shear force associated with flexural failure modes. The high shear stresses may lead to a direct global shear failure and it may occur very early (within a few milliseconds of shock wave arrival to the facing structure's surface) even prior to any significant bending deformations.

13.5.6.2 Localized Structural Behavior

The close-in effect of an explosion may cause localized shear or flexural failure in the closest structural elements. This depends mainly on the distance between the explosion center and the target, and the relative strength/ductility of the structural elements. The localized shear failure takes the form of localized punching and spalling, which produces low and high-speed fragments. The punching effect is frequently referred to as breaching, which is well known in high-velocity impact applications and in the case of explosions close to the surface of structural members. Breaching failures are typically accompanied by spalling and scabbing of concrete covers, as well as fragments and debris (Figure 13.29).

FIGURE 13.29 Breaching failure due to a close-in explosion of 6000 kg TNT equivalent (photograph by Tuan Ngo).

FIGURE 13.30 Typical pressure-impulse (P - I) diagram.

13.5.6.3 Pressure-Impulse (P - I) Diagrams

The P - I diagram is an easy way to mathematically relate a specific damage level to a combination of blast pressures and the corresponding impulses for a particular structural element. An example P - I diagram is given in Figure 13.30. This figure shows the levels of damage of a structural member, in which region (I) corresponds to severe structural damage and region (II) refers to no or minor damage. There are other P - I diagrams that are concerned with human responses to blasts, in which three categories of blast-induced injury are identified as primary, secondary, and tertiary injury (Baker et al., 1983).

13.5.7 Blast Wave-Structure Interaction

The structural behavior of an object or structure exposed to such a wave may be analyzed by dealing with two main issues. Firstly, blast-loading effects, that is, forces that result from the action of the blast pressure; secondly, the structural response, or the expected damage criteria associated with such loading effects. It is important to consider the interaction of the blast waves with target structures. This might be quite complicated in the case of complex structural configurations. However, it is possible to consider some equivalent simplified geometry. Accordingly, in analyzing the dynamic response to blast loading, two types of target structures can be considered: diffraction-type and drag-type structures. As these names imply, the former would be affected mainly by diffraction (engulfing) loading and the latter by drag loading. It should be emphasized that actual buildings will respond to both types of loading and the distinction is made primarily to simplify the analysis. The structural response will depend upon the size, shape, and weight of the target, how firmly it is attached to the ground, and also on the existence of openings in each face of the structure.

13.5.8 Effect of Ground Shocks

Above ground or shallow-buried structures can be subjected to ground shock resulting from the detonation of explosive charges that are on, or close to, the ground surface. The energy imparted to the

ground by the explosion is the main source of ground shock. A part of this energy is directly transmitted through the ground as direct-induced ground shock, while part is transmitted through the air as air-induced ground shock. Air-induced ground shock results when the air-blast wave compresses the ground surface and sends a stress pulse into the ground underlayers. Generally, motion due to air-induced ground shock is maximum at the ground surface and attenuates with depth (TM 5-1300, 1990). The direct-induced shock results from the direct transmission of explosive energy through the ground. For a point of interest on the ground surface, the net experienced ground shock results from a combination of both the air-induced and direct-induced shocks.

13.5.8.1 Loads from Air-Induced Ground Shock

To overcome complications of predicting actual ground motion, one-dimensional wave propagation theory has been employed to quantify the maximum displacement, velocity, and acceleration in terms of the already known blast wave parameters (TM 5-1300). The maximum vertical velocity at the ground surface, V_v , is expressed in terms of the peak incident overpressure, P_{so} , as

$$V_v = \frac{P_{so}}{\rho C_p} \quad (13.37)$$

where ρ and C_p are, respectively, the mass density and the wave seismic velocity in the soil.

By integrating the vertical velocity in Equation 13.37 with time, the maximum vertical displacement at the ground surface, D_v , can be obtained as

$$D_v = \frac{i_s}{1000\rho C_p} \quad (13.38)$$

Accounting for the depth of soil layers, an empirical formula is given by TM 5-1300 to estimate the vertical displacement in meters so that

$$D_v = 0.09W^{1/6}(H/50)^{0.6}(P_{so})^{2/3} \quad (13.39)$$

where W is the explosion yield in 10^9 kg and H is the depth of the soil layer in meters.

13.5.8.2 Loads from Direct Ground Shock

As a result of the direct transmission of the explosion energy, the ground surface experiences vertical and horizontal motions. Some empirical equations were derived (TM 5-1300) to predict the direct-induced ground motions in three different ground media; dry soil, saturated soil, and rock media. The peak vertical displacement in m/sec at the ground surface for rock, $D_{V_{rock}}$ and dry soil, $D_{V_{soil}}$ are given as

$$D_{V_{rock}} = \frac{0.25R^{1/3}W^{1/3}}{Z^{1/3}} \quad (13.40)$$

$$D_{V_{soil}} = \frac{0.17R^{1/3}W^{1/3}}{Z^{2.3}} \quad (13.41)$$

The maximum vertical acceleration, A_v , in m/sec^2 for all ground media is given by

$$A_v = \frac{1000}{W^{1/8}Z^2} \quad (13.42)$$

13.5.9 Technical Design Manuals for Blast-Resistant Design

This section summarizes applicable military design manuals and computational approaches to predicting blast loads and the responses of structural systems. Although the majority of these design guidelines were focused on military applications, this knowledge is relevant for civil design practice.

Structures to Resist the Effects of Accidental Explosions, TM 5-1300 (U.S. Departments of the Army, Navy, and Air Force, 1990): This manual appears to be the most widely used publication by both military and civilian organizations for designing structures to prevent the propagation of explosion, and to provide protection for personnel and valuable equipment. It includes step-by-step analysis and design procedures, including information on such items as (1) blast, fragment, and shock-loading; (2) principles of dynamic analysis; (3) reinforced and structural steel design; and (4) a number of special design considerations, including information on tolerances and fragility, as well as shock isolation. Guidance is provided for the selection and design of security windows, doors, utility openings, and other components that must resist blast and forced-entry effects.

A Manual for the Prediction of Blast and Fragment Loadings on Structures, DOE/TIC-11268 (U.S. Department of Energy, 1992): This manual provides guidance to the designers of facilities subject to accidental explosions and aids in the assessment of the explosion-resistant capabilities of existing buildings.

Protective Construction Design Manual, ESL-TR-87-57 (Air Force Engineering and Services Center, 1989): This manual provides procedures for the analysis and design of protective structures exposed to the effects of conventional (nonnuclear) weapons, and is intended for use by engineers with a basic knowledge of weapons effects, structural dynamics, and hardened protective structures.

Fundamentals of Protective Design for Conventional Weapons, TM 5-855-1 (U.S. Department of the Army, 1986): This manual provides procedures for the design and analysis of protective structures subjected to the effects of conventional weapons. It is intended for use by engineers involved in designing hardened facilities.

The Design and Analysis of Hardened Structures to Conventional Weapons Effects (DAHS CWE, 1998): This new joint services manual, written by a team of more than 200 experts in conventional weapons and protective structures engineering, supersedes U.S. Department of the Army TM 5-855-1, *Fundamentals of Protective Design for Conventional Weapons* (1986), and Air Force Engineering and Services Centre ESL-TR-87-57, *Protective Construction Design Manual* (1989).

Structural Design for Physical Security — State of the Practice Report (Conrath et al., 1995): This report is intended to be a comprehensive guide for civilian designers and planners who wish to incorporate physical security considerations into their designs or building retrofit efforts.

13.5.10 Computer Programs for Blast and Shock Effects

Computational methods in the area of blast effects mitigation are generally divided into those used for the prediction of blast loads on the structure and those for the calculation of structural responses to the loads. Computational programs for blast prediction and structural response use both first-principle and semiempirical methods. Programs using the first-principle method can be categorized into uncouple and couple analyses. The uncouple analysis calculates blast loads as if the structure (and its components) were rigid, and then applies these loads to a responding model of the structure. The shortcoming of this procedure is that, when the blast field is obtained with a rigid model of the structure, the loads on the structure are often overpredicted, particularly if significant motion or the failure of the structure occurs during the loading period.

For a coupled analysis, the blast simulation module is linked with the structural response module. In this type of analysis, the computational fluid mechanics (CFD) model for blast-load prediction is solved simultaneously with the computational solid mechanics (CSM) model for structural response. By accounting for the motion of the structure while the blast calculation proceeds, the pressures that arise due to the motion and failure of the structure can be predicted more accurately. Examples of this type of computer software are AUTODYN, DYNA3D, LS-DYNA, and ABAQUS. [Table 13.8](#) provides a listing of computer programs that are currently being used to model blast effects on structures.

Prediction of the blast-induced pressure field on a structure and its response involves highly nonlinear behavior. Computational methods for blast-response prediction must therefore be validated by comparing calculations to experiments. Considerable skill is required to evaluate the output of the

computer software, both as to its correctness and its appropriateness to the situation modeled; without such judgment, it is possible through a combination of modeling errors and poor interpretation to obtain erroneous or meaningless results. Therefore, successful computational modeling of specific blast scenarios by engineers unfamiliar with these programs is difficult, if not impossible.

13.6 Impact Loading

Impact effects on structures arise over a very broad range of circumstances, from high-velocity missiles or aircraft impact to high-mass ship or vehicle collisions. The requirement may be for the structure to withstand the impact without serious damage, or major inelastic deformation may be permitted.

13.6.1 Structural Impact between Two Bodies — Hard Impact and Soft Impact

Impact loads differ from blast loads in duration, and they are applied to a localized area. Blast loads propagate as a wave front, while an impact load is caused by the force resulting from the collision between a moving object and a structure. Impact loading can be classified as either hard or soft, depending upon the relative characteristics of the impactor and the target structure. Impulsive loading can be considered to be a special case of soft impact. Soft impact occurs when the impactor deforms substantially with respect to a hard structure, and a portion of the impactor's kinetic energy is absorbed by the impactor's plastic deformation. For hard impact, the striking object is rigid and the kinetic energy is transmitted to the target and absorbed by deformation and damage in the structure.

Impact problems essentially involve all three fundamental conservation laws: conservation of mass, conservation of momentum, and conservation of energy. These three laws are outlined in the following equations (Zukas, 1990), respectively

$$\int_v \rho \, dV = \text{const} \quad (13.43)$$

$$F = m \, dv/dt \quad (13.44)$$

$$\sum E_i + \sum \frac{1}{2} \rho v_i^2 = \sum E_f + \sum \frac{1}{2} \rho v_f^2 + W \quad (13.45)$$

where

ρ = material density

V = volume

F = force

m = mass

v = velocity

E = stored internal energy

W = work

i, f = initial and final states

Upon impact, stresses and strains are induced in the target material. The layers of particles in the target are compressed upon contact, creating compressive stress. When the compression stress between two layers is equal to the applied pressure, compression supports the entire pressure. Through this process, stress waves are developed similar to the shock waves generated by blast loading. The stress waves propagate throughout the material at a speed inherent to that material and reflect multiple times as interfaces are reached.

Various types of stress waves are developed, depending on the energy imparted into the target. The impact velocity determines the strain rate, mode of response, and the type of impact damage (Zukas et al., 1982). If the impact is below a certain level, only elastic stress waves are generated. Higher velocity impacts create inelastic stress waves. Historically, impact has been considered a localized phenomenon that may cause plastic deformation and/or failure of the target and/or the impactor. During an impact event, some or all of the kinetic energy of the impactor is transferred to the target. This process is a function of the wave propagation in the target, the impactor's deformation of the target upon contact, and the contact velocity. Because the impact has been considered to be localized, the local behavior deformation and penetration has been the prime consideration.

Impact causes elastic and plastic stress waves, and propagation through the structural thickness can cause failure by spalling. Such effects usually occur within microseconds of the impact, and may be referred to as the early time response. The overall dynamic response of the structure usually occurs on a timescale several orders of magnitude longer, and can thus reasonably be decoupled from the early time response and subjected to an initial check against spalling.

Impact imparts impulsive loadings to a structure, producing responses within the structure. Three different types of solutions to the impact problem are available: theoretical (analytical), semiempirical, and numerical. Theoretical methods provide closed-form solutions for the governing partial differential

FIGURE 13.31 Transient deformation of a reinforced concrete beam under impact at midspan. (Source: Data from Ngo, T. et al., *Proc. of 18th Australasian Conference on the Mechanics of Structures and Materials*, Perth, Australia. 2004a. With permission.)

equations. Semiempirical methods rely on extensive test data to produce a curve-fit solution for a class of similar impact problems. Numerical solutions replace the continuous system with discrete domains and treat the problem as it progresses over time (Figure 13.31).

13.6.2 Example — Aircraft Impact

Design loads resulting from aircraft impacts are governed by the absorption of kinetic energy from the aircraft by the building at its maximum deflection. These loads are limited by the yield, buckling, and crushing of the aircraft. Total impact load $F(t)$ at the interface of the collapsing aircraft and the building is given by

$$F(t) = F_c + \mu[m(t)]V(t) \quad (13.46)$$

in which $m(t)$ is the mass of the aircraft reaching the building per unit time; μ is a coefficient for change in momentum (which can be taken conservatively as one); F_c is the crushing load, a constant which can be determined from the design acceleration for failure of the aircraft; and $V(t)$ is the velocity of the aircraft.

Figure 13.32 compares the impact loads produced by a Boeing 707-320 and a Boeing 767, which hit the World Trade Center. It should be noted that World Trade Center was designed to resist the equivalent impact of a Boeing 707.

Figure 13.33 compares the impact loads produced by different aircraft. The peak loads and the duration of loading for different aircraft are given in Table 13.9. These loads were calculated by the method suggested by Kar in 1979 (Mendis and Ngo, 2002).

Kinsella and Jowett (1981) suggested a more accurate method in which the crash event is treated as a combination of the separate time-dependent impacts of the aircraft's frame and engines. The frame is classed as a soft missile which will suffer considerable deformation, and a finite difference method of calculation is employed to describe its perfectly plastic impact. The engines, which are considered separately, are assumed to constitute a much harder missile which will undergo little deformation. The results obtained by this method for a Phantom F4 aircraft are shown in Figure 13.34. This method gave a maximum load of 233 MN compared with the 145 MN obtained from Kar's method.

13.7 Floor Vibration

13.7.1 Introduction

Annoying floor vibrations may be caused by occupant activities. Walking, dancing, jumping, aerobics, and audience participation at music concerts and sporting events are some prime examples of occupant activities that create floor vibrations. The operation of mechanical equipment is another cause for concern. Heating, ventilation, and air-conditioning systems, if not properly isolated, can cause serious vibration problems. The current trend towards longer spans and lighter floor systems has resulted in a significant increase in the number of floor vibration complaints by building owners and occupants.

Most of the sources contributing to reported human discomfort rest on the floor system itself. However, human activities or machinery off a floor can cause significant floor vibrations. On more than one occasion, aerobics on one floor of a high-rise building has been reported to cause vibration discomfort on another level in the building. The vibrations caused by automobiles on parking levels below have been reported to disrupt sensitive laboratory work on upper floors. Other equipment and activities off the floor that can contribute to a floor vibration problem are ground or air traffic, drilling, the impact of falling objects, and other construction-related events.

When the natural frequency of a floor system is close to a forcing frequency and the deflection of the system is significant, motion will be perceptible, and perhaps even annoying. Perception is related to the activity of the occupants: a person at rest or engaged in quiet work will tolerate less vibration than a person performing an active function, such as dancing or aerobics. If a floor system dissipates the imparted energy in a very short period of time, the motion is likely to be perceived as less annoying. Thus, the damping characteristics of the system affect acceptability.

In design guidelines for floor vibration analysis, limits are stated as a minimum natural frequency of a structural system. These limits depend on the permissible peak accelerations (as a fraction of gravitational acceleration) on the mass affected by an activity, the environment in which the vibration occurs, the effectiveness of interaction between connected structural components, and the degree of damping, among other factors.

Recently, excessive floor vibrations have become a common problem due to a decrease in the natural frequency at which buildings vibrate due, in turn, to increased floor spans and a decrease in the amount of damping and mass used in standard construction practice, because of the availability of stronger and lighter materials. Some methods have been developed in the recent past to check the floor vibrations of structures. These methods are summarized in this section. More details can be found in the texts given in the list of references.

13.7.2 Types of Vibration

13.7.2.1 Walking

A walking person's foot touching the floor causes a vibration of the floor system. This vibration may be annoying to other persons sitting or lying in the same area, such as an office, a church, or a residence. Although more than one person may be walking in the same area at the same time, their footsteps are normally not synchronized. Therefore, the analysis is based on the effect of the impact of the individual walking.

13.7.2.2 Rhythmic Activities

In some cases, more than a few people may engage in a coordinated activity that is at least partially synchronized. Spectators at sporting events, rock concerts, and other entertainment events often move in unison in response to music, a cheer, or other stimuli. In these cases, the vibration is caused by many people moving together, usually at a more or less constant tempo.

The people disturbed by the vibration may be those participating in the rhythmic activity, or those in nearby part of the structure engaged in a more quiet activity. The people engaged in the rhythmic activity

have higher level of tolerance for the induced vibrations, while those nearby will have a lower level of tolerance.

13.7.2.3 Mechanical Equipment

Mechanical equipment may produce a constant impulse at a fixed frequency, causing the structure to vibrate.

13.7.2.4 Analysis Methods

Because the nature of the input varies for these three types of loads, each of the three requires a somewhat different solution. However, all cases require knowledge of an important response parameter of the floor system, its natural frequency of vibration, and all three analysis methods are based on finding a required minimum frequency.

13.7.3 Natural Frequency of Vibration

The natural frequency of a floor system is important for two reasons. It determines how the floor system will respond to forces causing vibrations. It is also important in determining how human occupants will perceive the vibrations. It has been found that certain frequencies set up resonance with internal organs of the human body, making these frequencies more annoying to people.

Figure 13.35 shows the human sensitivity over a range of frequencies during various activities. The human body is most sensitive to frequencies in the range of 4 to 8 Hz. This range of natural frequencies is commonly found in typical floor systems. Recommended acceleration limits for vibrations due to rhythmic activities are given in Table 13.10.

FIGURE 13.35 Recommended permissible peak vibration acceleration levels acceptable for human comfort while in different environments. (Source: Data from Mast, R.F., Vibration of precast prestressed concrete floors, PCI J., Nov–Dec, 2001. With permission.)

TABLE 13.10 Recommended Acceleration Limits for Vibrations Due to Rhythmic Activities

Occupancies Affected by the Vibration	Acceleration Limit (%g)
Office and residential	0.4–0.7
Dining and weightlifting	1.5–2.5
Rhythmic activity only	4–7

Source: Data from Alen, D.E., Building vibration from human activities, *Concr. Int.*, 66–73, 1990.

13.7.3.1 Computing the Natural Frequency

The natural frequency of a vibrating beam is determined by the ratio of its stiffness to its mass (or weight). The deflection of simple-span beam is also dependent on its weight and stiffness. A simple relationship exists between the self-weight deflection and the natural frequency of a uniformly loaded simple-span beam on rigid supports:

$$f_n = 0.18\sqrt{g/\Delta_j} \tag{13.47}$$

where

f_n = natural frequency in the fundamental mode of vibration

g = acceleration due to gravity

Δ_j = instantaneous simple-span deflection of floor panel due to dead load plus actual live load

13.7.3.2 Computing Deflection

The equation for the deflection Δ_j for a uniformly loaded simple-span beam is

$$\Delta_j = \frac{5wl^4}{384EI} \tag{13.48}$$

where

l = span length of member

I = gross moment of inertia, for prestressed concrete members

Many vibration problems are more critical when the mass (or weight) is low.

For continuous spans of equal length, the natural frequency is the same as for simple spans. This may be understood by examining Figure 13.36. For static loads, all spans deflect downward simultaneously, and continuity significantly reduces the deflection. But for vibration, one span deflects downward while the adjacent spans deflect upward. An inflection point exists at the supports, and the deflection and natural frequency are the same as for a simple span.

For unequal continuous spans, and for partially continuous spans with supports, the natural frequency may be increased by a small amount.

FIGURE 13.36 Natural frequency of simple and continuous spans.

13.7.3.3 Damping

Damping determines how quickly a vibration will decay and die out. This is important because human perception and tolerance of vibration or motion is dependent on how long it lasts. Damping of a floor system is highly dependent on the nonstructural items (partitions, ceilings, furniture, and other items) present. The modal damping ratio of a bare structure undergoing low-amplitude vibrations can be very low, on the order of 1%. Nonstructural elements may increase this damping ratio up to 5% (see Table 13.11). It must be appreciated that the results of a vibration analysis are highly influenced by the choice of the assumed damping, which can vary widely.

13.7.3.4 Resonance

Resonance occurs when the frequency of a forcing input nearly matches the natural frequency of a system. In order to avoid excessive amplification of vibration, the natural frequency must be higher than the frequency of the input forces by an amount related to the damping of the floor system.

13.7.4 Vibration Caused by Walking

Vibrations caused by walking can often be objectionable in lighter constructions of wood or steel. Because of the greater mass and stiffness of concrete floor systems, vibrations caused by walking are seldom a problem in these systems. However, when designing concrete floor systems of long span, the serviceability requirement on vibrations may become critical.

13.7.4.1 Minimum Natural Frequency

People are most sensitive to vibrations when engaged in sedentary activities while seated or lying. Much more vibration is tolerated by people who are standing, walking, or active in other ways. Thus, different criteria are given for offices, residences, and churches than for shopping malls and footbridges.

An empirical formula, based on the resonant effects of walking, has been developed to determine the minimum natural frequency of a floor system needed to prevent disturbing vibrations caused by walking:

$$f_n \geq 2.861 \ln \left(\frac{K}{\beta W} \right) \tag{13.49}$$

where

K = a constant, given in Table 13.11

β = modal damping ratio

W = weight of area of floor panel affected by a point load

13.7.5 Design for Rhythmic Excitation

Rhythmic excitation may occur when a group of people exercise or respond to a musical beat. Because a group is acting in unison at a constant frequency, the input forces are much more powerful than those produced by random walking. Resonance can occur when the input frequency is at or near the

TABLE 13.11 Values of K and β

Occupancies Affected by the Vibration	K (kN)	β
Offices, residences, churches	58	0.02 ^a ; 0.03 ^b ; 0.05 ^c
Shopping malls	20	0.02
Outdoor footbridges	8	0.01

^a For floors with few nonstructural components and furnishings, open work areas, and churches.

^b For floors with nonstructural components and furnishings, and cubicles.

^c For floors with full-height partitions.

Source: Data from Alen, D.E. and Murray, T.M., Design criterion for vibrations due to walking, *Am. Inst. Steel Const. Eng. J.*, Fourth Quarter, 117–129, 1993

fundamental frequency of vibration, and so the fundamental frequency of the floor must be sufficiently higher than the input frequency as to prevent resonance.

13.7.5.1 Harmonics

A harmonic of frequency is any higher frequency that is equal to the fundamental frequency multiplied by an integer. For instance, if the frequency of an input excitation is 2.5 Hz, the harmonics are $2.5 \times 2 = 5$ Hz, $2.5 \times 3 = 7.5$ Hz, and so on. If the fundamental frequency of a floor system is equal to a harmonic of the exciting frequency, resonance may occur.

This process is less efficient than one which is in resonance striking at each cycle of vibration. Nevertheless, the 2.5 Hz forcing frequency can cause resonance in the 5 Hz fundamental frequency due to the input force striking every second cycle in the fundamental frequency.

Higher harmonics should not be confused with higher modes of vibration. The second mode of vibration of a simple span has a frequency four times the fundamental frequency. This high a frequency is almost never excited. Harmonics refers to the forcing frequency, compared with the fundamental mode of vibration.

13.7.5.2 Minimum Natural Frequency

The following design criterion for minimum natural frequency for a floor subjected to rhythmic excitation is based on the dynamic response of the floor system to dynamic loading. The objective is to avoid the possibility of being close to a resonant condition:

$$f_n \geq f \sqrt{1 + \frac{k}{a_0/g} \frac{\alpha_i w_p}{w_t}} \quad (13.50)$$

where

f = forcing frequency = $(i) (f_{\text{step}})$

f_{step} = step frequency

i = number of harmonic = 1, 2, 3

k = a dimensionless constant (1.3 for dancing, 1.7 for a lively concert or sport events, 2.0 for aerobics)

α_i = dynamic coefficient

a_0/g = ratio of peak acceleration limited to the acceleration due to gravity

W_p = effective distributed weight per unit area of participants

W_t = effective total distributed weight per unit area of participants (weight of participants plus weight of floor system).

The natural frequency of the floor system, f_n , can be found as discussed previously.

13.7.6 Example — Vibration Analysis of a Reinforced Concrete Floor

A concrete floor of a tall building is analyzed in this example. The plan view and structural configuration of the building are shown in Figure 13.37. Perimeter columns are spaced at 12 m centers and are connected by spandrel beams to support the facade. The example floor will be used for aerobic exercises and needs to be checked for vibration. Aerobic exercises are usually undertaken in the range of 2 to 2.75 Hz, with a maximum value in the order of 3.0 Hz. Ideally aerobic

FIGURE 13.37 Structural configuration.

exercise floors should be designed so that the floor's natural frequency exceeds the third harmonic by a factor of 1.2, resulting in $f_n > 1.2 \times 3 \times 2.75 = 9.9$ Hz. This is not always achievable in practice, especially for long span floors that have the natural frequency in the range from 4 to 8 Hz. Hence, a floor with natural frequency greater than 7.5 Hz is considered a minimum standard, although in some cases floor vibrations may be quite noticeable.

The modal analysis of the floor system was carried out with the assumed damping factor β of 2% (see Table 13.11). It was found that the floor natural frequency is 6.75 Hz, which may result in some problems in floor vibration. To reduce the vibration problem the following approaches can be used:

- Reduce mass (normally not very effective)
- Increase damping (e.g., using dampers)
- Reduce vibration transmission (stiffening joists at columns may reduce transmission)

Summary

This chapter concerns vibration and shock in reinforced concrete structures, addressing how to design reinforced concrete structures that will be subjected to vibration or shock, for example, due to a missile attack. The chapter is intended to apply vibration theory to concrete structures. Section 14.1 describes the fundamental properties of vibration theory. Section 14.2 proposes analytical models for reinforced concrete structures that are subjected to flexure, shear, and dynamic loading. Section 14.3 discusses reinforced concrete beams under harmonic excitations, including mechanical properties and designs for machine vibration. Section 14.4 indicates the step-by-step procedure for designing reinforced concrete columns or walls that will be subjected to seismic loads or shocks, respectively.

14.1 Introduction

14.1.1 Basic Concepts

Reinforced concrete structures are capable of free and forced vibration when disturbed from their equilibrium configuration (see Chapter 1 and Chapter 2). Free vibration takes place when a structure vibrates under the action inherent to the structure itself without being impressed by external forces. The structure under *free vibration* vibrates at its *natural frequency*, which is one of the dynamic properties of the structure. Forced vibration takes place under the excitation of an external force and at the frequency of the exciting force, which is independent of the natural frequency of the structure. When the frequency of the exciting force coincides with the natural frequency of a structure, resonance occurs and dangerously large amplitudes may result. Therefore, the calculation of natural frequency and the examination of resonance are of practical importance. Also, in reality, the influence of viscous dampening on a vibrating structure should be taken into account. In this section, the fundamental dynamic properties are introduced.

14.1.2 Natural Frequencies

An undamped single-degree-of-freedom (single-DoF) system (Figure 14.1) is used to explain natural frequency. Figure 14.1(c) shows the free-body diagram with inclusion of the inertial force $m\ddot{y}$. This force is equal to the mass, m , multiplied by the acceleration, \ddot{y} , and should always be directed negatively with respect to the corresponding coordinate; note that k is the spring constant of the system. The summation of forces in the y -direction directly gives the following equation of motion:

$$m\ddot{y} + ky = 0 \quad (14.1)$$

To solve Equation 14.1, we assume

$$y = A \cos wt \quad (14.2)$$

or

$$y = B \sin wt \quad (14.3)$$

where A and B are constants depending on the initiation of the motion and w is a quantity denoting a physical characteristic of the system. The substitution of Equation 14.2 or Equation 14.3 into Equation 14.1 gives

$$(-mw^2 + k)A \cos wt = 0 \quad (14.4)$$

If this equation is to be satisfied at any time, the factor in parentheses must be equal to zero:

$$-mw^2 + k = 0 \quad (14.5)$$

The positive root of Equation 14.5

$$w = \sqrt{\frac{k}{m}} \text{ rad/sec} \quad (14.6)$$

is known as the circular or angular natural frequency of the system (Paz, 1997; Clough and Penzien, 1993).

Note: The Greek symbol ω is commonly used rather than w to denote this natural frequency in the literature, which is expressed in rad/sec and is called “angular” natural frequency.

The “cyclic” natural frequency f is usually expressed in hertz (Hz) or cycles per second (cps). The quantity w differs from the natural frequency f only by the constant factor, 2π . The period, T , is usually expressed in seconds per cycle (i.e., the value reciprocal to the natural frequency, f). Therefore, it gives

$$f = \frac{1}{T} = \frac{w}{2\pi} \quad (14.7)$$

Example 14.1

Determine the natural frequency of the system shown in Figure 14.2, consisting of a weight of $W = 230 \text{ kN}$ attached to a horizontal reinforced concrete cantilever beam through the coil spring k_2 .

FIGURE 14.1 Free-body diagrams: (a) showing single-DoF; (b) showing only external forces; (c) showing external and inertial forces.

The cantilever beam has a cross section of 305 mm (h) \times 152 mm (b), modulus of elasticity $E = 30 \text{ kN/mm}^2$, and a length $L = 3 \text{ m}$. The coil spring has stiffness $k_2 = 200 \text{ N/mm}$.

Solution

The deflection, Δ , at the free end of a cantilever beam that is acted upon by a static force, P , at the free end is given by

$$\Delta = \frac{PL^3}{3EI}$$

The corresponding spring constant, k_1 , is then

$$k_1 = \frac{P}{\Delta} = \frac{3EI}{L^3}$$

where $I = (1/12)bh^3$ (for rectangular section) when the contribution of reinforcing bars is neglected. The cantilever and the coil spring of this system are connected as springs in series. Consequently, the equivalent spring constant is

$$\frac{1}{k_e} = \frac{1}{k_1} + \frac{1}{k_2}$$

Substituting corresponding numerical values, we obtain

$$I = \frac{1}{12} \times 152(305)^3 = 3.59 \times 10^8 \text{ mm}^4$$

$$k_1 = \frac{3 \times 30,000 \times 3.59 \times 10^8}{(3000)^3} = 1197 \text{ N/mm}$$

and

$$\frac{1}{k_e} = \frac{1}{1197} + \frac{1}{200}$$

$$k_e = 171 \text{ N/mm}$$

The natural frequency for this system is then given by Equation 14.6 as

$$\omega = \sqrt{k_e/m} \quad (m = W/g \text{ and } g = 9.8 \text{ m/sec}^2)$$

$$\omega = \sqrt{171 \times 9.8/230}$$

$$\omega = 2.7 \text{ rad/sec}$$

or, using Equation 14.7

$$f = 0.43 \text{ Hz}$$

FIGURE 14.2 System for Example 14.1.

14.1.3 Viscous Damping

Let us assume that we have modeled a structural system as a simple oscillator with viscous damping, as shown in Figure 14.3. In this figure, m and k are the mass and spring constant of the oscillator, respectively, and c is the viscous *damping coefficient* (or *damping constant*). The summation of forces in

the y -direction gives the differential equation of motion.

$$m\ddot{y} + c\dot{y} + ky = 0 \tag{14.8}$$

To solve Equation 14.8, we try $y = C e^{pt}$. Substituting this function into Equation 14.8 results in the equation

$$mCp^2 e^{pt} + cCp e^{pt} + kC e^{pt} = 0 \tag{14.9}$$

After cancellation of the common factors, Equation 14.9 reduces to an equation called the characteristic equation for the system, given by

$$mp^2 + cp + k = 0 \tag{14.10}$$

The roots of this quadratic equation are

$$p_1, p_2 = -\frac{c}{2m} \pm \sqrt{\left(\frac{c}{2m}\right)^2 - \frac{k}{m}} \tag{14.11}$$

For a system oscillating with critical damping, the expression under the radical in Equation 14.11 is equal to zero, that is

$$\left(\frac{c_{cr}}{2m}\right)^2 - \frac{k}{m} = 0 \tag{14.12}$$

$$c_{cr} = 2\sqrt{km} \tag{14.13}$$

where c_{cr} designates the *critical damping* value (Clough and Penzien, 1993; Paz, 1997).

In general, the damping of the system is expressed as

$$c = \xi c_{cr} \tag{14.14}$$

where ξ is the *damping ratio* of the system.

Note: Often the symbol ζ is used instead of ξ to denote the damping ratio.

The dampening value depends on structural materials. According to Dowrick (1987), the values for concrete structures are listed in Table 14.1. It can be seen from this table that for reinforced and prestressed concrete the values are 5 and 2%, respectively.

Example 14.2

A reinforced concrete beam consists of a weight of 5.0 kN and a stiffness of $k = 4.0$ kN/cm. Find

- 1. the undamped natural frequency
- 2. the damping coefficient

FIGURE 14.3 (a) Viscous damped oscillator; (b) free-body diagram.

TABLE 14.1 Typical Damping Ratios for Concrete Structures

Type of Construction	Damping ξ , % of Critical
Concrete frame, with all walls of flexible construction	5
Concrete frame, with stiff cladding and all internal walls flexible	7
Concrete frame, with concrete or masonry shear walls	10
Concrete and/or masonry shear wall buildings	10
Prestressed concrete	2

Notes: (1) The term *frame* indicates beam and column bending structures as distinct from shear structures. (2) The term *concrete* includes both reinforced and prestressed concrete in buildings. For isolated prestressed concrete members such as in bridge decks, damping values less than 5% may be appropriate, e.g., a value of 1 to 2% may apply if the structure remains substantially uncracked.

FIGURE 14.4 (a) Damped oscillator harmonically excited; (b) free-body diagram.

Solution

1. $w = \sqrt{k/m} = \sqrt{(4.0 \text{ kN/cm} \times 980 \text{ cm/sec}^2)/5.0 \text{ kN}} = 28.0 \text{ rad/sec.}$
2. $c = \xi c_{cr} = 0.05 \times 2 \times \sqrt{(5.0 \times 4.0)/980} = 14 \text{ N sec/cm.}$

14.1.4 Damped Harmonic Excitation

Now consider the case of one-DoF system in Figure 14.4, vibration due to an external load of a sine function under the influence of viscous damping. The differential equation of motion is obtained by equating to zero the sum of the forces in the free-body diagram of Figure 14.4(b). Hence,

$$m\ddot{y} + c\dot{y} + ky = F_0 \sin \bar{\omega}t \quad (14.15)$$

The total response is then obtained by summing the complementary solution and the particular solution

$$y(t) = e^{-\xi \bar{\omega} t} (A \cos w_D t + B \sin w_D t) + \frac{y_{st} \sin(\bar{\omega} t - \theta)}{\sqrt{(1 - r^2)^2 + (2r\xi)^2}} \quad (14.16)$$

where r is the frequency ratio that is equal to forced vibration frequency, $\bar{\omega}$, divided by natural frequency, w .

Note: A further discussion of this topic is found in Chapter 2.

By examining the transient component of the response, it may be seen that the presence of the exponential factor, $e^{-\xi \bar{\omega} t}$, will cause this component to vanish, leaving only the steady-state motion, Y , which is given by the second term of Equation 14.16.

The ratio of the steady-state amplitude of Y to the static deflection y_{st} , defined above, is known as the *dynamic magnification factor*, D .

$$D = \frac{Y}{y_{st}} = \frac{1}{\sqrt{(1 - r^2)^2 + (2r\xi)^2}} \quad (14.17)$$

D varies with the frequency ratio, r , and the damping ratio, ξ . Equation 14.17 is plotted in Figure 14.5 (Paz, 1997; Clough and Penzien, 1993). It can be seen from this figure that $0.8 \leq r \leq 1.2$ is in the resonance zone. Therefore, for design, $r > 1.2$ or $r < 0.8$ is required to avoid resonance.

FIGURE 14.5 Dynamic magnification factor as a function of the frequency ratio for various amounts of damping.

14.2 Analytical Models

14.2.1 Model-Based Simulation

When a structure is analyzed for its vibrational characteristics, it first must be presented by a simple model that reflects its mechanical properties adequately. In many analyses, mass is assumed to be concentrated at the nodes of the models. By using this assumption, a single-story structure can be simplified as a single-DoF system subjected to a time-varying force, $F(t)$. In general, dynamic models of reinforced concrete structures depend on the structural systems. Figure 14.6 indicates the structural systems and the corresponding dynamic models (Mo, 1994).

14.2.2 Flexural Behavior

Using the trilinear theory (Mo, 1992), the primary curve (the load–deflection curve) of a reinforced/ prestressed concrete beam can be determined. The trilinear theory is described as follows. To find the load–deflection curve of a beam, first the moment–curvature relationship of each section needs to be determined. The trilinear moment–curvature relationship is shown in Figure 14.7. The first branch of the trilinear curve represents the behavior of the reinforced concrete section until flexural cracking (M_c, ψ_c). The second branch describes the behavior from the cracking until the yielding of the longitudinal steel (M_y, ψ_y). The third branch gives the postyield behavior until flexural failure (M_u, ψ_u). For a given cross section, the shape of the moment–curvature curve can be determined by using the following equations. Basically, the parabola–rectangle stress–strain curve of concrete specified in the CEB code (1978) and the elastic–plastic stress–strain curve of steel are used in the computation.

FIGURE 14.6 Structures and corresponding dynamic models.

Moment–curvature curve:

1. Cracking state

$$M_c = \frac{bh^2}{6}f_r = \frac{bh^2}{6}(7.5\sqrt{f'_c}) \quad (14.18)$$

where

$$\psi_c = \frac{M_c}{EI} \quad (14.19)$$

and

M_c = cracking moment

f'_c = concrete compressive strength in psi

f_r = concrete rupture strength in psi

ψ_c = cracking curvature

b = beam width

h = beam depth

E = concrete Young's modulus

I = moment of inertia

2. Yielding state (Figure 14.8)

$$\epsilon_c = \epsilon_y \frac{x_y}{d - x_y} \quad (14.20)$$

$$\epsilon_{sc} = \epsilon_y \frac{x_y - d'}{d - x_y} \quad (14.21)$$

$$M_y = k_1 f'_c b x_y (d - 0.375 x_y) + \frac{x_y - d'}{x_y} \epsilon_c (E_s - E_c) A'_s (d - d') \quad (14.22)$$

and

$$\psi_y = \frac{\epsilon_c}{x_y} \quad (14.23)$$

where

$$k_1 = \frac{\epsilon_c}{\epsilon_0} \left(1 - \frac{1}{3} \frac{\epsilon_c}{\epsilon_0} \right) \quad (14.24)$$

M_y = yielding moment

y_y = yielding curvature

ϵ_{sc} = compression steel strain

ϵ_c = concrete strain when tension steel yields

ϵ_y = steel yielding strain

d = effective depth

d' = distance between surface of concrete compression block and center of compression steel

x_y = distance between surface of concrete compression block and neutral axis when tension steel yields

A'_s = area of compression steel

E_s = steel Young's modulus

E_c = concrete Young's modulus

FIGURE 14.7 Trilinear moment–curvature curve.

FIGURE 14.8 Strain diagram at yielding state.

FIGURE 14.9 Stress and strain diagrams at ultimate state.

3. Ultimate state (Figure 14.9)

If

$$x_u \geq d'$$

then

$$M_u = 0.81f'_c b x_u (d - 0.41x_u) + \frac{x_u - d'}{x_u} \times 0.0035(E_s - E_c)A'_s(d - d') \quad (14.25a)$$

If

$$x_u < d'$$

then

$$M_u = f_s A_s (d - 0.41x_u) + \frac{d' - x_u}{x_u} \times 0.0035 E_s A'_s (d' - 0.41x_u) \quad (14.25b)$$

$$\psi_u = \frac{0.0035}{x_u} \quad (14.26)$$

where

M_u = ultimate moment

ψ_u = curvature corresponding to ultimate moment

x_u = distance between surface of concrete compression block and neutral axis at ultimate state

f_s = steel stress at ultimate state

A_s = area of tension steel

Load–deflection curve:

Once the trilinear moment–curvature is found, we can convert it into the load–deflection curve (Figure 14.10).

$$M = \frac{P}{2} \frac{L}{2}, \quad \therefore P = \frac{4M}{L} \quad (14.27)$$

where

M = moment

P = load

L = beam length

FIGURE 14.10 Simple beam with a concentrated load.

Curvature diagram:

1. Cracking state (Figure 14.11)

$$\theta_c = \frac{1}{2} \frac{L}{2} \frac{M_c}{EI} = \frac{M_c L}{4EI} \quad (14.28)$$

$$\begin{aligned} \delta_c &= \theta_A \frac{L}{2} - \frac{1}{3} \frac{L}{2} \theta_A = \frac{2}{3} \frac{L}{2} \theta_A \\ &= \frac{M_c L^2}{12EI} \end{aligned} \quad (14.29)$$

where

θ_c = rotation at point A at cracking state

δ_c = midspan deflection at cracking state

2. Yielding state (Figure 14.12)

$$\begin{aligned} \theta_y &= (\text{area of triangle}) + (\text{area of trapezoid}) \\ &= \frac{1}{2} L_1 \psi_c + \frac{1}{2} (\psi_c + \psi_y) L_2 \end{aligned} \quad (14.30)$$

$$\begin{aligned} \delta_y &= (\text{first moment of triangle}) + (\text{first moment of trapezoid}) \\ &= \frac{2}{3} L_1 \frac{1}{2} L_1 \psi_c + L_3 \frac{1}{2} (\psi_c + \psi_y) L_2 = \frac{1}{3} \psi_c L_1^2 + \frac{1}{2} (\psi_c + \psi_y) L_2 L_3 \end{aligned} \quad (14.31)$$

where

$$L_3 = L_1 + \frac{\psi_c L_2 \frac{L_2}{2} + (\psi_y - \psi_c) \frac{L}{2} \frac{2L_2}{3}}{\psi_c L_2 + \frac{1}{2} L_2 (\psi_y - \psi_c)} \quad (14.32)$$

θ_y = rotation at point A at yielding state

δ_y = midspan deflection at yielding state

3. Ultimate state (Figure 14.13)

$$\begin{aligned} \theta_u &= (\text{area of triangle}) + (\text{area of first trapezoid}) + (\text{area of second trapezoid}) \\ &= \frac{1}{2} L_1 \psi_c + \frac{1}{2} (\psi_c + \psi_y) L_2 + \frac{1}{2} (\psi_y + \psi_u) L_4 \end{aligned} \quad (14.33)$$

δ_u = (first moment of triangle) + (first moment of first trapezoid)
+ (first moment of second trapezoid)

$$\begin{aligned} &= \frac{2}{3} L_1 \frac{1}{2} L_1 \psi_c + L_3 \frac{1}{2} (\psi_c + \psi_y) L_2 + L_5 \frac{1}{2} (\psi_y + \psi_u) L_4 \\ &= \frac{1}{3} \psi_c L_1^2 + \frac{1}{2} (\psi_c + \psi_y) L_2 L_3 \\ &\quad + \frac{1}{2} (\psi_y + \psi_u) L_4 L_5 \end{aligned} \quad (14.34)$$

where

$$L_3 = L_1 + \frac{\psi_c L_2 \frac{L_2}{2} + (\psi_y - \psi_c) \frac{L_2}{2} \frac{2}{3} L_2}{\psi_c L_2 + \frac{1}{2} L_2 (\psi_y - \psi_c)} \quad (14.35)$$

FIGURE 14.11 Curvature diagram at cracking state.

FIGURE 14.12 Curvature diagram at yielding state.

FIGURE 14.13 Curvature diagram at ultimate state.

$$L_5 = L_1 + L_2 + \frac{\psi_y L_4 \frac{L_4}{2} + (\psi_u - \psi_y) \frac{L_4}{2} \frac{2}{3} L_4}{\psi_y L_4 + \frac{1}{2} L_4 (\psi_u - \psi_y)} \quad (14.36)$$

θ_u = rotation at a point A at ultimate state

δ_u = midspan deflection at ultimate state

In this section, the maximum concrete strain at ultimate state (ϵ_{cu}) is assumed to be 0.0035 according to the CEB code (1978). If the ACI code (2002) is employed, the value is 0.003. However, in seismic structures there will be more stirrups. In these situations, reinforced concrete beams are confined. Therefore, the maximum concrete strain at ultimate state for *confined concrete* can be used as follows (Dowrick, 1987):

$$\epsilon_{cu} = 0.003 + 0.02 \left(\frac{b}{l_c} \right) + \left(\frac{\rho_v f_{yv}}{138} \right)^2 \quad (14.37)$$

where

b = beam width

l_c = distance from the critical section to the point of contraflexure

ρ_v = ratio of volume of confining steel (including the compression steel) to volume of concrete confined

f_{yv} = yielding stress of confining steel

14.2.3 Shear Behavior

Structural walls in a frame building should be so proportioned that they possess the necessary stiffness needed to reduce the relative inter-story distortions caused by explosion-induced motions. Such walls are termed structural (or shear) walls because their behavior is governed by shear if the ratio of height to length is less than unity. Their additional function is to reduce the possibility of damage to nonstructural elements that most buildings contain.

Buildings stiffened by structural walls are considerably more effective than rigid frame buildings with regard to damage control, overall safety, and integrity of the structure. This performance is due to the fact that structural walls are considerably stiffer than regular frame elements and thus can respond to or absorb the greater lateral forces induced by the earthquake motions, while controlling inter-story drift.

The past three decades saw a rapid development of knowledge regarding shear in reinforced concrete. Various rational models that are based on the smeared-crack concept can satisfy Navier's three principles of mechanics of materials (i.e., they satisfy stress equilibrium, strain compatibility, and constitutive laws of materials). These rational or mechanics-based models on the "smeared-crack level" (in contrast to the "discrete-crack level" or "local level") include: the compression field theory (CFT) (Vecchio and Collins, 1981); the rotating-angle softened truss model (RA-STM) (Belarbi and Hsu, 1994, 1995; Pang and Hsu 1995); the fixed-angle softened truss model (FA-STM) (Pang and Hsu, 1996; Hsu and Zhang, 1997; Zhang and Hsu, 1998); the softened membrane model (SMM) (Hsu and Zhu, 1999; Zhu, 2000); and the cyclic SMM (Mansour, 2001).

Vecchio and Collins (1981) proposed the earliest rational theory, CFT, to predict the nonlinear behavior of cracked reinforced concrete membrane elements. However, the CFT is unable to take into account the tension stiffening of the concrete in the prediction of deformations because the tensile stress of concrete was assumed to be zero.

The RA-STM, a rational theory developed at the University of Houston (UH) in 1994–1995, has two advantages over the CFT. (1) The tensile stress of concrete is taken into account so that the deformations can be correctly predicted. (2) The average stress–strain curve of steel bars embedded in concrete is derived on the “smeared crack level” so that it can be correctly used in the equilibrium and compatibility equations, which are based on continuous materials.

By 1996, the UH group reported that the FA-STM was capable of predicting the “concrete contribution” (V_c) by assuming the cracks to be oriented at the fixed angle.

Other significant advancements include the improvements on the softened truss models (rotating-angle and fixed-angle). As they were, these models could predict the ascending response curves of shear panels, but not the post-peak descending curves. By incorporating two new Hsu/Zhu ratios into the FA-STM, a new SMM was established (Hsu and Zhu, 1999; Zhu, 2000), which can satisfactorily predict entire response curves, including both the ascending and the descending branches.

More recently, Mansour et al. (2001a) tested 15 reinforced concrete panels under reversed cyclic stresses. Tests results showed that the orientation of the steel grids in a panel has an important effect on the shear stiffness, the shape of the hysteretic loops, the shear ductility, and the energy dissipation capacity of the panel. The cyclic SMM proposed by Mansour et al. (2001a) is able to predict rationally the pinching effect in the hysteretic loops, the shear ductility, and the energy dissipation capacity of the panels. In this chapter, only RA-STM will be introduced, as described below.

14.2.3.1 Principle of Transformation

The stresses in a membrane element are best analyzed by the principle of stress transformation (Hsu, 1993). Figure 14.14(a) shows a concrete element in the stationary l – t coordinate system, defined by the directions of the longitudinal and transverse steel. To find the three stress components in various directions, a rotating d – r coordinate system is introduced in Figure 14.14(b). The d – r axes have been rotated counterclockwise by an angle of α with respect to the stationary l – t axes. The three stress components in this rotating coordinate system are σ_d , σ_r , and τ_{dr} (or τ_{rd}). The relationship between the rotating stress components, σ_d , σ_r , and τ_{dr} , and the stationary stress components, σ_l , σ_t , and τ_{lt} , is the stress transformation. This relationship is a function of the angle α .

The relationship between the rotating d – r axes and the stationary l – t axes is shown by the transformation geometry in Figure 14.14(c). A positive unit length on the l axis will have projections of $\cos \alpha$ and $-\sin \alpha$ on the d and r axes, respectively. A positive unit length on the t axis should give

FIGURE 14.14 Transformation of stresses.

projections of $\sin \alpha$ and $\cos \alpha$. Hence, the rotation matrix $[R]$ is

$$[R] = \begin{bmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{bmatrix} \quad (14.38)$$

The relationship between the stresses in the l - t coordinate $[\sigma_{lt}]$ and the stresses in the d - r coordinate $[\sigma_{dr}]$ is

$$[\sigma_{lt}] = [R]^T [\sigma_{dr}] [R] \quad (14.39)$$

where

$$[\sigma_{lt}] = \begin{bmatrix} \sigma_l & \tau_{lt} \\ \tau_{tl} & \sigma_t \end{bmatrix} \quad (14.40)$$

$$[\sigma_{dr}] = \begin{bmatrix} \sigma_d & \tau_{dr} \\ \tau_{rd} & \sigma_r \end{bmatrix} \quad (14.41)$$

If the d - r axes are defined as the principal axes, τ_{dr} must vanish. Introducing the reinforced concrete sign convention, performing the matrix multiplications and noticing that $\tau_{lt} = \tau_{tl}$ and $\tau_{dr} = \tau_{rd}$ gives the following equations when only the concrete struts are considered.

$$\sigma_{lc} = \sigma_d \cos^2 \alpha + \sigma_r \sin^2 \alpha \quad (14.42)$$

$$\sigma_{tc} = \sigma_d \sin^2 \alpha + \sigma_r \cos^2 \alpha \quad (14.43)$$

$$\tau_{ltc} = (-\sigma_d + \sigma_r) \sin \alpha \cos \alpha \quad (14.44)$$

14.2.3.2 Equilibrium Equations

When one studies a concrete element reinforced orthogonally with longitudinal and transverse steel bars, as shown in Figure 14.15(a), the three stress components σ_l , σ_t , and τ_{lt} are the applied stresses on the reinforced concrete element viewed as a whole. The stresses on the concrete strut itself are denoted as σ_{lc} , σ_{tc} , and τ_{ltc} , as shown in Figure 14.15(b). The longitudinal and transverse steel provide the smeared stresses of $\rho_l f_l$ and $\rho_t f_t$, as shown in Figure 14.15(c).

It is significant to recognize the difference between the two sets of stresses: σ_l , σ_t , and τ_{lt} for the reinforced concrete element and σ_{lc} , σ_{tc} , and τ_{ltc} for concrete struts. Both sets of stresses (σ_l , σ_t , τ_{lt} and σ_{lc} , σ_{tc} , τ_{ltc}) satisfy the transformation equations. In summing the concrete stresses and the steel stresses in the l and t directions, a fundamental assumption is made according to Hsu (1993). It is assumed that the

FIGURE 14.15 Stress condition in reinforced concrete.

steel reinforcement can take only axial stresses. Any possible dowel action is neglected. Hence, the superposition principle for concrete and steel becomes valid and gives the general equilibrium equations for reinforced concrete:

$$\sigma_l = \sigma_d \cos^2 \alpha + \sigma_r \sin^2 \alpha + \rho_l f_l \quad (14.45)$$

$$\sigma_t = \sigma_d \sin^2 \alpha + \sigma_r \cos^2 \alpha + \rho_t f_t \quad (14.46)$$

$$\tau_{lt} = (-\sigma_d + \sigma_r) \sin \alpha \cos \alpha \quad (14.47)$$

14.2.3.3 Compatibility Equations

The same principle of transformation for stresses can be applied to strains. Therefore, the following compatibility equations can be derived:

$$\varepsilon_l = \varepsilon_d \cos^2 \alpha + \varepsilon_r \sin^2 \alpha \quad (14.48)$$

$$\varepsilon_t = \varepsilon_d \sin^2 \alpha + \varepsilon_r \cos^2 \alpha \quad (14.49)$$

$$\frac{\gamma_{lt}}{2} = (\varepsilon_d + \varepsilon_r) \sin \alpha \cos \alpha \quad (14.50)$$

14.2.3.4 Constitutive Laws

Softened compression stress–strain relationship of concrete. The truss model has been applied to treat the shear and torsion of reinforced concrete since the turn of the 20th century. However, the prediction based on the truss model consistently overestimated the shear and torsional strengths of tested specimens. This nagging mystery has plagued researchers for over half a century. The source of this difficulty was first understood by Peter (1964). He realized that a reinforced concrete panel element subjected to tension is actually subjected to biaxial compression–tension stresses. Viewing the action as a two-dimensional problem, he discovered that the compressive strength in one direction was reduced by cracking due to tension in the perpendicular direction. After applying the softening effect of concrete struts to the nine test panels, Peter concluded that a reduction of 15% of the effective compressive strength should be taken into account in biaxial compression–tension stresses. Apparently, the mistake in applying the truss model theory before 1964 was the use of the compressive stress–strain relationship of concrete that was obtained from the uniaxial test of standard cylinders without considering the two-dimensional softening effect.

Peter's tests could not delineate the variables that govern the softening parameter because of technical difficulties in the biaxial testing of large panels. The quantification of the softening phenomenon, therefore, did not occur for almost two decades, when a unique “shear rig” test facility was built in 1981 by Vecchio and Collins (1981). Based on their tests of 17 panels, each 89 cm² and 7 cm thick, they proposed a softening parameter that was a function of the ratio of the tensile principal strains to the compression principal strain, $\varepsilon_r/\varepsilon_d$.

The discovery and the quantification of this softening phenomenon have allowed a major breakthrough in understanding the shear problem in reinforced concrete. During the past 20 years, a number of diverse analytical models have been proposed according to the test results (Peter, 1964; Robinson and Demorieux, 1968; Vecchio and Collins, 1981; Schlaich et al. 1982; Schlaich and Schafer, 1983; Vecchio and Collins, 1986; Eibl and Neuroth, 1988; Miyahara et al. 1988; Kollegger and Mehlhorn, 1990; Mikame et al. 1991; Ueda et al. 1991; Hsu, 1993; Vecchio and Collins, 1993; Vecchio et al. 1994; Belarbi and Hsu, 1995). The effect of these softening models on low-rise framed shear walls is studied by Mo and Rothert (1997). In this section, the softening model proposed by Belarbi and Hsu (1994, 1995) is briefly introduced.

The original softening model derived from test data proposed the use of a *softening parameter* ζ , where ζ is a function of the ratio of principal tensile strain to principal compressive strain (ϵ_r/ϵ_d). The proposed model by Belarbi and Hsu (1995) involves modification of the Hognestad parabola (Figure 14.16), which is used as the base curve describing the uniaxial compressive response of concrete.

FIGURE 14.16 Compression softening models with Hognestad curve.

$$\sigma_d = \begin{cases} \zeta f'_c \left[2 \left(\frac{\epsilon_d}{\zeta \epsilon_o} \right) - \left(\frac{\epsilon_d}{\zeta \epsilon_o} \right)^2 \right], & \epsilon_d / \zeta \epsilon_o \leq 1 \\ \zeta f'_c \left[1 - \left(\frac{\epsilon_d / \zeta \epsilon_o - 1}{2 / \zeta - 1} \right)^2 \right], & \epsilon_d / \zeta \epsilon_o > 1 \end{cases} \quad (14.51a)$$

$$\zeta = \frac{0.9}{\sqrt{1 + 600 \epsilon_r}} \quad (14.51b)$$

Tensile stress–strain relationship of concrete. From the tests involving panels subjected to shear, it was clear that the tensile stress of concrete, σ_r , is not zero as assumed in the simple truss model. Based on the tests of 35 full-size panels (Hsu, 1993), a set of formulas were recommended as follows:

$$\text{If } \epsilon_r \leq \epsilon_{cr}, \quad \sigma_r = E_c \epsilon_r \quad (14.52)$$

$$\text{If } \epsilon_r > \epsilon_{cr}, \quad \sigma_r = f_{cr} \left(\frac{\epsilon_r}{\epsilon_{cr}} \right)^{0.4} \quad (14.53)$$

where

$E_c = 47,000 \sqrt{f'_c}$, and both f'_c and $\sqrt{f'_c}$ are in pounds per square inch

ϵ_{cr} = strain at cracking of concrete = 0.00008

$f_{cr} = 3.75 \sqrt{f'_c}$

Stress–strain relationship of steel. The stress–strain curve of a steel bar in concrete relates the average stress to the average strain of a long bar crossing several cracks, whereas the stress–strain curve of a bare bar relates the stress to the strain at a local point (Okamura and Maekawa, 1991). In other words, a steel bar in concrete is stiffened by the tensile stress of the concrete. If the tensile strength of concrete is neglected, as it is in the most of truss models, the following equations are used:

$$\text{If } \epsilon_t \leq \epsilon_{ly}, \quad f_l = E_s \epsilon_l \quad (14.54)$$

$$\text{If } \epsilon_l > \epsilon_{ly}, \quad f_l = f_{ly} \quad (14.55)$$

where

E_s = modulus of elasticity of steel bars

f_{ly} = yield stress of longitudinal steel bars

ϵ_{ly} = yield strain of longitudinal steel bars

It was recommended by Belarbi and Hsu (1995) that both the tensile strength of concrete, presented in the previous section, and the average stress–strain curve of steel stiffened by concrete, be taken into account. In this model, the following equations are used for describing the stress–strain relationship of steel:

$$\text{If } \epsilon_l E_s \leq f'_{ly}, \quad f_l = E_s \epsilon_l \quad (14.56)$$

$$\text{If } \varepsilon_l E_s \leq f'_{ly}, \quad f_l = \left[1 - \frac{2 - \alpha/45^\circ}{1000\rho_l} \right] [(0.91 - 2B)f_{ly} + (0.02 + 0.25B)E_s \varepsilon_l] \quad (14.57)$$

where

$$B = (1/\rho_l)(f_{cr}/f_{ly})^{1.5} \quad (14.58)$$

$$f'_{ly} = [1 - (2 - \alpha/45^\circ)/1000\rho_l](0.93 - 2B)f_{ly} \quad (14.59)$$

14.2.3.5 Solution Procedures

Figure 14.17 shows a framed shear wall. This kind of shear wall will be analyzed in this section. As discussed by Hsu and Mo (1985), in the design of low-rise structural walls, the boundary elements are reinforced to resist the applied bending moment, while the webs are designed to resist the applied shear force. The size and shape of the boundary elements do not have a significant influence on the shear behavior, as long as they are sufficient to carry the required bending moment. The effect of the boundary elements on structural walls has been studied by Mo and Kuo (1998). Owing to the restriction of the boundary elements, the strain of transverse steel in low-rise framed shear walls can be neglected, as verified by the PCA tests; i.e., $\varepsilon_t = 0$. Therefore, adding Equation 14.48 and Equation 14.49 gives

$$\varepsilon_r = \varepsilon_l - \varepsilon_d \quad (14.60)$$

Inserting $\varepsilon_r \sin^2 \alpha = \varepsilon_r - \varepsilon_r \cos^2 \alpha$ into Equation 14.20 gives

$$\cos^2 \alpha = \frac{\varepsilon_r - \varepsilon_l}{\varepsilon_r - \varepsilon_d} \quad (14.61)$$

Substituting Equation (14.60) and Equation (14.61) into Equation 14.45 results in

$$f_l = \frac{1}{\rho_l} \left[\sigma_l - \sigma_d \frac{(-\varepsilon_d)}{(\varepsilon_l - 2\varepsilon_d)} - \sigma_r \frac{(\varepsilon_l - \varepsilon_d)}{(\varepsilon_l - 2\varepsilon_d)} \right] \quad (14.62)$$

FIGURE 14.17 A framed shear wall.

Neglecting the tensile strength of concrete, i.e., $\sigma_r = 0$, gives

$$f_l = \frac{1}{\rho_l} \left[\sigma_l - \sigma_d \frac{(-\varepsilon_d)}{(\varepsilon_l - 2\varepsilon_d)} \right] \quad (14.63)$$

For low-rise framed shear walls, the average shear stress τ on the horizontal cross section is defined as

$$\tau = \frac{V}{bd} \quad (14.64)$$

where d is the effective depth, which is defined as the distance between the centroids of the longitudinal bars in the two flanges, b is the width of the web, and V is the horizontal shear force. The deflection at the top of the shear wall, δ , is determined by

$$\delta = \gamma h \quad (14.65)$$

where h = height of the shear wall.

Based on the softened truss model theory presented above, the algorithm is shown in Figure 14.18 (Mo and Jost, 1993; Mo and Shiau, 1993) and is explained below.

1. Select a given ε_d .
2. Assume a value of ε_l .
3. Calculate ε_r from Equation 14.60.
4. Calculate ζ using Equation 14.51b.
5. Calculate σ_d from Equation 14.51a.
6. Calculate σ_r from Equation 14.52 or Equation 14.53.
7. Calculate f_l from Equation 14.62 or Equation 14.63.
8. Check f_l using Equation 14.54 and Equation 14.55 or from Equation 14.56 to Equation 14.59.
- 9a. If the calculated value for f_l determined in Step 8 is not sufficiently close to the value shown in step 7, repeat steps 2 to 7.
- 9b. If the calculated value for f_l determined in Step 8 is sufficiently close to the value shown in Step 7, proceed to calculate τ (or V) and γ (or δ) from Equation 14.47 (or Equation 14.64) and Equation 14.49 (or Equation 14.65), respectively. This will provide one set of solutions.

Select other values of ε_d and repeat Steps 1 to 9 for each ε_d . This will provide a number of sets of quantities. From these sets of quantities, one can plot the shear stress vs. distortion curve (or shear force vs. deflection curve), the longitudinal steel strain vs. deflection curve, and the longitudinal steel strain vs. concrete strain curve. In general, the maximum ε_d value can be chosen as 0.003 with an increment of 0.00005.

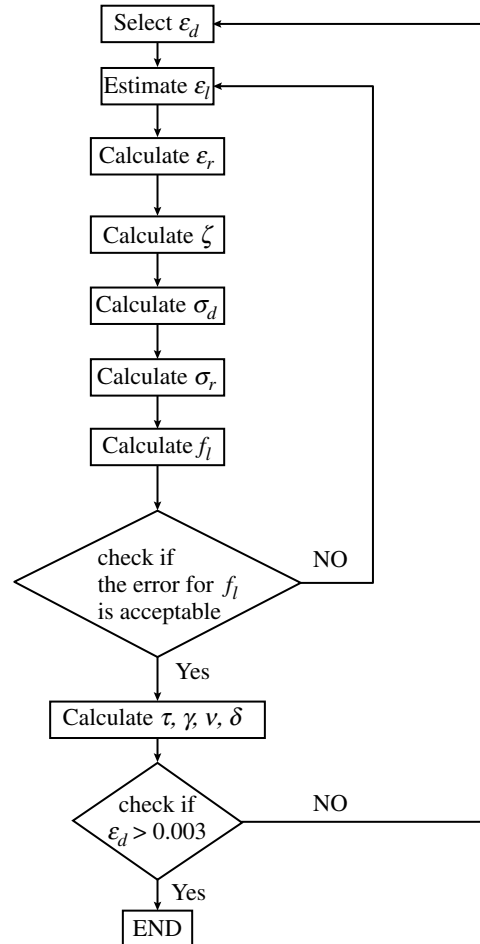

FIGURE 14.18 Algorithm for framed shear wall analysis.

14.2.4 Time-History Analysis

To accurately determine the dynamic behavior of concrete structures, the *time-history analysis* (Clough and Penzien, 1993; Paz, 1997) is preferred. This section will show an example for single-DoF systems, such as simple beams, torsional box tubes, spandrel beams, continuous beams, one-story frames and one-story framed shear walls. All of these structures will be discussed later.

In time-history analysis, a framed shear wall can be modeled as a nonlinear single-DoF system (Figure 14.19). The dynamic incremental equilibrium is shown in Figure 14.19(c).

The equation of the equilibrium is

$$m\Delta\ddot{y}_i + c_i\Delta\dot{y}_i + k_i\Delta y_i = \Delta F_i \quad (14.66)$$

where m is the mass at the top.

c_i and k_i are calculated for values of velocity and displacement corresponding to time t and assumed to remain constant during the increment of time Δt . Incremental acceleration, incremental velocity, and incremental displacement are $\Delta\ddot{y}_i$, $\Delta\dot{y}_i$, and Δy_i , respectively.

To perform the step-by-step integration of Equation 14.66, the linear acceleration method is employed. In this method, it is assumed that the acceleration may be expressed by a linear function of time during the time interval Δt . Let t_i and $t_{i+1} = t_i + \Delta t$ be, respectively, the designation for the time at the beginning and at the end of the time interval Δt . When the acceleration is assumed to be a linear function of time for the interval of time t_i to $t_{i+1} = t_i + \Delta t$, as shown in Figure 14.20, the acceleration may be expressed as

$$\ddot{y}(t) = \ddot{y}_i + \frac{\Delta\ddot{y}_i}{\Delta t}(t - t_i) \quad (14.67)$$

Integrating Equation 14.67 twice with respect to time between the limits t_i and $t = t_i + \Delta t$ and using the incremental displacement Δy as the basic variable gives

$$\Delta\ddot{y}_i = \frac{6}{\Delta t^2}\Delta y_i - \frac{6}{\Delta t}\dot{y}_i - 3\ddot{y}_i \quad (14.68)$$

and

$$\Delta\dot{y}_i = \frac{3}{\Delta t}\Delta y_i - 3\dot{y}_i - \frac{\Delta t}{2}\ddot{y}_i \quad (14.69)$$

FIGURE 14.19 (a) Framed shear wall with a mass m at the top; (b) model for a nonlinear single-DoF system, and (c) free body diagram showing the incremental inertial force, the incremental damping force, the incremental spring force and the incremental external force.

FIGURE 14.20 Linear variation of acceleration during time interval.

The substitution of Equation 14.68 and Equation 14.69 into Equation 14.66 leads to the following form of the equation of motion:

$$m\left(\frac{6}{\Delta t^2}\Delta y_i - \frac{6}{\Delta t}\dot{y}_i - 3\ddot{y}_i\right) + c_i\left(\frac{3}{\Delta t}\Delta y_i - 3\dot{y}_i - \frac{\Delta t}{2}\ddot{y}_i\right) + k_i\Delta y_i = \Delta F_i \quad (14.70)$$

Transferring all the terms containing the unknown incremental displacement, Δy_i , to the left-hand side gives

$$\bar{k}_i\Delta y_i = \Delta \bar{F}_i \quad (14.71)$$

where

$$\bar{k}_i = k_i + \frac{6m}{\Delta t^2} + \frac{3c_i}{\Delta t} \quad (14.72)$$

and

$$\Delta \bar{F}_i = \Delta F_i + m\left(\frac{6}{\Delta t}\dot{y}_i + 3\ddot{y}_i\right) + c_i\left(3\dot{y}_i + \frac{\Delta t}{2}\ddot{y}_i\right) \quad (14.73)$$

It should be noted that Equation 14.71 is equivalent to the static incremental-equilibrium equation and may be solved for the incremental displacement by simply dividing the equivalent incremental load, $\Delta \bar{F}_i$, by the equivalent spring constant \bar{k}_i .

The displacement y_{i+1} and the velocity \dot{y}_{i+1} at time $t_{i+1} = t_i + \Delta t$ are

$$y_{i+1} = y_i + \Delta y_i \quad (14.74)$$

and

$$\dot{y}_{i+1} = \dot{y}_i + \Delta \dot{y}_i \quad (14.75)$$

The acceleration \ddot{y}_{i+1} at the end of the time step is obtained directly from the differential equation of motion to avoid the errors that generally might tend to accumulate from step to step. It follows

$$\ddot{y}_{i+1} = \frac{1}{m}[F(t_{i+1}) - c_{i+1}\dot{y}_{i+1} - k_{i+1}y_{i+1}] \quad (14.76)$$

where the coefficients c_{i+1} and k_{i+1} are now evaluated at time t_{i+1} .

After the displacement, velocity, and acceleration have been determined at time $t_{i+1} = t_i + \Delta t$, the procedure just outlined is repeated to calculate these quantities at the following time step, $t_{i+2} = t_{i+1} + \Delta t$.

In general, sufficiently accurate results can be obtained if the time interval is taken to be no longer than one tenth of the natural period of the structure (Clough and Penzien, 1993; Paz, 1997).

14.3 Beams under Harmonic Excitations

14.3.1 Mechanical Properties

A 6-m-long beam is simply supported. The cross section and material properties are shown in Figure 14.2(b).

$$f'_c = 39 \text{ N/mm}^2$$

$$A'_s = 142 \text{ mm}^2$$

$$d = 305 - 12.7 - 6.35 - \frac{1}{2}(19.05) = 276 \text{ mm}$$

$$A_s = 852 \text{ mm}^2$$

Find the moment (M)–curvature (f) relationship of the cross section at the midspan and the force (P)–displacement (d) relationship of the beam.

Solution

1. Moment–curvature relationship

$$E = 1500\sqrt{f'_c} \text{ (N/mm}^2\text{)} = 29614.9 \text{ N/mm}^2$$

Using the derived equations in Section 14.2.2 gives

$$M_u = 86,122,000 \text{ N mm,}$$

$$\psi_u = 5.63 \times 10^{-5} \text{ rad/mm}$$

$$M_y = 82,491,700 \text{ N mm,}$$

$$\psi_y = 1.22 \times 10^{-5} \text{ rad/mm}$$

$$M_c = 9,263,000 \text{ N mm} \quad \psi_c = 8.66 \times 10^{-7} \text{ rad/mm}$$

They are plotted in Figure 14.21, and the corresponding loads are determined below.

2. Force–displacement relationship

$$P_U = \frac{4 \times 86,122,000}{6000} = 57,415 \text{ N}$$

$$P_Y = \frac{4 \times 82,491,700}{6000} = 54,994 \text{ N}$$

$$P_C = \frac{4 \times 9,263,000}{6000} = 6175 \text{ N}$$

The corresponding deflections can be determined as follows:

1. Cracking state (Figure 14.22)

$$\delta_c = \frac{M_c L^2}{12EI}$$

$$= \frac{9,263,000 \times (6000)^2}{12 \times (29,614.9) \times \frac{1}{12} \times (152.4) \times (305)^3}$$

$$= 2.6 \text{ mm}$$

2. Yielding state (Figure 14.23)

$$L_1 = 3000 \times \frac{9,263,000}{82,491,700} = 336.9 \text{ mm}$$

FIGURE 14.21 Moment–curvature curve for the example beam.

FIGURE 14.22 Curvature diagram at cracking state.

FIGURE 14.23 Curvature diagram at yielding state.

$$L_2 = 3000 - 336.9 = 2663.1 \text{ mm}$$

$$L_3 = 336.9 + \frac{8.66 \times 10^{-7} \times 2663.1 \times \frac{2663.1}{2} + (1.22 \times 10^{-5} - 8.66 \times 10^{-7}) \times \frac{2663.1}{2} \times \frac{2}{3} \times 2663.1}{8.66 \times 10^{-7} \times 2663.1 + \frac{1}{2} \times 2663.1 \times (1.22 \times 10^{-5} - 8.66 \times 10^{-5})}$$

$$= 2053 \text{ mm}$$

$$\delta_y = \frac{1}{3} \times 8.66 \times 10^{-7} \times (342.2)^2 + \frac{1}{2} \times (8.66 \times 10^{-7} + 1.22 \times 10^{-5}) \times (2663.1) \times 2053 = 35.75 \text{ mm}$$

3. Ultimate state (Figure 14.24)

$$L_1 = 3000 \times \frac{9,263,000}{86,122,000} = 322.7 \text{ mm}$$

$$L_2 = 3000 \times \frac{82,491,600}{86,122,000} - 322.7$$

$$= 2550.8 \text{ mm}$$

$$L_4 = 3000 - 322.7 - 2550.8 = 126.5 \text{ mm}$$

FIGURE 14.24 Curvature diagram at yielding state.

$$L_3 = 322.7 + \frac{8.66 \times 10^{-7} \times 2550.8 \times \frac{2550.8}{2} + (1.22 \times 10^{-5} - 8.66 \times 10^{-7}) \times \frac{2550.8}{2} \times \frac{2}{3} \times 2550.8}{8.66 \times 10^{-7} \times 2550.8 + \frac{1}{2} \times 2550.8 \times (1.22 \times 10^{-5} - 8.66 \times 10^{-7})}$$

$$= 1967.3 \text{ mm}$$

$$L_5 = 322.7 + 2550.8 + \frac{1.22 \times 10^{-5} \times 126.5 \times \frac{126.5}{2} + (5.63 \times 10^{-5} - 1.22 \times 10^{-5}) \times \frac{126.5}{2} \times \frac{2}{3} \times 126.5}{1.22 \times 10^{-5} \times 126.5 + \frac{1}{2} \times 126.5 \times (5.63 \times 10^{-5} - 1.22 \times 10^{-5})}$$

$$= 2950.4 \text{ mm}$$

$$\delta_u = \frac{1}{3} \times 8.66 \times 10^{-7} \times (322.7)^2$$

$$+ \frac{1}{2} \times (8.66 \times 10^{-7} + 1.22 \times 10^{-5})$$

$$\times 2550.8 \times 1967.3$$

$$+ \frac{1}{2} \times (5.63 \times 10^{-5} + 1.22 \times 10^{-5})$$

$$\times 126.5 \times 2950.4 = 45.6 \text{ mm}$$

FIGURE 14.25 Load-deflection curve.

The load-deflection curve is shown in Figure 14.25.

14.3.2 Design for Machine Vibration

The same beam as described in Section 14.3.1 is supporting a machine with a rotating frequency of 9 Hz at the midspan of the beam. The mass of the rotating machine and the beam is 1 N sec²/mm. Check if resonance will occur.

Solution

Find the stiffness, k , the natural frequency, f , and the frequency ratio, r , for each of the three states, namely the elastic, cracking, and yield states.

1. Elastic state

$$k = \frac{617.5}{2.6} = 2375 \text{ N/mm}$$

$$f = \frac{1}{2\pi} \sqrt{\frac{2375}{1}} = 7.76 \text{ Hz}$$

$$r = \frac{7.76}{9} = 0.862$$

Since $0.8 < r < 1.2$, it is in the resonance zone. The beam needs to be redesigned to avoid resonance.

2. Cracking state

$$k = \frac{5499.4 - 617.5}{35.75 - 2.6} = 1472.7 \text{ N/mm}$$

$$f = \frac{1}{2\pi} \sqrt{\frac{1472.7}{1}} = 6.11 \text{ Hz}$$

$$r = \frac{6.11}{9} = 0.68 < 0.8$$

OK

3. Yield state

$$k = \frac{5741.5 - 5499.4}{45.6 - 35.75} = 245.8 \text{ N/mm}$$

$$f = \frac{1}{2\pi} \sqrt{\frac{245.8}{1}} = 2.50 \text{ Hz}$$

$$r = \frac{2.50}{9} = 0.28 < 0.8$$

OK

14.4 Design for Explosions/Shocks

14.4.1 Column

A 3-m-tall viaduct column supporting a mass of 50 N sec²/cm is subjected to a shock acceleration that is the same as the 1940 El Centro seismogram.

14.4.1.1 Load–Displacement Relationship

Using the same procedures presented in Section 14.3, the moment–curvature relationship of the cross section and the force–displacement relationship of the column can be determined. It is assumed that the force–displacement relationship of the column was found to be the same as that shown in [Figure 14.25](#).

14.4.1.2 Dynamic Response

To perform the dynamic response analysis, the computer program in Mo (1994) can be used. The required input data may be determined as follows:

$$\text{Stiffness 1} = \frac{0.6175}{2.6} = 0.2375 \text{ T/mm}$$

$$\text{Stiffness 2} = \frac{5.4994 - 0.6175}{35.75 - 2.6} = 0.1473 \text{ T/mm}$$

$$\text{Stiffness 3} = \frac{5.7415 - 5.4994}{45.6 - 35.75} = 0.246 \text{ T/mm}$$

$$\delta_c = 2.6 \text{ mm}$$

$$\delta_y = 35.75 \text{ mm}$$

$$\delta_u = 45.6 \text{ mm}$$

Result:

Maximum deflection = 38.33 mm

14.4.2 Shear Walls

14.4.2.1 Design Approach

14.4.2.1.1 Design Considerations

To insure ductile failure, the two design limitations for overreinforcement and minimum reinforcement can be derived in terms of the inclination angle, α , of the diagonal concrete struts.

1. *Overreinforcement.* Mo (1987) shows the inclination angle of the diagonal compression struts in the “lower balanced reinforcement,” α_{lb} , to be

$$\alpha_{lb} = \cos^{-1} \left\{ \frac{1}{2} \left[\left(\frac{\epsilon_{ly}}{2\epsilon_0} \right) \left(\sqrt{1 + \frac{8\epsilon_0^2}{\epsilon_{ly}^2}} - 1 \right) \right] \right\} \quad (14.77)$$

α_{lb} is a function of only one variable — the yield strain of longitudinal steel ϵ_{ly} . In underreinforced design, the chosen angle α should be greater than α_{lb} .

2. *Minimum reinforcement.* Mo (1987) also shows the inclination angle for minimum reinforcement, α_m , to be

$$\alpha_m = \cos^{-1} \left[\left(0.0025 \frac{f_{ly}}{f'_c} \right)^{1/3} \right] \quad (14.78)$$

α_m is a function of two variables — the yield strain in longitudinal steel, ϵ_{ly} , and the concrete strength, f'_c . Equation 14.77 and Equation 14.78 give the lower and upper limits, respectively, for the range of α , which insures ductile failure.

After the range of the inclination angle, α , is found, a preliminary angle, α , can be selected within this range. The wall size, bd , can then be determined by substituting $\tau = V/bd$ and $\sigma_d = f'_c \cos \alpha$ into $\tau = \sigma_d \sin \alpha \cos \alpha$ (Hsu and Mo, 1985; Mo, 1988).

$$bd = \frac{V}{f'_c \sin \alpha \cos^2 \alpha} \quad (14.79)$$

The effective length, d , in Equation 14.79 is usually given in design and the web width, b , needs to be chosen by the designer. After the wall size, bd , is determined, the actual inclination angle, α , can be refined by solving α in Equation 14.79.

The longitudinal steel can be determined from $A_l f_l = \tau b d \cot \alpha$ (Hsu and Mo, 1985; Mo, 1988), noting that $\tau b d$ becomes V_n at maximum shear

$$A_l f_l = V_n \cot \alpha \quad (14.80)$$

The transverse (horizontal) steel can be determined by the specified minimum value (Hsu, 1993):

$$\rho_t = 0.0045 \quad (14.81)$$

14.4.2.1.2 Design Procedure

For a given dynamic loading history (or seismogram) and given material properties (f'_c, f_{ly}, ξ), the procedure to design the size of the wall, the vertical steel, and the horizontal steel is as follows:

1. Assume a shear force (V_n).
2. Determine the range of α using Equation 14.77 and Equation 14.78.
3. Select an α value and find b and d using Equation 14.79. After b and d are selected, the actual angle of inclination can be refined.
4. Determine the longitudinal steel using Equation 14.80 and the horizontal steel using Equation 14.81.
5. Determine the load–deflection relationship using the algorithm mentioned in Figure 14.18.
6. Calculate the stiffness at the ultimate state.
7. Determine the natural period at the ultimate state.
8. Select the time interval $\Delta t \leq 0.1$ times the natural period at the ultimate state.
9. Calculate the initial stiffness using the load–deflection relationship.
10. Calculate the damping coefficient using Equation 14.14.
11. Calculate the effective stiffness using Equation 14.72.
12. Calculate the incremental effective force using Equation 14.73.
13. Solve for the incremental displacement using Equation 14.71.
14. Calculate the incremental velocity using Equation 14.69.
15. Calculate displacement and velocity at the end of time interval using Equation 14.74 and Equation 14.75.
16. Calculate shear force using the load–deflection relationship.
17. Calculate acceleration at the end of time interval by Equation 14.76. Steps 9 to 17 will provide one set of solutions.
18. Repeat Steps 9 to 17 for each time interval. This will provide a number of sets of solutions.
19. Determine the calculated maximum shear force in the entire loading history.
 - a. If the value of the calculated maximum shear force is not greater than the shear force assumed, the design is finished.
 - b. If the value of the calculated maximum shear forces is greater than the shear force assumed, reassume a new value for shear force V_n and repeat Steps 2 to 19 until Step 19a is satisfied.

The algorithm presented in this section has been extended to box tubes subjected to dynamic shear and torsion and to hybrid reinforced concrete frame–steel wall systems.

14.4.2.2 Missile Impact

A shear wall 10 ft (3.05 m) high by 15 ft (4.57 m) wide (Figure 14.26(a)) is designed to withstand a missile impact having the force–time relationship shown in Figure 14.26(b) and acting at the top of the wall (Mo, 1988). For simplicity, the force–time relationship of the missile impact is used instead of the earthquake seismogram. It is assumed that the mass at the top of the wall and one third of the mass of the wall m are 0.5 kip sec²/in. (0.088 kN sec²/mm). The material properties are given as follows: $f_{ly} = 60$ ksi (414 MPa), $f'_c = 4000$ psi (27.6 MPa), $E_s = 29 \times 10^6$ psi (2.0×10^5 MPa), $\varepsilon_0 = 0.002$, and $\xi = 0.07$. The wall thickness, b , and the reinforcement of the wall, ρ_l and ρ_t , are to be determined.

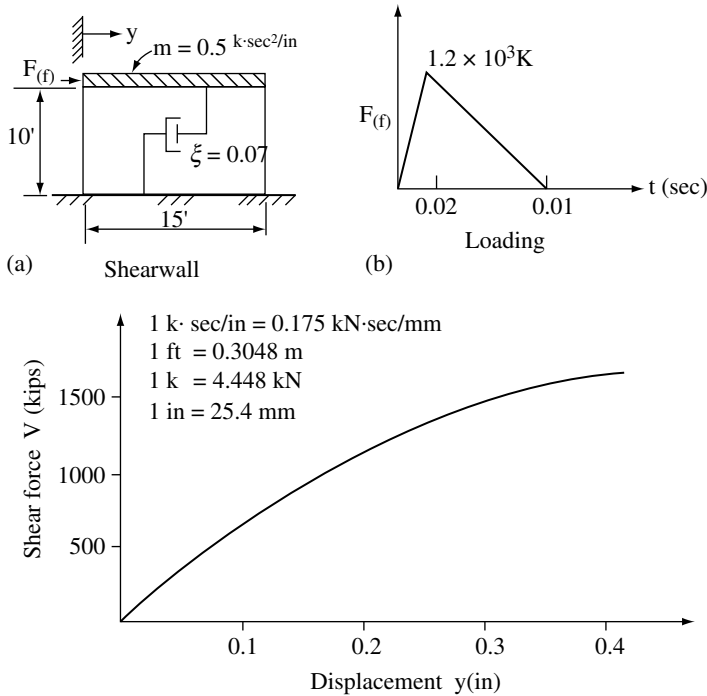

FIGURE 14.26 Shear wall subjected to missile impact.

The design of the boundary columns, which should be able to withstand the bending moment, will not be considered in this example.

Solution

1. Assume $V_n = 1600$ kips (7117 kN)
2. Determine the range of α

$$\alpha > \cos^{-1} \left\{ \frac{1}{2} \left[\left(\frac{0.00207}{2(0.002)} \right) \left(\sqrt{1 + \frac{8(0.002)^2}{(0.00207)^2}} - 1 \right) \right] \right\} \quad (14.77)$$

$$\alpha = 60.4^\circ$$

$$\alpha \leq \cos^{-1} \left[\left(\frac{(0.0025)(60,000)}{4000} \right)^{1/3} \right] \quad (14.78)$$

$$\alpha = 70.4^\circ$$

$$\therefore 60.4^\circ < \alpha \leq 70.4^\circ$$

3. Select $\alpha = 60.4^\circ$ and $d = 180$ in. (4572 mm)

$$b \geq \frac{1,600,000}{(180)(4000) \sin 60.4 \cos^2 60.4} \quad (14.79)$$

$$b \geq 10.48 \text{ in. (266 mm)}$$

Let us select $b = 12$ in. (305 mm). Calculate $\alpha = 62.9^\circ$ from Equation 14.79.

$$\alpha = 62.9^\circ < 70.4^\circ$$

OK

4. Determine ρ_l and ρ_t

$$\rho_l = \frac{1,600,000 \cot 62.9}{(12)(180)(60,000)} = 0.0063 \quad (14.80)$$

$$\rho_t = 0.0045 \quad (14.81)$$

5. Determine the load–deflection relationship using the algorithm mentioned in Figure 14.18. The load–deflection relationship is determined as shown in Figure 14.26(c).
6. Calculate the stiffness at the ultimate state

$$k_u = \frac{1609.9}{0.415} = 3879.3 \text{ kip/in. (679 kN/mm)}$$

7. Determine the natural period at the ultimate state

$$T_u = 2\pi \sqrt{\frac{0.5}{3879.3}} = 0.071 \text{ sec} \quad (14.82)$$

8. Select Δt

$$\Delta t = (0.1)(0.071) = 0.0071 \text{ sec}$$

Let us select $\Delta t = 0.005 \text{ sec}$

$$\Delta t = 0.005 < 0.0071 \text{ sec}$$

OK

9. Calculate the initial stiffness k

$$k = \frac{572.2}{0.0778} = 7354.8 \text{ kip/in. (1288 kN/mm)}$$

10. Calculate the damping coefficient C

$$C = (0.07)(2)[(0.5)(7354.8)]^{1/2} = 8.49 \text{ kip sec/in. (1.49 kN sec/mm)} \quad (14.83)$$

11. Calculate the effective stiffness \bar{k}

$$\bar{k} = 7354.8 + \frac{6(0.5)}{(0.005)^2} + \frac{3(8.49)}{0.005} = 132,448.8 \text{ kip/in. (23194 kN/mm)}$$

12. Calculate the incremental effective force

$$\Delta F = 300 \text{ kips (1334 kN)}$$

$$\Delta \bar{F} = 300 + (0.5) \left[\frac{6(0)}{0.005} + 3(0) \right] + (8.49) \left[3(0) + \frac{0.005(0)}{2} \right] = 300 \text{ kips (1334 kN)}$$

13. Determine the incremental displacement Δy

$$\Delta y = \frac{300}{132,448.8} = 0.002265 \text{ in. (0.058 mm)} \quad (14.84)$$

14. Determine the incremental velocity
- $\Delta\dot{y}$

$$\Delta\dot{y} = \frac{3}{0.005}(0.002265) - 3(0) - \frac{0.005}{2}(0) = 1.359 \text{ in./sec (34.52 mm/sec)} \quad (14.85)$$

15. Calculate the displacement and velocity at the end of the time interval

$$y_{i+1} = 0 + 0.002265 = 0.002265 \text{ in. (0.058 mm)} \quad (14.86)$$

$$\dot{y}_{i+1} = 0 + 1.359 = 1.359 \text{ in./sec (34.52 mm/sec)} \quad (14.87)$$

16. Determine the shear force
- V
- . From Figure 14.26(c),
- $V = 16.7$
- kips (74.3 kN) when
- $y = 0.002265$
- in. (0.058 mm).

17. Calculate the acceleration at the end of the time interval

$$\ddot{y}_{i+1} = \frac{1}{0.5}[300 - (8.49)(1.359) - 16.7] = 543.5 \text{ in./sec}^2 (13,805 \text{ mm/sec}^2)$$

Steps 9 to 17 provide one set of solutions.

18. Repeating Steps 9 to 17 for each time interval gives a number of sets of solutions, as illustrated in Table 14.2.

TABLE 14.2 Nonlinear Response — Linear Acceleration Step-by-Step Method for Design Example

t (sec)	F (kip)	\dot{y} (in.)	\ddot{y} (in./sec)	V (kip)	\ddot{y} (in./sec)	k_p (kip/in.)	\bar{k} (kip/in.)	ΔF (kip)	$\Delta \bar{F}$ (kip)	Δy (in.)	$\Delta \dot{y}$ (in./sec)

1 kip = 4.448 kN; 1 in. = 25.4 mm; 1 in./sec = 25.4 mm/sec; 1 in./sec² = 25.4 mm/sec²; 1 kip/in. = 0.175 kN/mm.

FIGURE 14.27 Comparison of inelastic with elastic response.

19. Determine the calculated maximum shear force. From Table 14.2, $V_{\max} = 1530$ kips (6805 kN) < assumed $V_n = 1600$ kips (7117 kN).
OK

The dynamic *inelastic response* calculated in Table 14.2 is plotted in Figure 14.27. Also plotted for comparison is the linear elastic response obtained by a similar step-by-step analysis. The effect of the inelastic response on the displacement shows up clearly in this comparison.

14.4.2.3 Explosion Interaction

The basic algorithm of Section 14.2.4 is modified to allow the analysis of a framed shear wall which interacts with a steel structure as shown in Figure 14.28.

FIGURE 14.28 A framed shear wall that interacts with a steel structure.

When a collision between the two structures is assumed to be elastic, the new velocities \dot{y}_{i1}^* and \dot{y}_{i2}^* can be computed by assuming the conservation of momentum and energy:

$$m_1 \dot{y}_{i1} + m_2 \dot{y}_{i2} = m_1 \dot{y}_{i1}^* + m_2 \dot{y}_{i2}^* \quad (14.88)$$

and

$$\frac{1}{2} m_1 \dot{y}_{i1}^2 + \frac{1}{2} m_2 \dot{y}_{i2}^2 = \frac{1}{2} m_1 \dot{y}_{i1}^{*2} + \frac{1}{2} m_2 \dot{y}_{i2}^{*2} \quad (14.89)$$

These equations give the post-impact velocity as a function of the preimpact velocity:

$$\dot{y}_{i1}^* = \dot{y}_{i1} - \frac{2R}{1+R} (\dot{y}_{i1} - \dot{y}_{i2}) \quad (14.90)$$

and

$$\dot{y}_{i2}^* = \dot{y}_{i2} - \frac{2}{1+R} (\dot{y}_{i2} - \dot{y}_{i1}) \quad (14.91)$$

where R is the mass ratio m_2/m_1 and \dot{y}_{i1}^* and \dot{y}_{i2}^* are the relative postimpact velocities for systems 1 and 2 at time t_i .

The algorithm in Section 14.2.4 may be modified to accommodate explosion interaction by allowing for two structures instead of one and inserting the following step. If the two structures collide, (a) determine the postimpact velocities using Equation 14.90 and Equation 14.91, and (b) recalculate the acceleration using the postimpact velocities.

When the explosion interaction occurs, the response is shown in Figure 14.29(c) and Figure 14.29(d) with the assumption that the initial gap between the two structures is zero. For Figure 14.29(a) and Figure 14.29(b), the gap is so large that the two structures cannot collide. A comparison of Figure 14.29(b) and Figure 14.29(d) shows that the maximum force is significantly greater when the explosion interaction occurs than it is when no explosion interaction occurs.

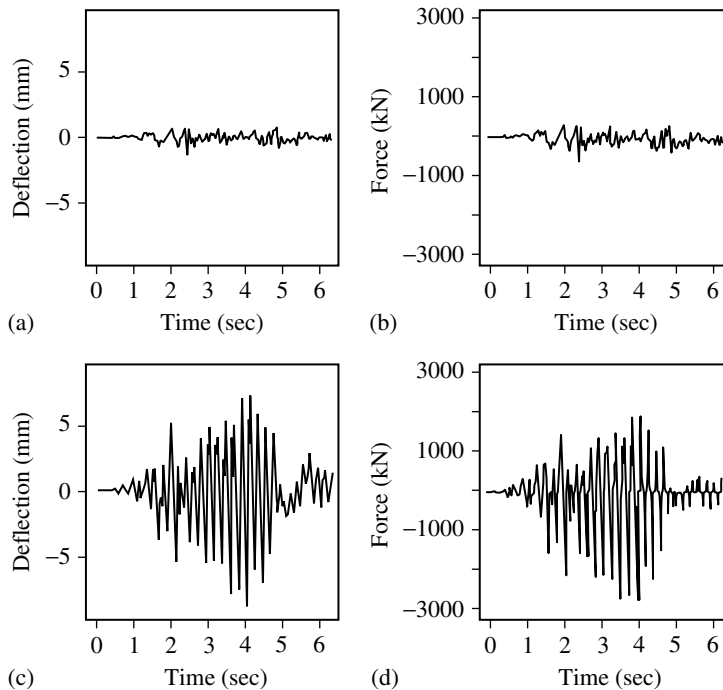

FIGURE 14.29 In (a) and (b) no explosion interaction occurs, but in (c) and (d) explosion interaction does occur.

Summary

Devices useful in instrumenting a mechanical vibrating system are presented in this chapter. Shakers, which generate vibration excitations, are discussed and compared. A variety of sensors, including motion sensors, proximity sensors, force/torque sensors, and other miscellaneous sensors, are considered. Performance specification in the time domain and the frequency domain is addressed. Rating parameters of instruments are given.

15.1 Introduction

Measurement and associated experimental techniques play a significant role in the practice of vibration. Academic exposure to vibration instrumentation usually arises in laboratories, in the context of learning, training, and research. In vibration practice, perhaps the most important task of instrumentation is the measurement or sensing of vibration. Vibration sensing is useful in the following applications:

1. Design and development of a product
2. Testing (screening) of a finished product for quality assurance
3. Qualification of a good-quality product to determine its suitability for a specific application

4. Mechanical aging of a product prior to carrying out a test program
5. Exploratory testing of a product to determine its dynamic characteristics such as resonances, mode shapes, and even a complete dynamic model
6. Vibration monitoring for performance evaluation
7. Control and suppression of vibration

Figure 15.1 indicates a procedure typical of experimental vibration, highlighting the essential instrumentation. Vibrations are generated in a device, the test object, in response to some excitation. In some experimental procedures, primarily in vibration testing (see Figure 15.1), the excitation signal has to be generated in a signal generator in accordance with some requirement (specification), and applied to the object through an exciter after amplification and conditioning. In some other situations, primarily in performance monitoring and vibration control, the excitations are generated as an integral part of the operating environment of the vibrating object and may originate either within the object (e.g., engine excitations in an automobile) or in the environment with which the object interacts during operation (e.g., road disturbances on an automobile). Sensors are needed to measure vibrations in the test object. In particular, a control sensor is used to check whether the specified excitation is applied to the object, and one or more response sensors may be used to measure the resulting vibrations at key locations of the object.

The sensor signals have to be properly conditioned, for example by filtering and amplification, and modified, for example through modulation, demodulation, and analog-to-digital conversion, prior to recording, analyzing, and display. The purpose of the controller is to guarantee that the excitation is correctly applied to the test object. If the signal from the control sensor deviates from the required excitation, the controller modifies the signal to the exciter so as to reduce this deviation. Furthermore, the controller will stabilize or limit (compress) the vibrations in the object. It follows that instruments in experimental vibration may be generally classified into the following categories:

1. Signal-generating devices
2. Vibration exciters
3. Sensors and transducers
4. Signal conditioning/modifying devices
5. Signal analysis devices
6. Control devices
7. Vibration recording and display devices

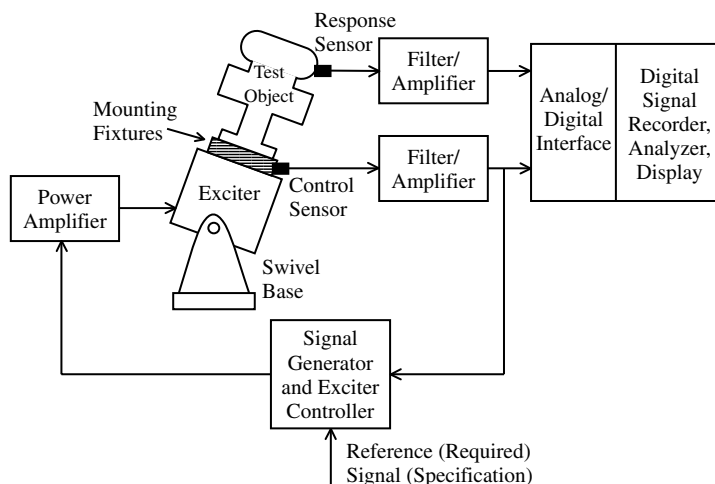

FIGURE 15.1 Typical instrumentation in experimental vibration.

Note that one instrument may perform the tasks of more than one category listed here. Also, more than one instrument may be needed to carry out tasks in a single category. In the following sections we will provide some examples of the types of vibration instrumentation, giving characteristics, operating principles, and important practical considerations. Also, we will describe several experiments which can be found in a typical vibration laboratory.

An experimental vibration system generally consists of four main subsystems:

1. Test object
2. Excitation system
3. Control system
4. Signal acquisition and modification system

These are schematically shown in Figure 15.2. Note that various components shown in Figure 15.1 may be incorporated into one of these subsystems. In particular, component matching hardware and object mounting fixtures may be considered interfacing devices that are introduced through the interaction between the main subsystems, as shown in Figure 15.2. Some important issues of vibration testing and instrumentation are summarized in Box 15.1.

FIGURE 15.2 Interactions between major subsystems of an experimental vibration system.

15.2 Vibration Exciters

Vibration experimentation may require an external exciter to generate the necessary vibration. This is the case in controlled experiments such as product testing where a specified level of vibration is applied to the test object and the resulting response is monitored. A variety of vibration exciters are available, with different capabilities and principles of operation.

Three basic types of vibration exciters (shakers) are widely used: hydraulic shakers, inertial shakers, and electromagnetic shakers. The operation-capability ranges of typical exciters in these three categories are summarized in Table 15.1. Stroke, or maximum displacement, is the largest displacement the exciter is capable of imparting onto a test object whose weight is assumed to be within its design load limit. Maximum velocity and acceleration are similarly defined. Maximum force is the largest force that could be applied by the shaker to a test object of acceptable weight (one within the design load). The values given in Table 15.1 should be interpreted with caution. Maximum displacement is achieved only at very low frequencies. The achievement of maximum velocity corresponds to intermediate frequencies in the operating frequency range of the shaker. Maximum acceleration and force ratings are usually achieved at high frequencies. It is not feasible, for example, to operate a vibration exciter at its maximum displacement and its maximum acceleration simultaneously.

Consider a loaded exciter that is executing harmonic motion. Its displacement is given by

$$x = s \sin \omega t \quad (15.1)$$

in which s is the displacement amplitude (or stroke). Corresponding velocity and acceleration are

$$\dot{x} = s\omega \cos \omega t \quad (15.2)$$

$$\ddot{x} = -s\omega^2 \sin \omega t \quad (15.3)$$

Box 15.1

VIBRATION INSTRUMENTATION

Vibration Testing Applications for Products:

- Design and Development
- Production Screening and Quality Assessment
- Utilization and Qualification for Special Applications

Testing Instrumentation:

- Exciter (excites the test object)
- Controller (controls the exciter for accurate excitation)
- Sensors and Transducers (measure excitations and responses and provide excitation error signals to controller)
- Signal Conditioning (converts signals to appropriate form)
- Recording and Display (perform processing, storage, and documentation)

Exciters:

- Shakers
 1. Electrodynamic (high bandwidth, moderate power, complex and multifrequency excitations)
 2. Hydraulic (moderate to high bandwidth, high power, complex and multifrequency excitations)
 3. Inertial (low bandwidth, low power, single-frequency harmonic excitations)
- Transient/Initial Condition
 1. Hammers (impulsive, bump tests)
 2. Cable Release (step excitations)
 3. Drop (impulsive)

Signal Conditioning:

- Filters Amplifiers
- Amplifiers
- Modulators/Demodulators
- ADC/DAC

Sensors:

- Motion (displacement, velocity, acceleration)
- Force (strain, torque)

If the velocity amplitude is denoted by v and the acceleration amplitude by a , it follows from Equation 15.2 and Equation 15.3 that

$$v = \omega s \quad (15.4)$$

and

$$a = \omega v \quad (15.5)$$

TABLE 15.1 Typical Operation-Capability Ranges for Various Shaker Types

Shaker Type	Typical Operational Capabilities					
	Frequency	Maximum Displacement (Stroke)	Maximum Velocity	Maximum Acceleration	Maximum Force	Excitation Waveform
Hydraulic (electrohydraulic)	Low (0.1–500 Hz)	High (20 in; 50 cm)	Intermediate (50 in/sec; 125 cm/sec)	Intermediate (20 g)	High (100,000 lbf; 450,000 N)	Average flexibility (simple to complex and random)
Inertial (counter-rotating mass)	Intermediate (2–50 Hz)	Low (1 in; 2.5 cm)	Intermediate (50 in/sec; 125 cm/sec)	Intermediate (20 g)	Intermediate (1,000 lbf; 4,500 N)	Sinusoidal only
Electromagnetic (electrodynamic)	High (2–10,000 Hz)	Low (1 in; 2.5 cm)	Intermediate (50 in/sec; 125 cm/sec)	High (100 g)	Low to intermediate (450 lbf; 2,000 N)	High flexibility and accuracy (simple to complex and random)

An idealized performance curve of a shaker has a constant displacement–amplitude region, a constant velocity–amplitude region, and a constant acceleration–amplitude region for low, intermediate, and high frequencies, respectively, in the operating frequency range. Such an ideal performance curve is shown in Figure 15.3(a) on a frequency–velocity plane. Logarithmic axes are used. In practice, typical shaker performance curves would be fairly smooth yet nonlinear, curves, similar to those shown in Figure 15.3(b). As the mass increases, the performance curve compresses. Note that the acceleration limit of a shaker depends on the mass of the test object (load). Full load corresponds to the heaviest object that could be tested. The “no load” condition corresponds to a shaker without a test object. To standardize the performance curves, they are usually defined at the rated load of the shaker. A performance curve in the frequency–velocity plane may be converted to a curve in the frequency–acceleration plane simply by increasing the slope of the curve by a unit magnitude (i.e., 20 db/decade).

Several general observations can be made from Equation 15.4 and Equation 15.5. In the constant-peak displacement region of the performance curve, the peak velocity increases proportionally with the excitation frequency, and the peak acceleration increases with the square of the excitation frequency. In the constant-peak velocity region, the peak displacement varies inversely with the excitation frequency, and the peak acceleration increases proportionately. In the constant-peak acceleration region, the peak displacement varies inversely with the square of the excitation frequency, and the peak velocity varies inversely with the excitation frequency. This further explains why rated stroke, maximum velocity, and maximum acceleration values are not simultaneously realized.

15.2.1 Shaker Selection

Vibration testing is accomplished by applying a specified excitation to the test package, using a shaker apparatus, and monitoring the response of the test object. Test excitation may be represented by its response spectrum. The test requires that the response spectrum of the actual excitation, known as the test response spectrum (TRS), envelops the response spectrum specified for the particular test, known as the required response spectrum (RRS).

A major step in the planning of any vibration testing program is the selection of a proper shaker (exciter) system for a given test package. The three specifications that are of primary importance in selecting a shaker are the force rating, the power rating, and the stroke (maximum displacement) rating. Force and power ratings are particularly useful in moderate to high frequency excitations and the stroke rating is the determining factor for low frequency excitations. In this section, a procedure is given to determine conservative estimates for these parameters in a specified test for a given test package. Frequency domain considerations are used here.

FIGURE 15.3 Performance curve of a vibration exciter in the frequency–velocity plane (log): (a) ideal; (b) typical.

15.2.1.1 Force Rating

In the frequency domain, the (complex) force at the exciter (shaker) head is given by

$$F = mH(\omega)a_s(\omega) \quad (15.6)$$

in which ω is the excitation frequency variable, m is the total mass of the test package including mounting fixture and attachments, $a_s(\omega)$ is the Fourier spectrum of the support-location (exciter head) acceleration, and $H(\omega)$ is frequency response function that takes into account the flexibility and damping effects (dynamics) of the test package apart from its inertia. In the simplified case where the test package can be represented by a simple oscillator of natural frequency ω_n and damping ratio by ζ_t , this function becomes

$$H(\omega) = \{1 + 2j\zeta_t\omega/\omega_n\} / \{1 - (\omega/\omega_n)^2 + 2j\zeta_t\omega/\omega_n\} \quad (15.7)$$

in which $j = \sqrt{-1}$. This approximation is adequate for most practical purposes. The static weight of the test object is not included in Equation 15.6. Most heavy-duty shakers, which are typically hydraulic, have static load support systems such as pneumatic cushion arrangements that can exactly balance the dead load. The exciter provides only the dynamic force. In cases where shaker directly supports the gravity load, in the vertical test configuration Equation 15.6 should be modified by adding a term to represent this weight.

A common practice in vibration test applications is to specify the excitation signal by its response spectrum. This is simply the peak response of a simple oscillator expressed as a function of its natural frequency when its support location is excited by the specified signal. Clearly, the damping of the simple oscillator is an added parameter in a response spectrum specification. Typical damping ratios (ζ_r) used in response spectra specifications are less than 0.1 (or 10%). It follows that an approximate relationship between the Fourier spectrum of the support acceleration and its response spectrum is

$$a_s = 2j\zeta_r a_r(\omega) \quad (15.8)$$

The magnitude $|a_r(\omega)|$ is the response spectrum.

Equation 15.8 substituted into Equation 15.6 gives

$$F = mH(\omega)2j\zeta_r a_r(\omega) \quad (15.9)$$

In view of Equation 15.7, for test packages having low damping the peak value of $H(\omega)$ is approximately $1/(2j\zeta_t)$; this should be used in computing the force rating if the test package has a resonance within the frequency range of testing. On the other hand, if the test package is assumed to be rigid, then $H(\omega) \cong 1$. A conservative estimate for the force rating is

$$F_{\max} = m(\zeta_r/\zeta_t)|a_r(\omega)|_{\max} \quad (15.10)$$

It should be noted that $|a_r(\omega)|_{\max}$ is the peak value of the specified (required) response spectrum (RRS) for acceleration.

15.2.1.2 Power Rating

The exciter head does not develop its maximum force when driven at maximum velocity. Output power is determined by using

$$p = \text{Re}[Fv_s(\omega)] \quad (15.11)$$

in which $v_s(\omega)$ is the Fourier spectrum of the exciter velocity, and $\text{Re} [\]$ denotes the real part of a complex function. Note that $a_s = j\omega v_s$. Substituting Equation 15.6 and Equation 15.8 into Equation 15.11 gives

$$p = (4m\zeta_r^2/\omega)\text{Re}[jH(\omega)a_r^2(\omega)] \quad (15.12)$$

It follows that a conservative estimate for the power rating is

$$p_{\max} = 2m(\zeta_r^2/\zeta_t)[|a_r(\omega)|^2/\omega]_{\max} \quad (15.13)$$

Representative segments of typical acceleration RRS curves have slope n , as given by

$$a = k_1 \omega^n \quad (15.14)$$

It should be clear from Equation 15.13 that the maximum output power is given by

$$p_{\max} = k_2 \omega^{2n-1} \quad (15.15)$$

This is an increasing function for $n > 1/2$ and a decreasing function for $n < 1/2$. It follows that the power rating corresponds to the highest point of contact between the acceleration RRS curve and a line of slope equal to $1/2$. A similar relationship may be derived if velocity RRS curves (having slopes $n - 1$) are used.

15.2.1.3 Stroke Rating

From Equation 15.8, it should be clear that the Fourier spectrum, x_s , of the exciter displacement time history can be expressed as

$$x_s = 2\zeta_r a_r(\omega)/j\omega^2 \quad (15.16)$$

An estimate for stroke rating is

$$x_{\max} = 2\zeta_r [a_r(\omega)/\omega^2]_{\max} \quad (15.17)$$

This is of the form

$$x_{\max} = k\omega^{n-2} \quad (15.18)$$

It follows that the stroke rating corresponds to the highest point of contact between the acceleration RRS curve and a line of slope equal to two.

Example 15.1

A test package of overall mass 100 kg is to be subjected to dynamic excitation represented by the acceleration RRS (at 5% damping) as shown in Figure 15.4. The estimated damping of the test package is 7%. The test package is known to have a resonance within the frequency range of the specified test. Determine the exciter specifications for the test.

Solution

From the development presented in the previous section, it is clear that the point F (or P) in Figure 15.4 corresponds to the force and output power ratings, and the point S corresponds to the stroke rating. The co-ordinates of these critical points are $F, P = (4.2 \text{ Hz}, 4.0 \text{ g})$, and $S = (0.8 \text{ Hz}, 0.75 \text{ g})$. Equation 15.10 gives the force rating as

$$F_{\max} = 100 \times (0.05/0.07) \times 4.0 \times 9.81 \text{ N} = 2803 \text{ N}$$

Equation 15.13 gives the power rating as

$$p_{\max} = 2 \times 100 \times (0.05^2/0.07) \times [(4.0 \times 9.81)^2/4.2 \times 2\pi] \text{ watts} = 417 \text{ W}$$

Equation 15.17 gives the stroke rating as

$$x_{\max} = 2 \times 0.05 \times [(0.75 \times 9.8)/(0.8 \times 2\pi)^2] \text{ m} = 3 \text{ cm}$$

FIGURE 15.4 Test excitation specified by an acceleration RRS (5% damping).

15.2.1.4 Hydraulic Shakers

A typical hydraulic shaker consists of a piston-cylinder arrangement (also called a ram), a servo-valve, a fluid pump, and a driving electric motor. Hydraulic fluid (oil) is pressurized (typical operating pressure: 4000 psi) and pumped into the cylinder through a servo-valve by means of a pump that is driven by an electric motor (typical power, 150 hp). The flow (typical rate: 100 gal/min) that enters the cylinder is controlled (modulated) by the servo-valve, which, in effect, controls the resulting piston (ram) motion. A typical servo-valve consists of a two-stage spool valve, which provides a pressure difference and a controlled (modulated) flow to the piston, which sets it in motion.

The servo-valve itself is moved by means of a linear torque motor, which is driven by the excitation-input signal (electrical). A primary function of the servo-valve is to provide a stabilizing feedback to the ram. In this respect, the servo-valve complements the main control system of the test setup. The ram is coupled to the shaker table by means of a link with some flexibility. The cylinder frame is mounted on the support foundation with swivel joints. This allows for some angular and lateral misalignment, which might be caused primarily by test-object dynamics as the table moves.

Two-degree-of-freedom (Two-DoF) testing requires two independent sets of actuators, and three-DoF testing requires three independent actuator sets. Each independent actuator set can consist of several actuators operated in parallel, using the same pump and the same excitation-input signal to the torque motors.

If the test table is directly supported on the vertical actuators, they must withstand the total dead weight (i.e., the weight of the test table, the test object, the mounting fixtures, and the instrumentation). This requirement is usually prevented by providing a pressurized air cushion in the gap between the test table and the foundation walls. Air should be pressurized so as to balance the total dead weight exactly (typical required gage pressure: 3 psi).

Figure 15.5(a) shows the basic components of a typical hydraulic shaker. The corresponding operational block diagram is shown in Figure 15.5(b). It is desirable to locate the actuators in a pit in the test laboratory so that the test tabletop is flushed with the test laboratory floor under no-load conditions. This minimizes the effort required to place the test object on the test table. Otherwise, the test object has to be lifted onto the test table with a forklift. Also, installation of an aircushion to support the system dead weight is difficult under these circumstances of elevated mounting.

Hydraulic actuators are most suitable for heavy load testing and are widely used in industrial and civil engineering applications. They can be operated at very low frequencies (almost direct current [DC]), as well as at intermediate frequencies (see Table 15.1). Large displacements (stroke) are possible at low frequencies.

Hydraulic shakers have the advantage of providing high flexibility of operation during the test; their capabilities include variable-force and constant-force testing and wide-band random-input testing. The velocity and acceleration capabilities of hydraulic shakers are moderate. Although any general excitation-input motion (for example, sine wave, sine beat, wide-band random) can be used in hydraulic shakers, faithful reproduction of these signals is virtually impossible at high frequencies because of distortion and higher-order harmonics introduced by the high noise levels that are common in hydraulic systems. This is only a minor drawback in heavy-duty, intermediate-frequency applications. Dynamic interactions are reduced through feedback control.

15.2.1.5 Inertial Shakers

In inertial shakers, or “mechanical exciters,” the force that causes the shaker-table motion is generated by inertia forces (accelerating masses). Counter-rotating-mass inertial shakers are typical in this category. To understand their principle of operation, consider two equal masses rotating in opposite directions at the same angular speed ω and in the same circle of radius r (see Figure 15.6). This produces a resultant force equal to $2m\omega^2r \cos \omega t$ in a fixed direction (the direction of symmetry of the two rotating arms). Consequently, a sinusoidal force with a frequency of ω and an amplitude proportional to ω^2 is generated. This reaction force is applied to the shaker table.

Figure 15.7 shows a sketch of a typical counter-rotating-mass inertial shaker. It consists of two identical rods rotating at the same speed in opposite directions. Each rod has a series of slots in which to

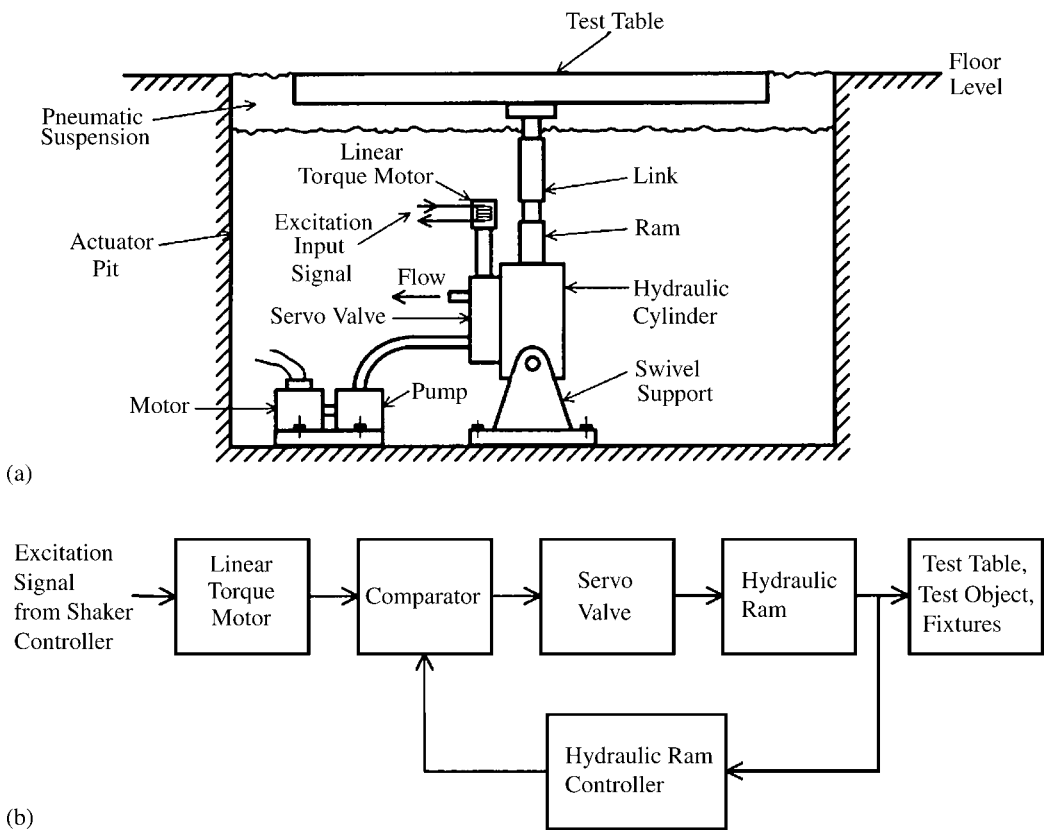

FIGURE 15.5 A typical hydraulic shaker arrangement: (a) schematic diagram; (b) operational block diagram.

place weights. In this manner, the magnitude of the eccentric mass can be varied to achieve various force capabilities. The rods are driven by a variable-speed electric motor through a gear mechanism that usually provides several speed ratios. A speed ratio is selected depending on the required test-frequency range. The whole system is symmetrically supported on a carriage that is directly connected to the test table. The test object is mounted on the test table. The preferred mounting configuration is horizontal so that the excitation force is applied to the test object in a horizontal direction. In this configuration, there are no variable gravity moments (weight \times distance to center of gravity) acting on the drive mechanism. Figure 15.7 shows the vertical configuration. In dynamic testing of large structures, the carriage can be mounted directly on the structure at a location where the excitation force should be applied. By incorporating two pairs of counter-rotating masses, it is possible to generate test moments as well as test forces.

FIGURE 15.6 Principle of operation of a counter-rotating-mass inertial shaker.

FIGURE 15.7 Sketch of a counter-rotating-mass inertial shaker.

Reaction-type shakers driven by inertia are widely used for the prototype testing of civil engineering structures. Their first application dates back to 1935. Inertial shakers are capable of producing intermediate excitation forces. The force generated is limited by the strength of the carriage frame. The frequency range of operation and the maximum velocity and acceleration capabilities are also intermediate for inertial shakers whereas the maximum displacement capability is typically low. A major limitation of inertial shakers is that their excitation force is exclusively sinusoidal and that the force amplitude is directly proportional to the square of the excitation frequency. As a result, complex and random excitation testing, constant-force testing (for example, transmissibility tests and constant-force sine-sweep tests), and flexibility to vary the force amplitude or the displacement amplitude during a test are not generally feasible with this type of shakers. Excitation frequency and amplitude can be varied during testing, however, by incorporating a variable-speed drive for the motor. The sinusoidal excitation generated by inertial shakers is virtually undistorted, which gives them an advantage over the other types of shakers when used in sine-dwell and sine-sweep tests. Small portable shakers with low-force capability are available for use in on-site testing.

15.2.1.6 Electromagnetic Shakers

In electromagnetic shakers or “electrodynamic exciters,” the motion is generated using the principle of operation of an electric motor. Specifically, the excitation force is produced when a variable excitation signal (electrical) is passed through a moving coil placed in a magnetic field.

The components of a commercial electromagnetic shaker are shown in Figure 15.8. A steady magnetic field is generated by a stationary electromagnet that consists of field coils wound on a ferromagnetic base that is rigidly attached to a protective shell structure. The shaker head has a coil wound around it. When the excitation electrical signal is passed through this drive coil, the shaker head, which is supported on flexure mounts, will be set in motion. The shaker head consists of the test table on which the test object is mounted. Shakers with interchangeable heads are available. The choice of appropriate shaker head is based on the geometry and mounting features of the test object. The shaker head can be turned to different angles by means of a swivel joint. In this manner, different directions of excitation (in biaxial and triaxial testing) can be obtained.

FIGURE 15.8 Schematic sectional view of a typical electromagnetic shaker, manufactured by Bruel and Kjaer, Denmark.

15.2.2 Dynamics of Electromagnetic Shakers

Consider a single axis electromagnetic shaker (Figure 15.8) with a test object having a single natural frequency of importance within the test frequency range. The dynamic interactions between the shaker and the test object give rise to two significant natural frequencies (and correspondingly, two significant resonances). These appear as peaks in the frequency response curve of the test setup. Furthermore, the natural frequency (resonance) of the test package alone causes a “trough” or depression (antiresonance) in the frequency response curve of the overall test setup. To explain this characteristic, consider the dynamic model shown in Figure 15.9. The following mechanical parameters are defined for Figure 15.9(a): m , k , and b are the mass, stiffness, and equivalent viscous damping constant, respectively, of the test package, and m_e , k_e , and b_e are the corresponding parameters of the exciter (shaker). Also, in the equivalent electrical circuit of the shaker head, as shown in Figure 15.9(b), the following electrical parameters are defined: R_e and L_e are the resistance and (leakage) inductance and k_b is the back electromotive force (back emf) of the linear motor. Assuming that the gravitational forces are supported

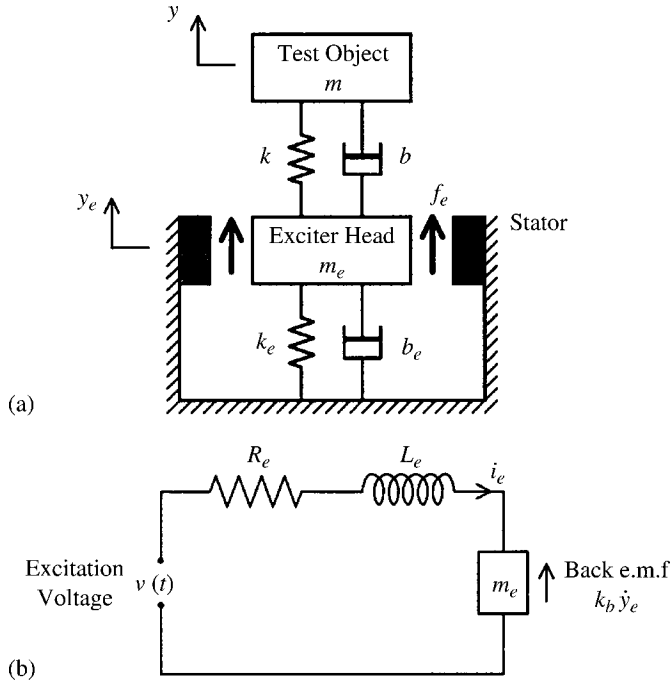

FIGURE 15.9 Dynamic models of an electromagnetic shaker and a flexible test package: (a) mechanical model; (b) electrical model.

by the static deflections of the flexible elements, and that the displacements are measured from the static equilibrium position, we have the following system equations:

$$\text{Test object: } m\ddot{y} = -k(y - y_e) - b(\dot{y} - \dot{y}_e) \quad (15.19)$$

$$\text{Shaker head: } m_e\ddot{y}_e = f_e + k(y - y_e) + b(\dot{y} - \dot{y}_e) - k_e y - b_e \dot{y}_e \quad (15.20)$$

$$\text{Electrical: } L_e \frac{di_e}{dt} + R_e i_e + k_b \dot{y}_e = v(t) \quad (15.21)$$

The electromagnetic force f_e generated in the shaker head is a result of the interaction of the magnetic field generated by the current i_e with coil of the moving shaker head and the constant magnetic field (stator) in which the head coil is located. Here, we have

$$f_e = k_b i_e \quad (15.22)$$

Note that $v(t)$ is the voltage signal that is applied by the amplifier to the shaker coil, y_e is the displacement of the shaker head, and y is the displacement response of the test package.

It is assumed that k_b has consistent electrical and mechanical units (V/m/sec and N/A). Usually, the electrical time constant of the shaker is quite small compared with the primarily mechanical time constants of the shaker and the test package. In such cases, the $L_e di_e/dt$ term in Equation 15.21 may be neglected. Consequently, the equations from Equation 15.19 through Equation 15.22 may be expressed in the Laplace (frequency) domain, with the Laplace variable s taking the place of the derivative d/dt , as

$$(ms^2 + bs + k)y = (bs + k)y_e \quad (15.23)$$

$$[m_e s^2 + (b + b_e)s + (k + k_e)]y_e = (bs + k)y + \frac{k_b}{R_e}v - \frac{k_b^2 s}{R_e}y_e \quad (15.24)$$

It follows that the transfer function of the shaker head motion with respect to the excitation voltage is given by

$$\frac{y_e}{v} = \frac{k_b}{R_e} \frac{\Delta(s)}{\Delta_d(s)} \quad (15.25)$$

where $\Delta(s)$ is the characteristic function of the primary dynamics of the test object

$$\Delta(s) = ms^2 + bs + k \quad (15.26)$$

and $\Delta_d(s)$ is the characteristic function of the primary dynamic interactions between the shaker and the test object

$$\Delta_c(s) = mm_e s^4 + [m(b_e + b + b_o) + m_e b]s^3 + [m(k_e + k) + m_e k + b(b_e + b_o)]s^2 + [bk_e + (b_e + b_o)k]s + kk_e \quad (15.27)$$

where

$$b_o = \frac{k_b^2}{R_e} \quad (15.28)$$

It is clear that under low damping conditions $\Delta_d(s)$ will produce two resonances as it is fourth order in s , and similarly $\Delta(s)$ will produce one antiresonance (trough) corresponding to the resonance of the test object. Note that in the frequency domain, $s = j\omega$, and hence the frequency response function given by Equation 15.25, is in fact

$$\frac{y_e}{v} = \frac{k_b}{R_e} \frac{\Delta(j\omega)}{\Delta_d(j\omega)} \quad (15.29)$$

The magnitude of this frequency response function for a typical test system is sketched in Figure 15.10. Note that this curve is for the “open-loop” case where there is no feedback from the shaker controller. In practice, the shaker controller will be able to compensate for the resonances and anti-resonances to some degree, depending on its effectiveness.

The main advantages of electromagnetic shakers are their high frequency range of operation, their high degree of operating flexibility, and the high level of accuracy of the generated shaker motion. Faithful reproduction of complex excitations is possible because of the advanced electronics and control systems used in this type of shakers. Electromagnetic shakers are not suitable for heavy-duty applications (large test objects), however. High test-input accelerations are possible at high frequencies when electromagnetic shakers are used, but their displacement and velocity capabilities are limited to low or intermediate values (see Table 15.1).

FIGURE 15.10 Frequency response curve of a typical electromagnetic shaker with a test object.

15.2.2.1 Transient Exciters

Other varieties of exciters are commonly used in transient-type vibration testing. In these tests, either an impulsive force or an initial excitation is applied to the test object and the resulting response is monitored. The excitations and the responses are “transient” in this case. Hammer test, drop tests, and pluck tests fall into this category. For example, a hammer test may be conducted by hitting the object with an instrumented hammer and then measuring the response of the object. The hammer has a force sensor at its tip, as sketched in Figure 15.11. A piezoelectric or strain-gage type force sensor may be used. More sophisticated hammers have impedance heads in place of force sensors. An impedance head measures force and acceleration simultaneously. The results of a hammer test will depend on many factors; for example, the dynamics of the hammer body, how firmly the hammer is held during the impact, how quickly the impact is applied, and whether there are multiple impacts.

FIGURE 15.11 An instrumented hammer used in bump tests or hammer tests.

15.3 Control System

The two primary functions of the shaker control system in vibration testing are (1) to guarantee that the specified excitation is applied to the test object and (2) to ensure that the dynamic stability (motion constraints) of the test setup is preserved. An operational block diagram illustrating these control functions is given in Figure 15.12. The reference input to the control system represents the desired excitation force that should be applied to the test object. In the absence of any control, however, the force reaching the test object will be distorted, primarily because of: (1) dynamic interactions and nonlinearities of the shaker, the test table, the mounting fixtures, the auxiliary instruments, and the test object itself; (2) noise and errors in the signal generator, amplifiers, filters, and other equipment; and (3) external loads and disturbances acting on the test object and other components (for example, external restraints, aerodynamic forces, friction). To compensate for these distorting factors, response measurements (displacements, velocities, acceleration, and so on) are made at various locations in the test setup and are used to control the system dynamics. In particular, the responses of the shaker, the test table, and the test object are measured. These responses are used to compare the actual excitation felt by

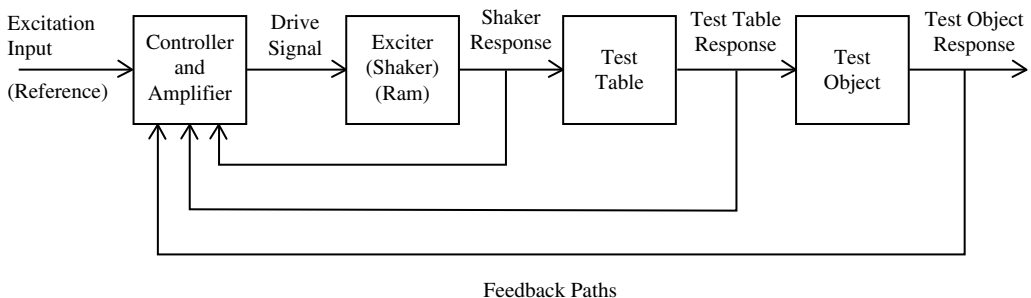

FIGURE 15.12 Operational block diagram illustrating a general shaker control system.

the test object at the shaker interface, with the desired (specified) input. The drive signal to the shaker is modified, depending on the error that is present.

Two types of control are commonly employed in shaker apparatus: simple manual control and complex automatic control. Manual control normally consists of simple, open-loop, trial-and-error methods of manual adjustments (or calibration) of the control equipment to obtain a desired dynamic response. The actual response is usually monitored (on an oscilloscope or frequency analyzer screen, for example) during manual-control operations. The pretest adjustments in manual control can be very time-consuming; as a result, the test object might be subjected to overtesting, which could produce cumulative damage, is undesirable, and could defeat the test purpose. Furthermore, the calibration procedure for the experimental setup must be repeated for each new test object.

The disadvantages of manual control suggest that automatic control is desirable in complex test schemes in which high accuracy of testing is desired. The first step of automatic control involves automatic measurement of the system response, using control sensors and transducers. The measurement is then fed back into the control system, which instantaneously determines the best drive signal to actuate the shaker in order to get the desired excitation. This may be done by either analog or digital methods.

Primitive control systems require an accurate mathematical description of the test object. This dependency of the control system on the knowledge of test-object dynamics is clearly undesirable. Performance of a good control system should not be considerably affected by the dynamic interactions and nonlinearities of the test object or by the nature of the excitation. Proper selection of feedback signals and control-system components can reduce such effects and will make the system robust.

In the response-spectrum method of vibration testing, it is customary to use displacement control at low frequencies, velocity control at intermediate frequency, and acceleration control at high frequencies. This necessitates feedback of displacement, velocity, and acceleration responses. Generally, however, the most important feedback is the velocity feedback. In sine-sweep tests, the shaker velocity must change steadily over the frequency band of interest. In particular, the velocity control must be precise near the resonances of the test object. Velocity (speed) feedback has a stabilizing effect on the dynamics, which is desirable. This effect is particularly useful in ensuring stability in motion when testing is done near resonances of lightly damped test objects. On the contrary, displacement (position) feedback can have a destabilizing effect on some systems, particularly when high feedback gains are used.

The controller usually consists of various instruments, equipment, and computation hardware and software. Often, the functions of the data-acquisition and processing system overlap with those of the controller to some extent. As an example, consider the digital-controller of vibration testing apparatus. First, the responses are measured through sensors (and transducers), filtered, and amplified (conditioned). These data channels may be passed through a multiplexer, whose purpose is to select one data channel at a time for processing. Most modern data acquisition hardware does not need a separate multiplexer to handle multiple signals. The analog data are converted into digital data using analog-to-digital converters (ADCs). The resulting sampled data are stored on a disk or as a block data in the computer memory. The reference input signal (typically, a signal recorded on an FM tape) is also sampled (if it is not already in the digital form), using an ADC, and fed into the computer. Digital processing is done on the reference signal and the response data, with the objective of computing the command signal to drive the shaker. The digital command signal is converted into an analog signal, using a digital-to-analog converter (DAC), and amplified (conditioned) before it is used to drive the exciter.

The nature of the control components depends to a large extent on the nature and objectives of the particular test to be conducted. Some of the basic components in a shaker controller are described in the following subsections.

15.3.1 Components of a Shaker Controller

15.3.1.1 Compressor

A compressor circuit is incorporated in automatic excitation control devices to control the excitation-input level automatically. The level of control depends on the feedback signal from a control sensor and

the specified (reference) excitation signal. Usually, the compressor circuit is included in the excitation-signal generator (for example, in a sine generator). The control by this means may be done on the basis of a single-frequency component (e.g., the fundamental frequency).

15.3.1.2 Equalizer (Spectrum Shaper)

Random-signal equalizers are used to shape the spectrum of a random signal in a desired manner. In essence, an equalizer consists of a bank of narrow-band filters (for example, 80 filters) in parallel over the operating frequency range. By passing the signal through each filter, the spectral density (or the mean square value) of the signal in that narrow frequency band (for example, each one-third-octave band) is determined. This is compared with the desired spectral level, and automatic adjustment is made in that filter in case there is an error. In some systems, response-spectrum analysis is made in place of power spectral density analysis. In that case, the equalizer consists of a bank of simple oscillators, whose resonant frequencies are distributed over the operating frequency range of the equalizer. The feedback signal is passed through each oscillator, and the peak value of its output is determined. This value is compared with the desired response spectrum value at that frequency. If there is an error, automatic gain adjustment is made in the appropriate excitation signal components.

Random-noise equalizers are used in conjunction with random signal generators. They receive feedback signals from the control sensors. In some digital control systems, there are algorithms (software) that are used to iteratively converge the spectrum of the excitation signal felt by the test object into the desired spectrum.

15.3.1.3 Tracking Filter

Many vibration tests are based on single-frequency excitations. In such cases, the control functions should be performed on the basis of the amplitudes of the fundamental-frequency component of the signal. A tracking filter is simply a frequency-tuned band-pass filter. It automatically tunes the center frequency of its very narrow-band-pass filter to the frequency of a carrier signal. Then, when a noisy signal is passed through the tuned filter, the output of the filter will be the required fundamental frequency component in the signal. Tracking filters also are useful in obtaining amplitude–frequency plots using an $X-Y$ plotter. In such cases, the frequency value comes from the signal generator (sweep oscillator), which produces the carrier signal to the tracking filter. The tracking filter then determines the corresponding amplitude of a signal that is fed into it. Most tracking filters have dual channels so that two signals can be handled (tracked) simultaneously.

15.3.1.4 Excitation Controller (Amplitude Servo-Monitor)

An excitation controller is typically an integral part of the signal generator. It can be set so that automatic sweep between two frequency limits can be performed at a selected sweep rate (linear or logarithmic). More advanced excitation controllers have the capability of an automatic switch-over between constant-displacement, constant-velocity and constant-acceleration excitation-input control at specified frequencies over the sweep frequency interval. Consequently, integrator circuits should be present within the excitation controller unit to determine velocities and displacements from acceleration signals. Sometimes, integration is performed by a separate unit called a *vibration meter*. This unit also offers the operator the capability of selecting the desired level of each signal (acceleration, velocity, or displacement). There is an automatic cut-off level for large displacement values that could result from noise in acceleration signals. A compressor is also a subcomponent of the excitation controller. The complete unit is sometimes known as an amplitude servo-monitor.

15.3.2 Signal-Generating Equipment

Shakers are force-generating devices that are operated using drive (excitation) signals generated from a source. The excitation-signal source is known as the signal generator. Three major types of signal generators are used in vibration testing applications: (1) oscillators, (2) random-signal generators, and (3) storage devices. In some units, oscillators and random-signal generators are combined. We shall

discuss these two generators separately, however, because of their difference in function. It also should be noted that almost any digital signal (deterministic or random) can be generated by a digital computer using a suitable computer program; the signal eventually can be passed through a DAC to obtain the corresponding analog signal. These 'digital' signal generators along with analog sources such as magnetic tape players (FM) are classified into the category of storage devices.

The dynamic range of equipment is the ratio of the maximum and minimum output levels (expressed in decibels) at which it is capable of operating without significant error. This is an important specification for many types of equipment, particularly for signal-generating devices. The output level of the signal generator should be set to a value within its dynamic range.

15.3.2.1 Oscillators

Oscillators are essentially single-frequency generators. Typically, sine signals are generated, but other waveforms (such as rectangular and triangular pulses) are also available in most oscillators. Normally, an oscillator has two modes of operation: (1) sweeping up and down between two frequency limits and (2) dwelling at a specified frequency. In the sweep operation, the sweep rate should be specified. This can be done either on a linear scale (Hz/min) or on a logarithmic scale (octaves/min). In the dwell operation, the frequency points (or intervals) should be specified. In either case, a desired signal level can be chosen using the gain-control knob. An oscillator that is operated exclusively in the sweep mode is called a sweep oscillator.

The early generation of oscillators employed variable inductor-capacitor types of electronic circuits to generate signals oscillating at a desired frequency. The oscillator is tuned to the required frequency by varying the capacitance or inductance parameters. A DC voltage is applied to energize the capacitor and to obtain the desired oscillating voltage signal, which subsequently is amplified and conditioned. Modern oscillators use operational amplifier circuits along with resistor, capacitor, and semiconductor (SC) elements. Also common are crystal (quartz) parallel-resonance oscillators, used to generate voltage signals accurately at a fixed frequency. The circuit is activated using a DC-voltage source. Other frequencies of interest are obtained by passing this high-frequency signal through a frequency converter. The signal is then conditioned (amplified and filtered). Required shaping (for example, rectangular pulse) is obtained using a shape circuit. Finally, the required signal level is obtained by passing the resulting signal through a variable-gain amplifier. A block diagram of an oscillator, illustrating various stages in the generation of a periodic signal, is given in Figure 15.13.

A typical oscillator offers a choice of several (typically six) linear and logarithmic frequency ranges and a sizable level of control capability (for example, 80 dB). Upper and lower frequency limits in a sweep can be preset on the front panel to any of the available frequency ranges. Sweep-rate settings are continuously

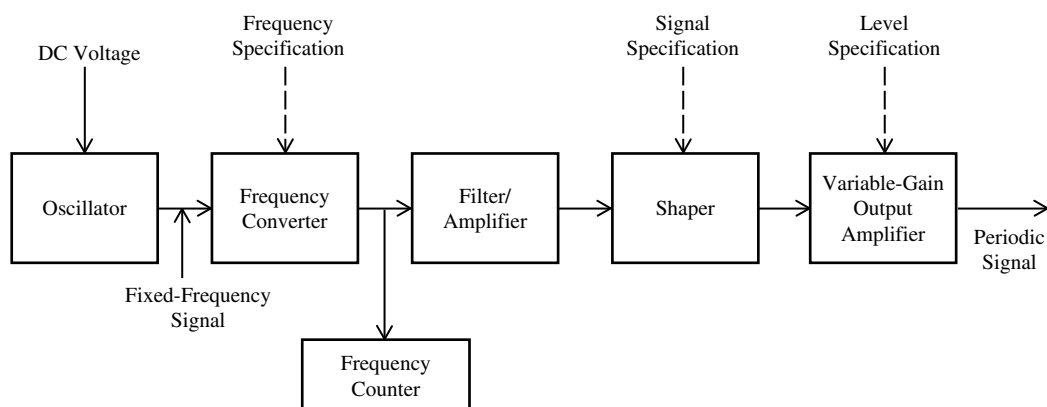

FIGURE 15.13 Block diagram of an oscillator-type signal generator.

variable (typically, 0 to 10 octaves/min in the logarithmic range, and 0 to 60 kHz/min in the linear range), but one value must be selected for a given test or part of a test. Most oscillators have a repetitive-sweep capability, which allows the execution of more than one sweep continuously, for example, for mechanical aging and in product-qualification single-frequency tests. Some oscillators also have the capability of varying the signal level (amplitude) during each test cycle (sweep or dwell). This is known as level programming. Also, automatic switching between acceleration, velocity, and displacement excitations at specified frequency points in each test cycle can be implemented with some oscillators. A frequency counter, which is capable of recording the fundamental frequency of the output signal, is usually an integral component of the oscillator.

15.3.2.2 Random Signal Generators

In modern random-signal generators, SC devices (e.g., zener diodes) are used to generate a random signal that has a required (e.g., Gaussian) distribution. This is accomplished by applying a suitable DC voltage to a SC circuit. The resulting signal is then amplified and passed through a bank of conditioning filters, which effectively acts as a spectrum shaper. In this manner, the bandwidth of the signal can be adjusted in a desired manner. Extremely wideband signals (white noise), for example, can be generated for random-excitation vibration testing in this manner. The block diagram in Figure 15.14 shows the essential steps in a random-signal generation process. A typical random-signal generator has several (typically eight) bandwidth selections over a wide frequency range (for example, 1 Hz to 100 kHz). A level-control capability (typically 80 dB) is also available.

15.3.2.3 Tape Players

Vibration testing for product qualification may be performed using a tape player as the signal source. A tape player is essentially a signal reproducer. The test-input signal that has a certain specified response spectrum is obtained by playing a magnetic tape and mixing the contents in the several tracks of the tape in a desirable ratio. Typically, each track contains a sine-beat signal, with a particular beat frequency, amplitude, and number of cycles per beat, or a random-signal component with a desired spectral characteristic).

In frequency modulation (FM) tapes, the signal amplitude is proportional to the frequency of a carrier signal. The carrier signal is recorded on the tape. When played back, the actual signal is reproduced, based on detecting the frequency content of the carrier signal in different time points. The FM method is usually favorable, particularly for low-frequency testing (below 100 Hz).

Performance of a tape player is determined by several factors, including tape type and quality, signal reproduction and recording circuitry, characteristics of the magnetic heads, and the tape-transport mechanism. Some important specifications for tape players are (1) the number of tracks per tape (for example, 14 or 28); (2) the available tape speeds (for example, 3.75, 7.5, 15, or 30 in./sec); (3) reproduction filter-amplifier capabilities (for example, 0.5% third-harmonic distortion in a 1 kHz signal recorded at 15 in./sec tape speed, peak-to-peak output voltage of 5 V at 100 Ω load, signal-to-noise ratio of 45 dB, output impedance of 50 Ω); and (4) the available control options and their capabilities (for example, stop, play, reverse, fast-forward, record, speed selection, channel selection). Tape player specifications for vibration testing are governed by an appropriate regulatory agency, according to a

FIGURE 15.14 Block diagram of a random signal generator.

specified standard (e.g., the Communication and Telemetry Standard of the Intermediate Range Instrumentation Group (IRIG Standard 106-66)).

A common practice in vibration testing is to generate the test-input signal by repetitively playing a closed tape loop. In this manner, the input signal becomes periodic but has the desired frequency content. Frequency modulation players can be fitted with special loop adaptors for playing tape loops. In spectral (Fourier) analysis of such signals, the analyzing-filter bandwidth should be several times more than the repetition frequency (tape speed/loop length). Extraneous noise is caused by discontinuities at the tape joint. This can be suppressed by using suitable filters or gating circuits.

A technique that can be employed to generate low-frequency signals with high accuracy is to record the signal first at a very low tape speed and then play it back at a high tape speed (for example, r times higher). This has the effect of multiplying all frequency components in the signal by the speed ratio (r). Consequently, the filter circuits in the tape player will allow some low-frequency components in the signal that would normally be cut off and will cut off some high-frequency components that would normally be allowed. Hence, this process is a way of emphasizing the low-frequency components in a signal.

15.3.2.4 Data Processing

A controller generally has some data processing functions, as well. A data-acquisition and processing system usually consists of response sensors (and transducers), signal conditioners, an input–output (I/O) board including a multiplexer, ADCs, etc., and a digital computer, with associated I/O devices. The functions of a digital data-acquisition and processing system may be quite general, as listed below:

1. Measuring, conditioning, sampling, and storing the response signals and operational data of test object (using input commands, as necessary)
2. Digital processing of the measured data according to the test objectives (and using input commands, as necessary)
3. Generating drive signals for the control system
4. Generating and recording test results (responses) in a required format

The capacity and the capabilities of a data-acquisition and processing systems are determined by such factors as:

1. The number of response data channels that can be handled simultaneously
2. The data-sampling rate (samples per second) for each data channel
3. Computer memory size
4. Computer processing speed
5. External storage capability (hard disks, floppy disks, and so forth)
6. The nature of the input and output devices
7. Software features

Commercial data-acquisition and processing systems with a wide range of processing capabilities are available for use in vibration testing. Some of the standard processing capabilities are the following:

1. Response-spectrum analysis
2. FFT analysis (spectral densities, correlations, coherence, Fourier spectra, and so on)
3. Frequency-response function, transmissibility, and mechanical-impedance analysis
4. Natural-frequency and mode-shape analysis
5. System-parameter identification (for example, damping parameters)

Most processing is done in real time, which means that the signals are analyzed as they are being measured. The advantage of this is that outputs and command signals are available simultaneously as the monitoring is done, so that any changes can be detected as they occur (for example, degradation in the

test object or deviations in the excitation signal from the desired form) and automatic feedback control can be effected. For real-time processing to be feasible, the data-acquisition rate (sampling rate) and the processing speed of the computer should be sufficiently fast. In real-time frequency analysis, the entire frequency range is analyzed at a given instant, as opposed to analyzing narrow bands separately. Results are presented as Fourier spectra, power spectral densities, cross-spectral densities, coherence functions, correlation functions, and response-spectra curves. Averaging of frequency plots can be done over small frequency bands (for example, one-third-octave analysis), or the running average of each instantaneous plot can be determined.

15.4 Performance Specification

Proper selection and integration of sensors and transducers are crucial in “instrumenting” a vibrating system. The response variable that is being measured (for example, acceleration) is termed the *measurand*. A measuring device passes through two stages in making a measurement. First, the measurand is sensed. Then, the measured signal is transduced (converted) into a form that is particularly suitable for signal conditioning, processing, or recording. Often, the output from the *transducer* stage is an electrical signal. It is common practice to identify the combined sensor–transducer unit as either a sensor or a transducer.

The measuring device itself might contain some of the signal-conditioning circuitry and recording (or display) devices or meters. These are components of an overall measuring system. For our purposes, we shall consider these components separately.

In most applications, the following four variables are particularly useful in determining the response and structural integrity of a vibrating system (in each case the usual measuring devices are indicated in parentheses):

1. Displacement (potentiometer or LVDT)
2. Velocity (tachometer)
3. Acceleration (accelerometer)
4. Stress and strain (strain gage)

It is somewhat common practice to measure acceleration first and then determine velocity and displacement by direct integration. Any noise and DC components in the measurement, however, could give rise to erroneous results in such cases. Consequently, it is good practice to measure displacement, velocity, and acceleration by using separate sensors, particularly when the measurements are employed in feedback control of the vibratory system. It is not recommended to differentiate a displacement (or velocity) signal to obtain velocity (or acceleration), because this process would amplify any noise present in the measured signal. Consider, for example, a sinusoidal signal given by $A \sin \omega t$. Since $d/dt(A \sin \omega t) = A\omega \cos \omega t$, it follows that any high-frequency noise would be amplified by a factor proportional to its frequency. Also, any discontinuities in noise components would produce large deviations in the results. Using the same argument, it may be concluded that the acceleration measurements are desirable for high-frequency signals and the displacement measurements are desirable for low-frequency signals. It follows that the selection of a particular measurement transducer should depend on the frequency content of the useful portion of the measured signal.

Transducers are divided into two broad categories: active transducers and passive transducers. Passive transducers do not require an external electric source for activation. Some examples are electromagnetic, piezoelectric, and photovoltaic transducers. Active transducers, however, do not possess self-contained energy sources and thus need external activation. A good example is a resistive transducer, such as a potentiometer.

In selecting a particular transducer (measuring device) for a specific vibration application, special attention should be given to its ratings, which usually are provided by the manufacturer, and the required performance specifications as provided by the customer (or developed by the system designer).

15.4.1 Parameters for Performance Specification

A *perfect measuring device* can be defined as one that possesses the following characteristics:

1. Output instantly reaches the measured value (fast response).
2. Transducer output is sufficiently large (high gain, low output impedance, high sensitivity).
3. Output remains at the measured value (without drifting or being affected by environmental effects and other undesirable disturbances and noise) unless the measurand itself changes (stability and robustness).
4. The output signal level of the transducer varies in proportion to the signal level of the measurand (static linearity).
5. Connection of a measuring device does not distort the measurand itself (loading effects are absent and impedances are matched).
6. Power consumption is small (high input impedance).

All these properties are based on dynamic characteristics and therefore can be explained in terms of dynamic behavior of the measuring device. In particular, items 1 to 4 can be specified in terms of the device (response), either in the *time domain* or in the *frequency domain*. Items 2, 5, and 6 can be specified using the *impedance* characteristics of a device. First, we shall discuss response characteristics that are important in performance specification of a sensor/transducer unit.

15.4.1.1 Time-Domain Specifications

Several parameters that are useful for the time-domain performance specification of a device are as follows:

1. *Rise time* (T_r): This is the time taken to pass the steady-state value of the response for the first time. In overdamped systems, the response is nonoscillatory; consequently, there is no overshoot. So that the definition is valid for all systems, rise time is often defined as the time taken to pass 90% of the steady-state value for the first time. Rise time is often measured from 10% of the steady-state value in order to leave out irregularities occurring at start-up and time lags that might be present in a system. Rise time represents the speed of response of a device: a small rise time indicates a fast response.
2. *Delay time* (T_d): This is usually defined as the time taken to reach 50% of the steady-state value for the first time. This parameter is also a measure of the speed of response.
3. *Peak time* (T_p): This is the time at the first peak. This parameter also represents the speed of response of the device.
4. *Settling time* (T_s): This is the time taken for the device response to settle down within a certain percentage (e.g., $\pm 2\%$) of the steady-state value. This parameter is related to the degree of damping present in the device as well as the degree of stability.
5. *Percentage overshoot* (PO): This is defined as

$$PO = 100(M_p - 1)\% \quad (15.30)$$

using the normalized-to-unity step response curve, where M_p is the peak value. Percentage overshoot is a measure of damping or relative stability in the device.

6. *Steady-state error*: This is the deviation of the actual steady-state value from the desired value. Steady-state error may be expressed as a percentage with respect to the (desired) steady-state value. In a measuring device, steady-state error manifests itself as an offset. This is a systematic (deterministic) error that normally can be corrected by recalibration. In servo-controlled devices, steady-state error can be reduced by increasing the loop gain or by introducing a lag compensation. Steady-state error can be completely eliminated using the integral control (*reset*) action.

For the best performance of a measuring device, we wish to have the values of all the foregoing parameters as small as possible. In actual practice, however, it might be difficult to meet all specifications, particularly under conflicting requirements. For instance, T_r can be decreased by increasing the dominant natural frequency ω_n of the device. This, however, increases the PO and sometimes the T_s . On the other hand, the PO and T_s can be decreased by increasing device damping, but this has the undesirable effect of increasing T_r .

15.4.1.2 Frequency-Domain Specifications

Since any time signal can be decomposed into sinusoidal components through Fourier transformation, it is clear that the response of a system to an arbitrary input excitation also can be determined using transfer-function (frequency response-function) information for that system. For this reason, one could argue that it is redundant to use both time-domain specifications and frequency-domain specifications, as they carry the same information. Often, however, both specifications are used simultaneously, because this can provide a better understanding of the system performance. Frequency-domain parameters are more suitable in representing some characteristics of a system under some types of excitation.

Consider a device with the frequency-response function (transfer function) $G(j\omega)$. Some useful parameters for performance specification of the device in the frequency domain are:

1. Useful frequency range (operating interval): This is given by the flat region of the frequency response magnitude, $|G(j\omega)|$, of the device.
2. Bandwidth (speed of response): This may be represented by the primary natural frequency (or resonant frequency) of the device.
3. Static gain (steady-state performance): Since static conditions correspond to zero frequencies; this is given by $G(0)$.
4. Resonant frequency (speed and critical frequency region) ω_r : This corresponds to the lowest frequency at which $|G(j\omega)|$ peaks.
5. Magnitude at resonance (stability): This is given by $|G(j\omega_r)|$.
6. Input impedance (loading, efficiency, interconnectability): This represents the dynamic resistance as felt at the input terminals of the device. This parameter will be discussed in more detail under component interconnection and matching.
7. Output impedance (loading, efficiency, interconnectability): This represents the dynamic resistance as felt at the output terminals of the device.
8. Gain margin (stability): This is the amount by which the device gain could be increased before the system becomes unstable.
9. Phase margin (stability): This is the amount by which the device phase lead could be decreased (i.e., phase lag increased) before the system becomes unstable.

15.4.2 Linearity

A device is considered linear if it can be modeled by linear differential equations, with time t as the independent variable. Nonlinear devices are often analyzed using linear techniques by considering small excursions about an operating point. This linearization is accomplished by introducing incremental variables for the excitations (inputs) and responses (outputs). If one increment can cover the entire operating range of a device with sufficient accuracy, it is an indication that the device is linear. If the input/output relations are nonlinear algebraic equations, that represents a *static nonlinearity*. Such a situation can be handled simply by using nonlinear calibration curves, which linearize the device without introducing nonlinearity errors. If, on the other hand, the input/output relations are nonlinear differential equations, analysis usually becomes quite complex. This situation represents a *dynamic nonlinearity*.

Transfer-function representation is a “linear” model of an instrument. Hence, it implicitly assumes linearity. According to industrial terminology, a linear measuring instrument provides a measured value that varies linearly with the value of the measurand. This is consistent with the definition of static linearity.

All physical devices are *nonlinear* to some degree. This stems from any deviation from the ideal behavior, due to causes such as saturation, deviation from Hooke's Law in elastic elements, Coulomb friction, creep at joints, aerodynamic damping, backlash in gears and other loose components, and component wearout. Nonlinearities in devices are often manifested as some peculiar characteristics. In particular, the following properties are important in detecting nonlinear behavior in dynamic systems:

1. *Saturation*: The response does not increase when the excitation is increased beyond some level. This may result from such causes as magnetic saturation, which is common in transformer devices such as differential transformers, plasticity in mechanical components, or nonlinear deformation in springs.
2. *Hysteresis*: In this case, the input/output curve changes depending on the direction of motion, resulting in a hysteresis loop. This is common in: loose components such as gears, which have backlash; in components with nonlinear damping, such as Coulomb friction; and in magnetic devices with ferromagnetic media and various dissipative mechanisms (e.g., eddy current dissipation).
3. *The jump phenomenon*: Some nonlinear devices exhibit an instability known as the jump phenomenon (or *fold catastrophe*). Here, the frequency response (transfer) function curve suddenly jumps in magnitude at a particular frequency, while the excitation frequency is increased or decreased. A device with this nonlinearity will exhibit a characteristic "tilt" of its resonant peak either to the left (softening nonlinearity) or to the right (hardening nonlinearity). Furthermore, the transfer function itself may change with the level of input excitation in the case of nonlinear devices.
4. *Limit cycles*: A limit cycle is a closed trajectory in the state space that corresponds to sustained oscillations without decay or growth. The amplitude of these oscillations is independent of the location at which the response began. In the case of a stable limit cycle, the response will return to the limit cycle irrespective of the location near the limit cycle from which the response was initiated. In the case of an unstable limit cycle, the response will steadily move away from the location with the slightest disturbance.
5. *Frequency creation*: At steady state, nonlinear devices can create frequencies that are not present in the excitation signals. These frequencies might be harmonics (integer multiples of the excitation frequency), subharmonics (integer fractions of the excitation frequency), or nonharmonics (usually rational fractions of the excitation frequency).

Several methods are available to reduce or eliminate nonlinear behavior in vibrating systems. They include calibration (in the static case), use of linearizing elements, such as resistors and amplifiers to neutralize the nonlinear effects, and the use of nonlinear feedback. It is also good practice to take the following precautions:

1. Avoid operating the device over a wide range of signal levels.
2. Avoid operation over a wide frequency band.
3. Use devices that do not generate large mechanical motions.
4. Minimize Coulomb friction.
5. Avoid loose joints and gear coupling (i.e., use *direct-drive* mechanisms).

15.4.3 Instrument Ratings

Instrument manufacturers do not usually provide complete dynamic information for their products. In most cases, it is unrealistic to expect complete dynamic models (in the time or the frequency domain) and associated parameter values for complex instruments. Performance characteristics provided by manufacturers and vendors are primarily static parameters. Known as instrument ratings, these are available as parameter values, tables, charts, calibration curves, and empirical equations. Dynamic characteristics such as transfer functions (e.g., transmissibility curves expressed with respect to excitation

frequency) might also be provided for more sophisticated instruments, but the available dynamic information is never complete. Furthermore, the definitions of rating parameters used by manufacturers and vendors of instruments are in some cases not the same as analytical definitions used in textbooks. This is particularly true in relation to the term *linearity*. Nevertheless, instrument ratings provided by manufacturers and vendors are very useful in the selection, installation, operation, and maintenance of instruments. Some of these performance parameters are indicated below.

15.4.3.1 Rating Parameters

Typical rating parameters supplied by instrument manufacturers are:

1. Sensitivity
2. Dynamic range
3. Resolution
4. Linearity
5. Zero drift and full-scale drift
6. Useful frequency range
7. Bandwidth
8. Input and output impedances

The conventional definitions given by instrument manufacturers and vendors are summarized below.

Sensitivity of a transducer is measured by the magnitude (peak, root-mean-square [RMS] value, etc.) of the output signals corresponding to a unit input of the measurand. This may be expressed as the ratio of (incremental output)/(incremental input) or, analytically, as the corresponding partial derivative. In the case of vectorial or tensorial signals (e.g., displacement, velocity, acceleration, strain, force), the direction of sensitivity should be specified.

Cross-sensitivity is the sensitivity along directions that are orthogonal to the direction of primary sensitivity; it is expressed as a percentage of the direct sensitivity. High sensitivity and low cross-sensitivity are desirable for measuring instruments. Sensitivity to parameter changes, disturbances, and noise has to be small in any device, however; this is an indication of its *robustness*. Often, sensitivity and robustness are conflicting requirements.

Dynamic range of an instrument is determined by the allowed lower and upper limits of its input or output (response) so as to maintain a required level of measurement accuracy. This range is usually expressed as a ratio, in *decibels*. In many situations, the lower limit of the dynamic range is equal to the resolution of the device. Hence, the dynamic range is usually expressed as the ratio (range of operation)/(resolution), in decibels.

Resolution is the smallest change in a signal that can be detected and accurately indicated by a transducer, a display unit, or other instrument. It is usually expressed as a percentage of the maximum range of the instrument or as the inverse of the dynamic range ratio, as defined above. It follows that dynamic range and resolution are very closely related.

Linearity is determined by the calibration curve of an instrument. The curve of output amplitude (a peak or rms value) vs. input amplitude under static conditions within the dynamic range of an instrument is known as the *static calibration curve*. Its closeness to a straight line measures the degree of linearity. Manufacturers provide this information either as the maximum deviation of the calibration curve from the least squares straight-line fit of the calibration curve or from some other reference straight line. If the least squares fit is used as the reference straight line, the maximum deviation is called *independent linearity* (or more correctly, the independent nonlinearity, because the larger the deviation, the greater the nonlinearity). Nonlinearity may be expressed as a percentage of either the actual reading at an operating point or the full-scale reading.

Zero drift is defined as the drift from the null reading of the instrument when the measurand is maintained steady for a long period. Note that in this case, the measurand is kept at zero or any other level that corresponds to null reading of the instrument. Similarly, *full-scale drift* is defined with respect to the full-scale reading (the measurand is maintained at the full-scale value). Usual causes of drift include

instrument instability (e.g., instability in amplifiers), ambient changes (e.g., changes in temperature, pressure, humidity, and vibration level), changes in power supply (e.g., changes in reference DC voltage or alternating current [AC] line voltage), and parameter changes in an instrument (due to aging, wearout, nonlinearities, etc.). Drift due to parameter changes that are caused by instrument nonlinearities is known as *parametric drift*, *sensitivity drift*, or *scale-factor drift*. For example, a change in spring stiffness or electrical resistance due to changes in ambient temperature results in a parametric drift. Note that the parametric drift depends on the measurand level. Zero drift, however, is assumed to be the same at any measurand level if the other conditions are kept constant. For example, a change in reading caused by thermal expansion of the readout mechanism due to changes in the ambient temperature is considered a zero drift. In electronic devices, drift can be reduced by using AC circuitry rather than direct current (DC) circuitry. For example, AC-coupled amplifiers have fewer drift problems than DC amplifiers. Intermittent checking for the instrument response level for zero input is a popular way to calibrate for zero drift. In digital devices, this can be done automatically and intermittently, between sample points, when the input signal can be bypassed without affecting the system operation.

Useful frequency range corresponds to the interval of both flat gain and zero phase in the frequency response characteristics of an instrument. The maximum frequency in this band is typically less than half (say, one fifth of) the dominant resonant frequency of the instrument. This is a measure of instrument bandwidth.

Bandwidth of an instrument determines the maximum speed or frequency at which the instrument is capable of operating. High bandwidth implies faster speed of response. Bandwidth is determined by the dominant natural frequency, ω_n , or the dominant resonant frequency, ω_r , of the transducer. (Note: For low damping, ω_r is approximately equal to ω_n .) It is inversely proportional to the rise time and the dominant time constant. Half-power bandwidth is also a useful parameter. Instrument bandwidth must be several times greater than the maximum frequency of interest in the measured signal. The bandwidth of a measuring device is important, particularly when measuring transient signals. Note that the bandwidth is directly related to the useful frequency range.

15.4.4 Accuracy and Precision

The instrument ratings mentioned above affect the overall *accuracy* of an instrument. Accuracy can be assigned either to a particular reading or to an instrument. Note that instrument accuracy depends not only on the physical hardware of the instrument but also on the operating conditions (e.g., design conditions that are the normal, steady operating conditions or extreme transient conditions, such as emergency start-up and shutdown). *Measurement accuracy* determines the closeness of the measured value to the true value. *Instrument accuracy* is related to the worst accuracy obtainable within the dynamic range of the instrument in a specific operating environment. *Measurement error* is defined as

$$\text{Error} = (\text{measured value}) - (\text{true value}) \quad (15.31)$$

Correction, which is the negative of error, is defined as

$$\text{Correction} = (\text{true value}) - (\text{measured value}) \quad (15.32)$$

Each of these can also be expressed as a percentage of the true value. The accuracy of an instrument may be determined by measuring a parameter whose true value is known, and is near the extremes of the dynamic range of the instrument, under certain operating conditions. For this purpose, standard parameters or signals that can be generated at very high levels of accuracy would be needed. The National Institute for Standards and Testing (NIST) is usually responsible for the generation of these standards. Nevertheless, accuracy and error values cannot be determined to 100% exactness in typical applications, because the true value is not known. In a given situation, we can only make estimates for accuracy, by using ratings provided by the instrument manufacturer or by analyzing data from previous measurements and models.

Causes of error include instrument instability, external noise (disturbances), poor calibration, inaccurate information (e.g., poor analytical models, inaccurate control), parameter changes (e.g., due to environmental changes, aging, and wearout), unknown nonlinearities, and improper use of the instrument.

Errors can be classified as *deterministic* (or *systematic*) and *random* (or *stochastic*). Deterministic errors are those caused by well-defined factors, including nonlinearities and offsets in readings. These usually can be removed by applying proper calibration and analytical practices. Error ratings and calibration charts are used to remove systematic errors from instrument readings. Random errors are caused by uncertain factors entering into the instrument response. These include device noise, line noise, and the effects of unknown random variations in the operating environment. A statistical analysis using sufficiently large amounts of data is necessary to estimate random errors. The results are usually expressed as a mean error, which is the systematic part of random error, and a standard deviation or confidence interval for instrument response.

Precision is not synonymous with accuracy. Reproducibility (or repeatability) of an instrument reading determines the precision of an instrument. Two or more identical instruments that have the same high offset error might be able to generate responses at high precision, even though these readings are clearly inaccurate. For example, consider a timing device (clock) that very accurately indicates time increments (say, up to the nearest microsecond). If the reference time (starting time) is set incorrectly, the time readings will be in error, even though the clock has a very high precision.

Instrument error may be represented by a random variable that has a mean value μ_e and a standard deviation σ_e . If the standard deviation is zero, the variable is considered deterministic. In that case, the error is said to be deterministic or repeatable. Otherwise, the error is said to be random. The precision of an instrument is determined by the standard deviation of error in the instrument response. Readings of an instrument may have a large mean value of error (e.g., large offset), but if the standard deviation is small, the instrument has a high precision. Hence, a quantitative definition for precision is

$$\text{Precision} = (\text{measurement range})/\sigma_e \quad (15.33)$$

Lack of precision originates from random causes and poor construction practices. It cannot be compensated for by recalibration, just as the precision of a clock cannot be improved by resetting the time. On the other hand, accuracy can be improved by recalibration. Repeatable (deterministic) accuracy is inversely proportional to the magnitude of the mean error μ_e .

In selecting instruments for a particular application, in addition to matching instrument ratings with specifications, several additional features should be considered. These include geometric limitations (size, shape, etc.); environmental conditions (e.g., chemical reactions including corrosion, extreme temperatures, light, dirt accumulation, electromagnetic fields, radioactive environments, shock and vibration); power requirements; operational simplicity; availability; the past record and reputation of the manufacturer and of the particular instrument; and cost-related economic aspects (initial cost, maintenance cost, cost of supplementary components such as signal-conditioning and processing devices, design life and associated frequency of replacement, and cost of disposal and replacement). Often, these considerations become the ultimate deciding factors in the selection process.

15.5 Motion Sensors and Transducers

Motion sensing is considered the most important measurement in vibration applications. Other variables, such as force, torque, stress, strain, and material properties, are also important, either directly or indirectly, in the study of vibration. This section will describe some useful measuring devices of motion in the field of mechanical vibration.

15.5.1 Potentiometer

The potentiometer, or *pot*, is a displacement transducer. This active transducer consists of a uniform coil of wire or a film of high-resistive material, such as carbon, platinum, or conductive plastic, whose resistance is proportional to its length. A fixed voltage, v_{ref} is applied across the coil (or film) using an external, constant DC voltage supply. The transducer output signal, v_o , is the DC voltage between the movable contact (wiper arm) sliding on the coil and one terminal of the coil, as shown schematically in Figure 15.15(a). Slider displacement x is proportional to the output voltage

$$v_o = kx \quad (15.34)$$

This relationship assumes that the output terminals are open-circuit, which means that infinite-impedance load (or resistance in the present DC case) is present at the output terminal, so that the output current is zero. In actual practice, however, the load (the circuitry into which the pot signal is fed, e.g., conditioning or processing circuitry) has a finite impedance. Consequently, the output current (the current through the load) is nonzero, as shown in Figure 15.15(b). The output voltage thus drops to \tilde{v}_o , even if the reference voltage, v_{ref} , is assumed to remain constant under load variations (i.e., the voltage source has zero output impedance). This consequence is known as the *loading effect* of the transducer. Under these conditions, the linear relationship given by Equation 15.34 is no longer valid. This causes an error in the displacement reading. Loading can affect the transducer reading in two ways: by changing the reference voltage (i.e., loading the voltage source) or by loading the transducer. To reduce these effects, a voltage source that is not seriously affected by load variations (e.g., a regulated or stabilized power supply that has low output impedance) and data acquisition circuitry (including signal-conditioning circuitry) that has high input impedance should be used.

The resistance of a potentiometer should be chosen with care. On the one hand, an element with high resistance is preferred because this results in reduced power dissipation for a given voltage, which has the added benefit of reduced thermal effects. On the other hand, increased resistance increases the output impedance of the potentiometer and results in loading nonlinearity error unless the load resistance is also increased proportionately. Low-resistance pots have resistances less than 10 Ω . High-resistance pots can have resistances on the order of 100 k Ω . Conductive plastics can provide high resistances, typically about 100 Ω /mm, and are increasingly used in potentiometers. Reduced friction (low mechanical loading), reduced wear, reduced weight, and increased resolution are advantages of using conductive plastics in potentiometers.

15.5.1.1 Potentiometer Resolution

The force required to move the slider arm comes from the motion source, and the resulting energy is dissipated through friction. This energy conversion, unlike pure mechanical-to-electrical conversions,

FIGURE 15.15 (a) Schematic diagram of a potentiometer; (b) potentiometer loading.

involves relatively high forces, and the energy is wasted rather than converted into the output signal of the transducer. Furthermore, the electrical energy from the reference source is also dissipated through the resistor coil (or film), resulting in an undesirable temperature rise. These are two obvious disadvantages of this *resistively coupled transducer*. Another disadvantage is the finite *resolution* in coil-type pots.

Coils, instead of straight wire, are used to increase the resistance per unit travel of the slider arm in the coil-type pot. However, the slider contact jumps from one turn to the next in this case. Accordingly, the resolution of a coil-type potentiometer is determined by the number of turns in the coil. For a coil that has N turns, the resolution, r , expressed as a percentage of the output range, is given by

$$r = \frac{100}{N} \% \quad (15.35)$$

Resolutions better (smaller) than 0.1% (i.e., 1000 turns) are available with coil potentiometers. Infinitesimal (incorrectly termed infinite) resolutions are now possible with high-quality resistive film potentiometers that use conductive plastics, for example. In this case, the resolution is limited by other factors, such as mechanical limitations and signal-to-noise ratio. Nevertheless, resolutions on the order of 0.01 mm are possible with good rectilinear potentiometers.

Some limitations and disadvantages of potentiometers as displacement measuring devices are as follows:

1. The force needed to move the slider (against friction and arm inertia) is provided by the vibration source. This mechanical loading distorts the measured signal itself.
2. High-frequency (or highly transient) measurements are not feasible because of such factors as slider bounce, friction and inertia resistance, and induced voltages in the wiper arm and primary coil.
3. Variations in the supply voltage cause error.
4. Electrical loading error can be significant when the load resistance is low.
5. Resolution is limited by the number of turns in the coil and by the coil uniformity. This will limit small-displacement measurements such as fine vibrations.
6. Wearout and heating up (with associated oxidation) in the coil (film) and slider contact cause accelerated degradation.

There are several advantages associated with potentiometer devices, however, including the following:

1. They are relatively less costly.
2. Potentiometers provide high-voltage (low-impedance) output signals, requiring no amplification in most applications. Transducer impedance can be varied simply by changing the coil resistance and supply voltage.

15.5.1.2 Optical Potentiometer

The optical potentiometer, shown schematically in Figure 15.16(a), is a displacement sensor. A layer of photoresistive material is sandwiched between a layer of regular resistive material and a layer of conductive material. The layer of resistive material has a total resistance of R_c , and it is uniform (i.e., it has a constant resistance per unit length). The photoresistive layer is practically an electrical insulator when no light is projected on it. The displacement of the moving object whose displacement is being measured causes a moving light beam to be projected on a rectangular area of the photoresistive layer. This light-projected area attains a resistance of R_p , which links the resistive layer, which is above the photoresistive layer, and the conductive layer, which is below it. The supply voltage to the potentiometer is v_{ref} and the length of the resistive layer is L . The light spot is projected at a distance x from one end of the resistive element, as shown in Figure 15.16(a).

An equivalent circuit for the optical potentiometer is shown in Figure 15.16(b). Here, it is assumed that a load of resistance R_L is present at the output of the potentiometer, the voltage across which is v_o . Current through the load is v_o/R_L . Hence, the voltage drop across $(1 - \alpha)R_c + R_L$, which is also the voltage across R_p , is given by $[(1 - \alpha)R_c + R_L]v_o/R_L$. Note that $\alpha = x/L$ is the fractional position of

FIGURE 15.16 (a) An optical potentiometer; (b) equivalent circuit ($\alpha = x/L$).

the light spot. The current balance at the junction of the three resistors in Figure 15.16(b) is

$$\frac{v_{ref} - [(1 - \alpha)R_c + R_L]v_o/R_L}{\alpha R_c} = \frac{v_o}{R_L} + \frac{[(1 - \alpha)R_c + R_L]v_o/R_L}{R_p}$$

which can be written as

$$\frac{v_o}{v_{ref}} \left\{ \frac{R_c}{R_L} + 1 + \frac{x}{L} \frac{R_c}{R_p} \left[\left(1 - \frac{x}{L} \right) \frac{R_c}{R_L} + 1 \right] \right\} = 1 \quad (15.36)$$

When the load resistance R_L is quite large in comparison to the element resistance R_c , we have $R_c/R_L \approx 0$. Hence, Equation 15.36 becomes

$$\frac{v_o}{v_{ref}} = \frac{1}{\left[\frac{x}{L} \frac{R_c}{R_p} + 1 \right]} \quad (15.37)$$

This relationship is still nonlinear in v_o/v_{ref} vs. x/L . The nonlinearity decreases, however, with decreasing R_c/R_p .

15.5.2 Variable-Inductance Transducers

Motion transducers that employ the principle of electromagnetic induction are termed variable-inductance transducers. When the flux linkage (defined as magnetic flux density times the number of turns in the conductor) through an electrical conductor changes, a voltage is induced in the conductor. This, in turn, generates a magnetic field that opposes the primary field. Hence, a mechanical force is necessary to sustain the change of flux linkage. If the change in flux linkage is brought about by a relative motion, the mechanical energy is directly converted (induced) into electrical energy. This is the basis of electromagnetic induction, and it is the principle of operation of electrical generators and variable-inductance transducers. Note that, in these devices, the change of flux linkage is caused by a mechanical motion, and mechanical-to-electrical energy transfer takes place under near-ideal conditions.

The induced voltage or change in inductance may be used as a measure of the motion. Variable-inductance transducers are generally electromechanical devices coupled by a magnetic field.

There are many different types of variable-inductance transducers. Three primary types are:

1. Mutual-induction transducers
2. Selfinduction transducers
3. Permanent-magnet transducers

Variable-inductance transducers that use a nonmagnetized ferromagnetic medium to alter the reluctance (magnetic resistance) of the flux path are known as *variable-reluctance transducers*. Some of the mutual-induction transducers and most of the selfinduction transducers are of this type. Permanent-magnet transducers do not fall into category of variable-reluctance transducers.

15.5.2.1 Mutual-Induction Transducers

The basic arrangement of a mutual-induction transducer is constituted of two coils, the *primary windings* and the *secondary windings*. One of the coils, the primary windings, carries an AC excitation that induces a steady AC voltage in the other coil, the secondary windings. The level (amplitude, RMS value, etc.) of the induced voltage depends on the flux linkage between the coils. In mutual-induction transducers, a change in the flux linkage is effected by one of the two common techniques. One technique is to move an object made of ferromagnetic material within the flux path. This changes the reluctance of the flux path, with an associated change of the flux linkage in the secondary coil. This is the operating principle of the linear-variable differential transformer (LVDT), the rotatory-variable differential transformer (RVDT), and the mutual-induction proximity probe. All of these are variable-reluctance transducers. The other common way to change the flux linkage is to move one coil with respect to the other. This is the operating principle of the resolver, the synchro-transformer, and some types of AC tachometer. These are not variable-reluctance transducers, however.

The motion can be measured by using the secondary signal in several ways. For example, the AC signal in the secondary windings may be demodulated by rejecting the *carrier frequency* (primary-winding excitation frequency) and directly measuring the resulting signal, which represents the motion. This method is particularly suitable for measuring transient motions. Alternatively, the amplitude or the rms value of the secondary (induced) voltage may be measured. Another method is to measure the change of inductance in the secondary circuit directly by using a device such as an inductance bridge circuit.

15.5.2.2 Linear-Variable Differential Transformer

The LVDT is a displacement (vibration) measuring device, which can overcome most of the shortcomings of the potentiometer. It is considered a passive transducer because the measured displacement provides energy for “changing” the induced voltage, even though an external power supply is used to energize the primary coil, which in turn induces a steady carrier voltage in the secondary coil. The LVDT is a variable-reluctance transducer of the mutual induction type. In its simplest form, the LVDT consists of an insulating, nonmagnetic cylinder that has a primary coil in the midsegment and a secondary coil symmetrically wound in the two end segments, as depicted schematically in [Figure 15.17\(a\)](#). The primary coil is energized by an AC supply of voltage v_{ref} . This will generate, by mutual induction, an AC of the same frequency in the secondary winding. A core made of ferromagnetic material is inserted coaxially into the cylindrical form without actually touching it, as shown. As the core moves, the reluctance of the flux path changes.

Hence, the degree of flux linkage depends on the axial position of the core. The two secondary coils are connected in series opposition so that the potentials induced in these two coil segments oppose each other, therefore, the net induced voltage is zero when the core is centered between the two secondary winding segments. This is known as the *null position*. When the core is displaced from this position, a nonzero induced voltage will be generated. At steady state, the amplitude v_o of this induced voltage is proportional, in the linear (operating) region, to the core displacement x . Consequently, v_o may be used as a measure of the displacement. Note that, because of its opposed secondary windings, the LVDT

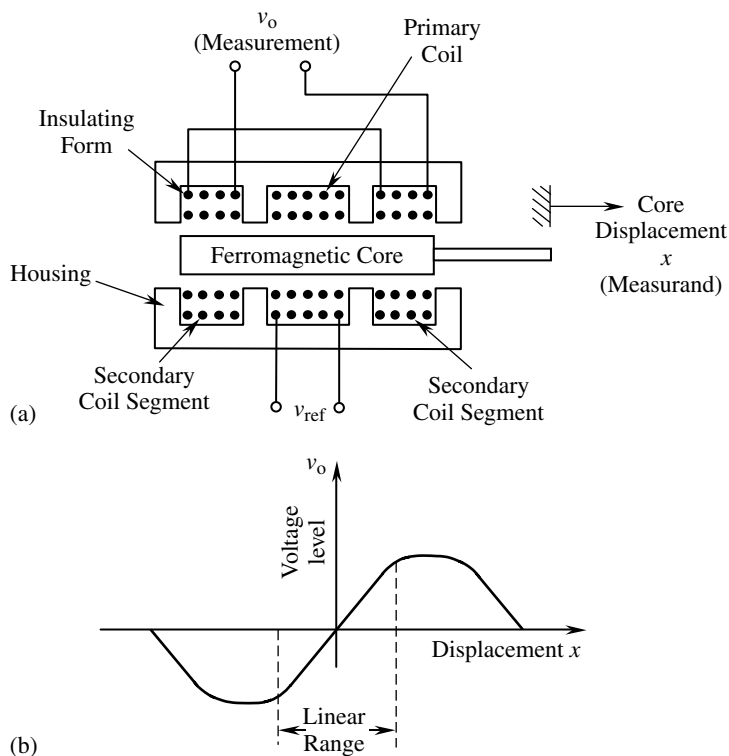

FIGURE 15.17 (a) Schematic diagram of an LVDT; (b) a typical operating curve.

provides the direction as well as the magnitude of displacement. If the output signal is not demodulated, the direction is determined by the phase angle between the primary (reference) voltage and the secondary (output) voltage, including the carrier signal.

For an LVDT to measure transient motions accurately, the frequency of the reference voltage (the carrier frequency) has to be about ten times larger than the largest significant frequency component in the measured motion. For quasi-dynamic displacements and slow transients on the order of a few hertz, a standard AC supply (at 60 Hz line frequency) is adequate. The performance, particularly the sensitivity and accuracy, is known to improve with the excitation frequency, however. Since the amplitude of the output signal is proportional to the amplitude of the primary signal, the reference voltage should be regulated to obtain accurate results. In particular, the power source should have a low output impedance.

The output signal from a differential transformer is normally not in phase with the reference voltage. Inductance in the primary windings and the leakage inductance in the secondary windings are mainly responsible for this phase shift. Since demodulation involves extraction of the modulating signal by rejecting the carrier frequency component from the secondary signal, it is important to understand the size of this phase shift. An error known as *null voltage* is present in some differential transformers. This manifests itself as a nonzero reading at the null position (i.e., at zero displacement). This is usually 90° out of phase from the main output signal and, hence, is known as *quadrature error*. Nonuniformities in the windings (unequal impedances in the two segments of the secondary windings) are a major reason for this error. The null voltage may also result from harmonic noise components in the primary signal and nonlinearities in the device. Null voltage is usually negligible (typically about 0.1% of the full scale). This error can be eliminated from the measurements by employing appropriate signal-conditioning and calibration practices.

15.5.2.3 Signal Conditioning

Signal conditioning associated with differential transformers includes filtering and amplification. Filtering is needed to improve the signal-to-noise ratio of the output signal. Amplification is necessary to increase the signal strength for data acquisition and processing. Since the reference frequency (carrier frequency) is embedded in the output signal, it is also necessary to interpret the output signal properly, particularly for transient motions. Two methods are commonly used to interpret the amplitude-modulated output signal from a differential transformer: (1) rectification; (2) demodulation.

In the first method, *rectification*, the AC output from the differential transformer is rectified to obtain a DC signal. This signal is amplified and then low-pass filtered to eliminate any high-frequency noise components. The amplitude of the resulting signal provides the transducer reading. In this method, phase shift in the LVDT output must be checked separately to determine the direction of motion. In the second method, *demodulation*, the carrier frequency component is rejected from the output signal by comparing it with a phase-shifted and amplitude-adjusted version of the primary (reference) signal. Note that phase shifting is necessary because the output signal is not in phase with the reference signal. The modulating signal which is extracted in this manner is subsequently amplified and filtered. As a result of advances in miniature integrated circuit (LSI and VLSI) technology, differential transformers with built-in microelectronics for signal conditioning are commonly available today. DC differential transformers have built-in oscillator circuits to generate the carrier signal powered by a DC supply. The supply voltage is usually on the order of 25 V, and the output voltage is about 5 V. Let us illustrate the demodulation approach to signal conditioning for an LVDT, using an example.

Example 15.2

Figure 15.18 shows a schematic diagram of a simplified signal conditioning system for an LVDT. The system variables and parameters are as indicated in Figure 15.18. In particular:

- $u(t)$ = displacement of the LVDT core (to be measured)
- ω_c = frequency of the carrier voltage
- v_o = output signal of the system (measurement)

The resistances R_1 , R_2 , and R , and the capacitance C are as marked. In addition, you may introduce a transformer parameter r for the LVDT, as required.

1. Explain the functions of the various components of the system shown in Figure 15.18.
2. Write equations for the amplifier and filter circuits and, using them, give expressions for the voltage signals v_1 , v_2 , v_3 , and v_o marked in Figure 15.18. Note that the excitation in the primary coil is $v_p \sin \omega_c t$.

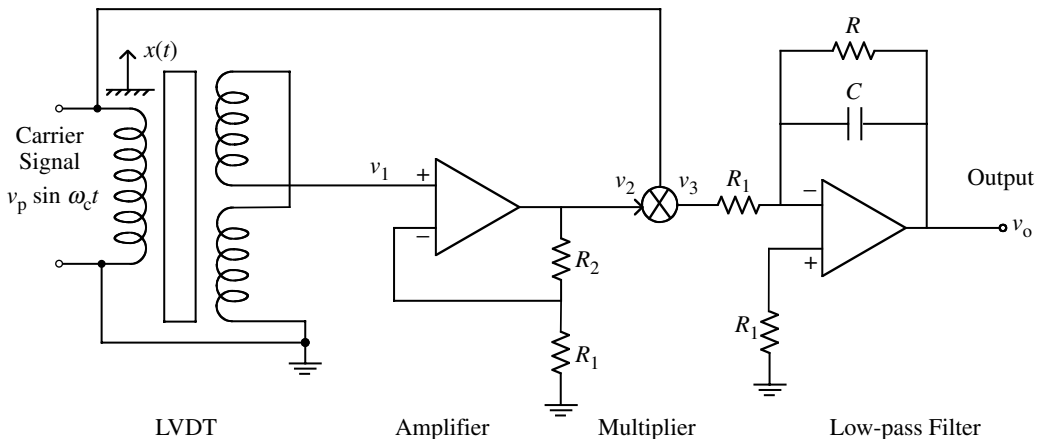

FIGURE 15.18 Signal-conditioning system for an LVDT.

3. Suppose that the carrier frequency is $\omega_c = 500$ rad/s and the filter resistance is $R = 100$ k Ω . If no more than 5% of the carrier component passes through the filter, estimate the required value of the filter capacitance, C . Also, what is the useful frequency range (measurement bandwidth) of the system in rad/sec, with these parameter values?

Solution

1. The LVDT has a primary coil that is excited by an AC voltage of $v_p \sin \omega_c t$. The ferromagnetic core is attached to the moving object whose displacement $x(t)$ is to be measured. The two secondary coils are connected in *series opposition* so that the LVDT output is zero at the null position, and that the direction of motion can be detected as well. The amplifier is a noninverting type. It amplifies the output of the LVDT which is an AC (carrier) signal of frequency ω_c , which is modulated by the core displacement $x(t)$.

The multiplier circuit determines the product of the primary (carrier) signal and the secondary (LVDT output) signal. This is an important step in demodulating the LVDT output.

The product signal from the multiplier has a high-frequency ($2\omega_c$) carrier component, added to the modulating component ($x(t)$). The low-pass filter removes this unnecessary high-frequency component to obtain the demodulated signal which is proportional to the core displacement $x(t)$.

2. Noninverting Amplifier: Note that the potentials at the positive and negative terminals of the operational amplifier (opamp) are nearly equal. Also, currents through these leads are nearly zero. (These are the two common assumptions used for an opamp.) Then, the current balance at node A gives

$$\frac{v_2 - v_1}{R_2} = \frac{v_1}{R_1}$$

or

$$v_2 = \frac{R_1 + R_2}{R_1} v_1$$

Then,

$$v_2 = k v_1 \quad (i)$$

with

$$k = \frac{R_1 + R_2}{R_1} = \text{amplifier gain}$$

Loss-Pass Filter: Since the $+$ lead of the opamp has approximately a zero potential (ground), the voltage at point B is also approximately zero. The current balance for node B gives

$$\frac{v_3}{R_1} + \frac{v_o}{R} + C\dot{v}_o = 0$$

Hence,

$$\tau \frac{dv_o}{dt} + v_o = -\frac{R}{R_1} v_3 \quad (ii)$$

where $\tau = RC$ = filter time constant. The transfer function of the filter is

$$\frac{v_o}{v_3} = -\frac{k_o}{(1 + \tau s)} \quad (iii)$$

with the filter gain $k_o = R/R_1$. In the frequency domain

$$\frac{v_o}{v_3} = -\frac{k_o}{(1 + \tau j\omega)} \quad (15.38)$$

Finally, neglecting the phase shift in the LVDT, we have

$$v_1 = v_p r u(t) \sin \omega_c t$$

$$v_2 = v_p r k u(t) \sin \omega_c t$$

or

$$v_3 = v_p^2 r k u(t) \sin^2 \omega_c t$$

$$v_3 = \frac{v_p^2 r k}{2} u(t) [1 - \cos 2 \omega_c t] \quad (\text{iv})$$

Owing to the low-pass filter, with an appropriate cut-off frequency, the carrier signal will be filtered out. Then,

$$v_o = \frac{v_p^2 r k_o}{2} u(t) \quad (15.39)$$

3. Filter magnitude = $k_o / \sqrt{1 + \tau^2 \omega^2}$. For no more than 5% of the carrier ($2\omega_c$) component to pass through, we must have

$$\frac{k_o}{\sqrt{1 + \tau^2 (2\omega_c)^2}} \leq \frac{5}{100} k_o \quad (\text{v})$$

or, $400 \leq 1 + 4\tau^2 \omega_c^2$; or, $\tau^2 \omega_c^2 \geq 399/4$; or $\tau \omega_c \geq 10$ (approximately). Pick $\tau \omega_c = 10$. With $R = 100 \text{ k}\Omega$ and $\omega_c = 500 \text{ rad/s}$, we have, $C \times 100 \times 10^3 \times 500 = 10$. Hence, $C = 0.2 \text{ }\mu\text{F}$.

According to the carrier frequency (500 rad/sec), we should be able to measure displacements $u(t)$ up to about 50 rad/sec. However, the flat region of the filter extends to approximately $\omega \tau = 0.1$, which, with the present value of $\tau = 0.02 \text{ sec}$, gives a bandwidth of only 5 rad/sec.

Advantages of the LVDT include the following:

1. It is essentially a noncontacting device with no frictional resistance. Its near-ideal electro-mechanical energy conversion and lightweight core will result in very small resistive forces. Hysteresis (both magnetic hysteresis and mechanical backlash) is negligible.
2. It has low output impedance, typically on the order of $100 \text{ }\Omega$ (signal amplification is usually not needed).
3. Directional measurements (positive/negative) are obtained.
4. It is available in small sizes (e.g., 1 cm long with maximum travel of 2 mm).
5. It has a simple and robust construction (inexpensive and durable).
6. Fine resolutions are possible (theoretically, infinitesimal resolution; practically, much finer resolution than that of a coil potentiometer).

The RVDT operates using the same principle as the LVDT, except that in an RVDT, a rotating ferromagnetic core is used. The RVDT is used for measuring angular displacements. The rotating core is shaped such that a reasonably wide linear operating region is obtained. Advantages of the RVDT are essentially the same as those cited for the LVDT. The linear range is typically $\pm 40^\circ$ with a nonlinearity error less than 1%.

In variable-inductance devices, the induced voltage is generated through the rate of change of the magnetic flux linkage. Therefore, displacement readings are distorted by velocity, and similarly, velocity readings are affected by acceleration. For the same displacement value, the transducer reading will depend on the velocity at that displacement. This error is known to increase with the ratio: (cyclic velocity of the core)/(carrier frequency). Hence, these *rate errors* can be reduced by increasing the carrier frequency. The reason for this is as follows.

At high frequencies, the induced voltage due to the transformer effect (frequencies of the primary signal) is greater than the induced voltage due to the rate (velocity) effect of the moving member. Hence, the error will be small. To estimate a lower limit for the carrier frequency in order to reduce rate effects,

we may proceed as follows:

1. For LVDT: max speed of operation/stroke of LVDT = ω_o
The excitation frequency of the primary coil should be chosen as at least $5\omega_o$.
2. For RVDT: for ω_o use the maximum angular frequency of operation (of the rotor).

15.5.3 Mutual-Induction Proximity Sensor

This displacement transducer operates on the mutual-induction principle. A simplified schematic diagram of such a device is shown in Figure 15.19(a). The insulated “E core” carries the primary windings in its middle limb. The two end limbs carry secondary windings that are connected in series. Unlike the LVDT and the RVDT, the two voltages induced in the secondary winding segments are additive in this case. The region of the moving surface (target object) that faces the coils has to be made of ferromagnetic material so that as it moves, the magnetic reluctance and the flux linkage will change. This, in turn, changes the induced voltage in the secondary windings, and this change is a measure of the displacement. Note that, unlike the LVDT, which has an “axial” displacement configuration, the proximity probe has a “transverse” displacement configuration. Hence, it is particularly suitable for measuring transverse displacements or proximities of moving objects (e.g., transverse vibrations of a beam or whirling of a rotating shaft). We can see from the operating curve shown in Figure 15.19(b) that the displacement-voltage relation of a proximity probe is nonlinear. Hence, these proximity sensors should be used only for measuring small displacements, such as linear vibrations (e.g., a linear range of 5.0 mm or 0.2 in.), unless accurate nonlinear calibration curves are available. Since the proximity sensor is a noncontacting device, mechanical loading is small and the product life is long. Because a ferromagnetic object is used to alter the reluctance of the flux path, the mutual-induction proximity sensor is a variable-reluctance device. The operating frequency limit is about one tenth the excitation frequency of the primary coil (carrier frequency). As for an LVDT, demodulation of the induced voltage (secondary) would be required to obtain direct (DC) output readings.

FIGURE 15.19 (a) Schematic diagram of the mutual-induction proximity sensor; (b) operating curve.

15.5.4 Selfinduction Transducers

These transducers are based on the principle of selfinduction. Unlike mutual-induction transducers, only a single coil is employed. This coil is activated by an AC supply voltage, v_{ref} . The current produces a magnetic flux, which is linked with the coil. The level of flux linkage (or selfinductance) can be varied by moving a ferromagnetic object within the magnetic field.

This changes the reluctance of the flux path and the inductance in the coil. This change is a measure of the displacement of the ferromagnetic object. The change in inductance is measured using an inductance measuring circuit (e.g., an inductance bridge). Note that selfinduction transducers are usually variable-reluctance devices.

A typical selfinduction transducer is a self-induction proximity sensor. A schematic diagram of this device is shown in Figure 15.20. This device can be used as a displacement or vibration sensor for transverse displacements. For instance, the distance between the sensor tip and ferromagnetic surface of a moving object, such as a beam or shaft, can be measured. Applications are essentially the same as those for mutual-induction proximity sensors. High-speed displacement (vibration) measurements can result in velocity error (rate error) when variable-inductance displacement sensors, including selfinduction transducers, are used. This effect may be reduced by increasing the carrier frequency, as in other AC-powered variable-inductance sensors.

FIGURE 15.20 Schematic diagram of a selfinduction proximity sensor.

15.5.5 Permanent-Magnet Transducers

In discussing this third type of variable-inductance transducer, we will first consider the permanent-magnet DC velocity sensors (DC tachometers). A distinctive feature of permanent-magnet transducers is that they have a permanent magnet to generate a uniform and steady magnetic field. A relative motion between the magnetic field and an electrical conductor induces a voltage that is proportional to the speed at which the conductor crosses the magnetic field. In some designs, a unidirectional magnetic field generated by a DC supply (i.e., an electromagnet) is used in place of a permanent magnet. Nevertheless, this is generally termed a permanent-magnet transducer.

The principle of electromagnetic induction between a permanent magnet and a conducting coil is used in speed measurement by permanent-magnet transducers. Depending on the configuration, either rectilinear speeds or angular speeds can be measured. Schematic diagrams of the two configurations are shown in Figure 15.21. Note that these are passive transducers, because the energy for the output signal v_o is derived from the motion (measured signal) itself. The entire device is usually enclosed in a steel casing to isolate it from ambient magnetic fields.

In the rectilinear velocity transducer, as shown in Figure 15.21(a), the conductor coil is wrapped on a core and placed centrally between two magnetic poles, which produce a cross-magnetic field. The core is attached to the moving object whose velocity must be measured. The velocity v is proportional to the induced voltage, v_o . An alternative design, consisting of a moving-magnet and fixed-coil arrangement, may be used as well, thus eliminating the need for any sliding contacts (slip rings and brushes) for the output leads, and thereby reducing mechanical loading error, wearout, and related problems. The tachogenerator (or tachometer) is a very common permanent-magnet device. The principle of operation of a DC tachogenerator is shown in Figure 15.21(a). The rotor is directly connected to the rotating object. The output signal that is induced in the rotating coil is picked up as DC voltage, v_o , using a suitable

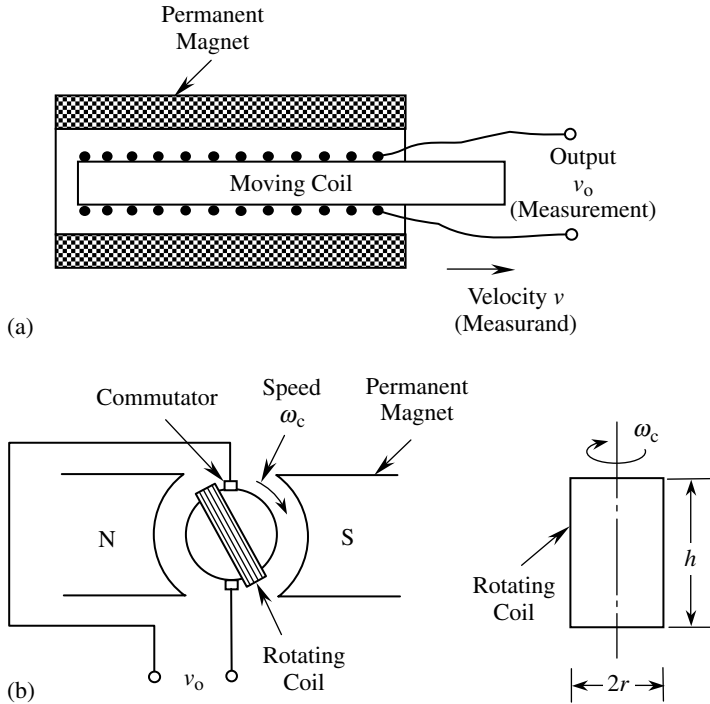

FIGURE 15.21 Permanent-magnet transducers: (a) rectilinear velocity transducer; (b) DC tachometer-generator.

commutator device, which typically consists of a pair of low-resistance carbon brushes, that is stationary but makes contact with the rotating coil through split slip rings so as to maintain the positive direction of induced voltage throughout each revolution. The induced voltage is given by

$$v_o = (2nhr\beta)\omega_c \quad (15.40)$$

for a coil of height h and width $2r$ that has n turns, moving at an angular speed ω_c in a uniform magnetic field of flux density β . This proportionality between v_o and ω_c is used to measure the angular speed ω_c .

When tachometers are used to measure transient velocities, some error will result from the rate (acceleration) effect. This error generally increases with the maximum significant frequency that must be retained in the transient velocity signal. Output distortion can also result because of reactive (inductive and capacitive) loading of the tachometer. Both types of error can be reduced by increasing the load impedance.

For an illustration, consider the equivalent circuit of a tachometer with an impedance load, as shown in Figure 15.22. The induced voltage $k\omega_c$ is represented by a voltage source. Note that the constant k depends on the coil geometry, the number of turns, and the magnetic flux density (see Equation 15.40). Coil resistance is denoted by R , and leakage inductance is denoted by L_ℓ . The load impedance is Z_L . From straightforward circuit analysis in the frequency domain, the output voltage at the load is given by

$$v_o = \left[\frac{Z_L}{R + j\omega L_\ell + Z_L} \right] k\omega_c \quad (15.41)$$

FIGURE 15.22 Equivalent circuit for a tachometer with an impedance load.

It can be seen that because of the leakage inductance, the output signal attenuates more at higher frequencies ω of the velocity transient. In addition, loading error is present. If Z_L is much larger than the coil impedance, however, the ideal proportionality, as given by

$$v_o = k\omega_c \quad (15.42)$$

is achieved.

Some tachometers operate in a different manner. For example, *digital tachometers* generate voltage pulses at a frequency proportional to the angular speed. These are considered to be digital transducers.

15.5.6 Alternating Current Permanent-Magnet Tachometer

This device has a permanent magnet rotor and two separate sets of stator windings as schematically shown in Figure 15.23(a). One set of windings is energized using an AC reference voltage. Induced voltage in the other set of windings is the tachometer output. When the rotor is stationary or moving in a quasi-static manner, the output voltage is a constant-amplitude signal much like the reference voltage. As the rotor moves at a finite speed, an additional induced voltage that is proportional to the rotor speed is generated in the secondary windings. This is due to the rate of change of flux linkage from the magnet in the secondary coil. The net output is an amplitude-modulated signal whose amplitude is proportional to the rotor speed. For transient velocities, it will be necessary to demodulate this signal in order to extract the transient velocity signal (i.e., the modulating signal) from the modulated output. The direction of velocity is determined from the phase angle of the modulated signal with respect to the carrier signal. Note that in an LVDT, the amplitude of the AC magnetic flux is altered by the position of the ferromagnetic core. But in an AC permanent-magnet tachometer, the DC magnetic flux generated by the magnetic rotor is linked with the stator windings, and the associated induced voltage is caused by the speed of rotation of the rotor.

For low-frequency applications (5 Hz or less), a standard AC supply (60 Hz) may be used to power an AC tachometer. For moderate-frequency applications, a 400 Hz supply is widely used. Typical sensitivity of an AC permanent-magnet tachometer is on the order of 50 to 100 mV/rad/sec.

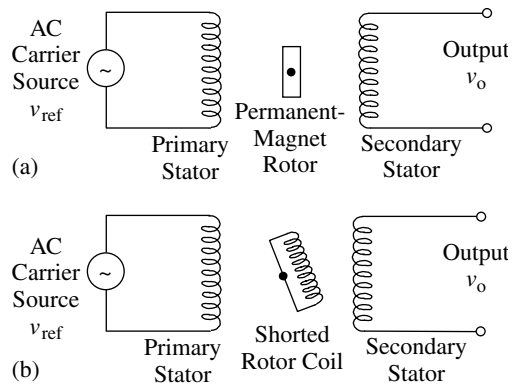

FIGURE 15.23 (a) AC permanent-magnet tachometer; (b) AC induction tachometer.

15.5.7 Alternating Current Induction Tachometer

These tachometers are similar in construction to the two-phase induction motors. The stator arrangement is identical to that of the AC permanent-magnet tachometer. The rotor, however, has windings that are shorted and not energized by an external source, as shown in Figure 15.23(b). One set of stator windings is energized with an AC supply. This induces a voltage in the rotor windings, and it has two components. One component is due to the direct transformer action of the supply AC. The other component is induced by the speed of rotation of the rotor and its magnitude is proportional to the speed of rotation. The nonenergized stator windings provide the output of the tachometer. Voltage induced in the output stator windings is due to both the primary stator windings and the rotor windings. As a result, the tachometer output has a carrier AC component and a modulating component that is proportional to the speed of rotation. Demodulation would be needed to extract the output component that is proportional to the angular speed of the rotor.

The main advantage of AC tachometers over their DC counterparts is the absence of slip-ring and brush devices. In particular, the signal from a DC tachometer usually has a voltage ripple, known as *commutator ripple*, which is generated as the split segments of the slip ring pass over the brushes. The frequency of the commutator ripple depends on the speed of operation; consequently, filtering out its effects using a notch filter is difficult (a tunable notch filter is necessary). Also, there are problems with frictional loading and contact bounce in DC tachometers, and these problems are absent in AC tachometers. It is known, however, that the output of an AC tachometer is somewhat nonlinear at high speeds due to the saturation effect. Furthermore, for measuring transient speeds, a sufficiently high carrier frequency and signal demodulation would be necessary. Another disadvantage of AC tachometers is that their output signal level depends on the supply voltage; hence, a stabilized voltage source that has a very small output impedance is necessary for accurate measurements.

15.5.8 Eddy Current Transducers

If a conducting (i.e., low-resistivity) medium is subjected to a fluctuating magnetic field, eddy currents are generated in the medium. The strength of eddy currents increases with the strength of the magnetic field and the frequency of the magnetic flux. This principle is used in eddy current proximity sensors. Eddy current sensors may be used as either dimensional gaging devices or high-frequency vibration sensors.

A schematic diagram of an eddy current proximity sensor is shown in [Figure 15.24\(a\)](#). Unlike variable-inductance proximity sensors, the target object of the eddy current sensor does not have to be made of a ferromagnetic material. A conducting target object is needed; however, a thin film conducting material, such as household aluminum foil glued onto a nonconducting target object, is adequate. The probe head has two identical coils, which form two arms of an impedance bridge. The coil closer to the probe face is the *active coil*. The other coil is the *compensating coil*. It compensates for ambient changes, particularly thermal effects. The other two arms of the bridge consist of purely resistive elements (see [Figure 15.24\(b\)](#)). The bridge is excited by a radio-frequency voltage supply. The frequency can range from 1 to 100 MHz. This signal is generated from a radio-frequency converter (an oscillator) that is typically powered by a 20 V DC supply. In the absence of the target object, the output of the impedance bridge is zero, which corresponds to the balanced condition. When the target object is moved close to the sensor, eddy currents are generated in the conducting medium because of the radio-frequency magnetic flux from the active coil. The magnetic field of the eddy currents opposes the primary field that generates these currents. Hence, the inductance of the active coil increases, creating an imbalance in the bridge. The resulting output from the bridge is an amplitude-modulated signal containing the radio-frequency carrier. This signal is demodulated by removing the carrier. The resulting signal (the modulating signal) measures the transient displacement (vibration) of the target object. Low-pass filtering is used to remove the high-frequency leftover noise in the output signal once the carrier is removed. For large displacements, the output is not linearly related to the displacement. Furthermore, the sensitivity of the eddy current probe depends nonlinearly on the nature of the conducting medium, particularly its resistivity. For example, for low resistivities, sensitivity increases with resistivity; for high resistivities, sensitivity decreases with resistivity. A calibrating unit is usually available with commercial eddy current sensors to accommodate various target objects and nonlinearities. The gage factor is usually expressed in volts/millimeter. Note that eddy current probes can also be used to measure resistivity and surface hardness (which affects resistivity) in metals.

The facial area of the conducting medium on the target object has to be slightly larger than the frontal area of the eddy current probe head. If the target object has a curved surface, its radius of curvature has to be at least four times the diameter of the probe. These are not serious restrictions, because the typical diameter of the probe head is about 2 mm. Eddy current sensors are medium-impedance devices; 1000 Ω output impedance is typical. Sensitivity is on the order of 5 V/mm. Since the carrier frequency is very high, eddy current devices are suitable for highly transient vibration measurements — for example,

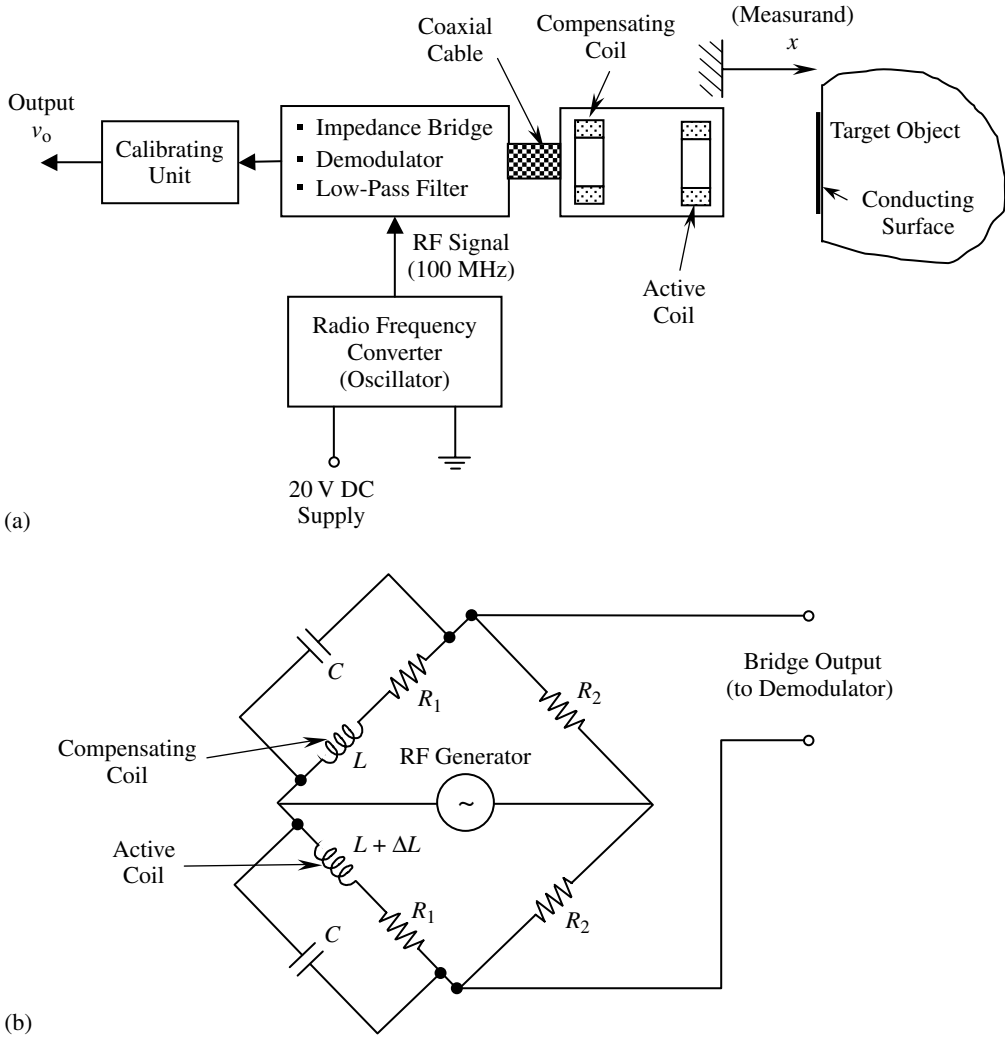

FIGURE 15.24 Eddy current proximity sensor: (a) schematic diagram; (b) impedance bridge.

bandwidths up to 100 kHz. Another advantage of an eddy current sensor is that it is a noncontacting device; there is no mechanical loading on the moving (target) object.

15.5.9 Variable-Capacitance Transducers

Capacitive or *reactive* transducers are commonly used to measure small transverse displacement such as vibrations, large rotations, and fluid level oscillations. They may also be employed to measure angular velocities. In addition to analog capacitive sensors, digital (pulse-generating) capacitive tachometers are also available.

Capacitance C of a two-plate capacitor is given by

$$C = \frac{kA}{x} \quad (15.43)$$

where A is the common (overlapping) area of the two plates, x is the gap width between the two plates, and k is the *dielectric constant* which depends on dielectric properties of the medium between the two plates. A change in any one of these three parameters may be used in the sensing process.

Schematic diagrams for measuring devices that use this feature are shown in Figure 15.25. In Figure 15.25(a), angular displacement of one of the plates causes a change in A . In Figure 15.25(b), a transverse displacement of one of the plates changes x . Finally, in Figure 15.25(c), a change in k is produced as the fluid level between the capacitor plates changes. Liquid oscillations may be sensed in this manner. In all three cases, the associated change in capacitance is measured directly or indirectly, and is used to estimate the measurand. A popular method is to use a capacitance bridge circuit to measure the change in capacitance, in a manner similar to that by which an inductance bridge is used to measure changes in inductance. Other methods include measuring a change in such quantities as charge (using a charge amplifier), voltage (using a high input-impedance device in parallel), and current (using a very low impedance device in series), as these changes will be results of the change in capacitance in a suitable circuit. An alternative method is to make the capacitor a part of an inductance–capacitance ($L - C$) oscillator circuit; the natural frequency of the oscillator ($1/\sqrt{LC}$) measures the capacitance. (Incidentally, this method may also be used to measure inductance.)

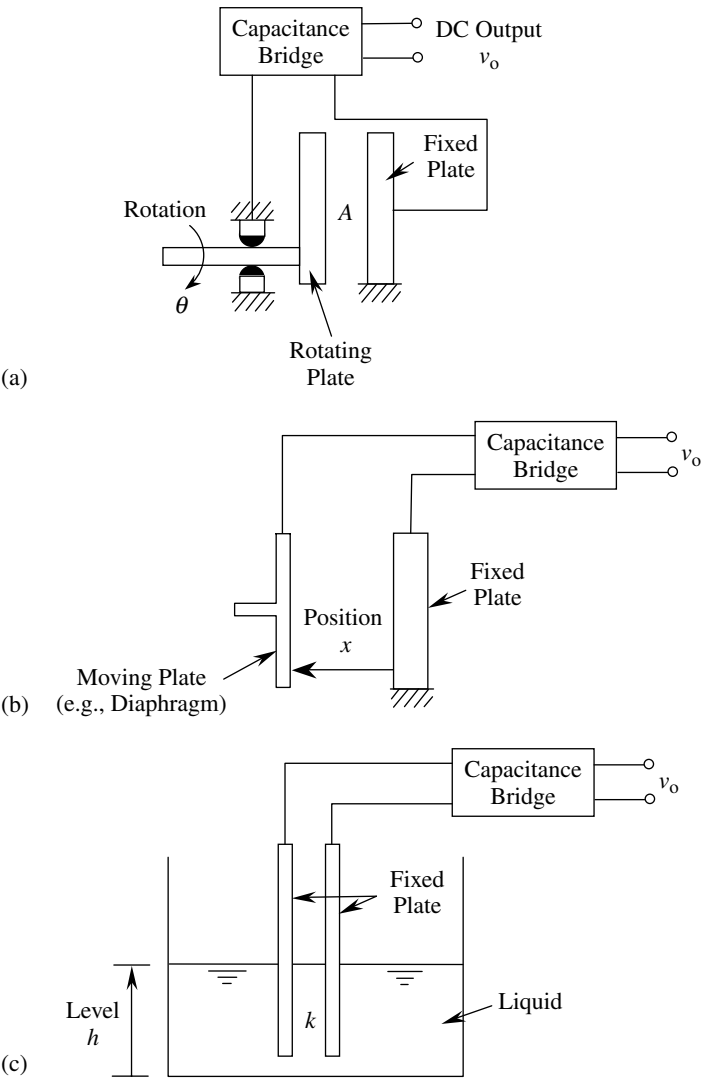

FIGURE 15.25 Schematic diagrams of capacitive sensors: (a) capacitive rotation sensor; (b) capacitive displacement sensor; (c) capacitive liquid oscillation sensor.

15.5.9.1 Capacitive Displacement Sensors

Consider the arrangement shown in Figure 15.25(a). Since the common area A is proportional to the angle of rotation θ , Equation 15.43 may be written as

$$C = K\theta \quad (15.44)$$

where K is a sensor constant. This is a linear relationship between C and θ . The capacitance may be measured by any convenient method. The sensor is linearly calibrated to give the angle of rotation.

For the arrangement shown in Figure 15.25(b), the sensor relationship is

$$C = \frac{K}{x} \quad (15.45)$$

The constant K has a different meaning here. Note that Equation 15.45 is a nonlinear relationship. A simple way to linearize this transverse displacement sensor is to use an inverting amplifier, as shown in Figure 15.26. Note that C_{ref} is a fixed, reference capacitance. Since the gain of the operational amplifier is very high, the voltage at the negative lead (point A) is zero for most practical purposes (because the positive lead is grounded). Furthermore, since the input impedance of the opamp is also very high, the current through the input leads is negligible. These are the two common assumptions used in opamp analysis. Accordingly, the charge balance equation for node point A is

$$v_{\text{ref}}C_{\text{ref}} + v_oC = 0$$

Now, in view of Equation 15.45, we obtain the following linear relationship for the output voltage, v_o , in terms of the displacement, x :

$$v_o = -\frac{v_{\text{ref}}C_{\text{ref}}}{K}x \quad (15.46)$$

Hence, measurement of v_o gives the displacement through linear calibration. The sensitivity of the device can be increased by increasing v_{ref} and C_{ref} . The reference voltage could be DC as well as AC. With an AC reference voltage, the output voltage is a modulated signal that has to be demodulated to measure transient displacements.

15.5.9.2 Capacitive Angular Velocity Sensor

The schematic diagram for an angular velocity sensor that uses a rotating-plate capacitor is shown in Figure 15.27. Since the current sensor has negligible resistance, the voltage across the capacitor is almost equal to the supply voltage v_{ref} , which is constant. It follows that the current in the circuit is given by

$$i = \frac{d}{dt}(Cv_{\text{ref}}) = v_{\text{ref}} \frac{dC}{dt}$$

which, in view of Equation 15.44, may be expressed as

$$\frac{d\theta}{dt} = \frac{i}{Kv_{\text{ref}}} \quad (15.47)$$

This is a linear relationship for the angular velocity in terms of the measured current i . Care must be exercised to guarantee that the current-measuring device does not interfere with the basic circuit.

FIGURE 15.26 Inverting amplifier circuit used to linearize the capacitive transverse displacement sensor.

FIGURE 15.27 Rotating-plate capacitive angular velocity sensor.

An advantage of capacitance transducers is that, because they are noncontacting devices, mechanical loading effects are negligible. There is some loading due to inertial and frictional resistance in the moving plate. This can be eliminated by using the moving object itself to function as the moving plate. Variations in the dielectric properties due to humidity, temperature, pressure, and impurities introduce errors. A capacitance bridge circuit can compensate for these effects. Extraneous capacitances, such as cable capacitance, can produce erroneous readings in capacitive sensors. This problem can be reduced by using a charge amplifier to condition the sensor signal. Another drawback of capacitance displacement sensors is low sensitivity. For a transverse displacement transducer, the sensitivity is typically less than one picofarad (pF) per millimeter ($1 \text{ pF} = 10^{-12} \text{ F}$). This problem is not serious, because high supply voltages and amplifier circuitry can be used to increase the sensor sensitivity.

15.5.9.3 Capacitance Bridge Circuit

Sensors that are based on the change in capacitance (reactance) will require some means of measuring that change. Furthermore, changes in capacitance that are not caused by a change in the measurand, for example, changes in humidity, temperature, and so on, will cause errors and should be compensated for. Both these goals are accomplished using a capacitance bridge circuit. An example is shown in Figure 15.28.

In this circuit:

Z_2 = reactance (i.e., capacitive impedance) of the capacitive sensor (of capacitance C_2)

$$= \frac{1}{j\omega C_2}$$

Z_1 = reactance of the compensating capacitor C_1

$$= \frac{1}{j\omega C_1}$$

Z_4, Z_3 = bridge completing impedances (typically reactances)

v_{ref} = excitation AC voltage

$$= v_a \sin \omega t$$

v_o = bridge output

$$= v_b \sin(\omega t - \phi)$$

ϕ = phase lag of the output with respect to the excitation.

Using the two assumptions for the opamp (potentials at the negative and positive leads are equal and the current through these leads is zero), we can write the current balance equations

$$\frac{v_{\text{ref}} - v}{Z_1} + \frac{v_o - v}{Z_2} = 0 \quad (\text{i})$$

$$\frac{v_{\text{ref}} - v}{Z_3} + \frac{0 - v}{Z_4} = 0 \quad (\text{ii})$$

where v is the common voltage at the opamp leads. Next, eliminate v in Equation i and Equation ii to obtain

$$v_o = \frac{(Z_4/Z_3 - Z_2/Z_1)}{1 + Z_4/Z_3} v_{\text{ref}} \quad (15.48)$$

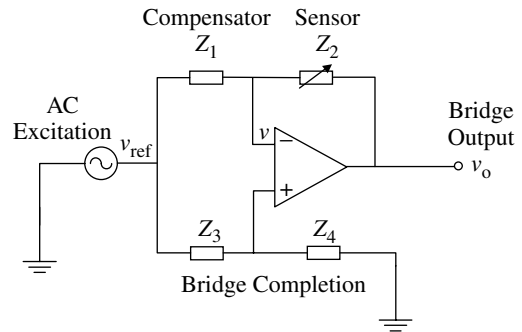

FIGURE 15.28 A bridge circuit for capacitive sensors.

It is noted that, when

$$\frac{Z_2}{Z_1} = \frac{Z_4}{Z_3} \quad (15.49)$$

the bridge output $v_o = 0$, and the bridge is said to be balanced. Since all capacitors in the bridge are similarly affected by ambient changes, a balanced bridge will maintain that condition even under ambient changes, unless the sensor reactance Z_2 is changed due to the measurand itself. It follows that the ambient effects are compensated for (at least up to the first order) by a bridge circuit. From Equation 15.48 it is clear that the bridge output due to a sensor change of δZ , starting from a balanced state, is given by

$$\delta v_o = -\frac{v_{\text{ref}}}{Z_1(1 + Z_4/Z_3)} \delta Z \quad (15.50)$$

The amplitude and phase angle of δv_o with respect to v_{ref} will determine δZ , assuming that Z_1 and Z_4/Z_3 are known.

15.5.10 Piezoelectric Transducers

Some substances, such as barium titanate and single-crystal quartz, can generate an electrical charge and an associated potential difference when they are subjected to mechanical stress or strain. This piezoelectric effect is used in piezoelectric transducers. Direct application of the piezoelectric effect is found in pressure and strain measuring devices, and many indirect applications also exist. They include piezoelectric accelerometers and velocity sensors, and piezoelectric torque sensors and force sensors. It is also interesting to note that piezoelectric materials deform when subjected to a potential difference (or charge). Some delicate test equipments (e.g., that used for vibration testing) use piezoelectric actuating elements (reverse piezoelectric action) to create fine motions. Also, piezoelectric valves (e.g., flapper valves), which are directly actuated using voltage signals, are used in pneumatic and hydraulic control applications and in ink-jet printers. Miniature stepper motors based on the reverse piezoelectric action are available.

Consider a piezoelectric crystal in the form of a disc with two electrodes plated on the two opposite faces. It is essentially a charge source. Furthermore, since the crystal is a dielectric medium, this device has a capacitor, which may be modeled by a capacitance, C , as in Equation 15.43. Accordingly, a piezoelectric sensor may be represented as a charge source with a capacitive impedance in series (Figure 15.29), in an equivalent circuit. The impedance from the capacitor is given by

$$Z = \frac{1}{j\omega C} \quad (15.51)$$

As is clear from Equation 15.51, the output impedance of piezoelectric sensors is very high, particularly at low frequencies. For example, a quartz crystal may present an impedance of several megohms at 100 Hz, increasing hyperbolically with decreasing frequencies. This is one reason why piezoelectric sensors have a limitation on the useful lower frequency. The other reason is charge leakage.

15.5.10.1 Sensitivity

The sensitivity of a piezoelectric crystal may be represented either by its charge sensitivity or by its voltage sensitivity. Charge sensitivity is defined as

$$S_q = \frac{\partial q}{\partial F} \quad (15.52)$$

FIGURE 15.29 Equivalent circuit representation of a piezoelectric sensor.

where q denotes the generated charge and F denotes the applied force. For a crystal with surface area A , Equation 15.52 may be expressed as

$$S_q = \frac{1}{A} \frac{\partial q}{\partial p} \tag{15.53}$$

where p is the stress (normal or shear) or pressure applied to the crystal surface. Voltage sensitivity S_v is given by the change in voltage due to a unit increment in pressure (or stress) per unit thickness of the crystal. Thus, in the limit, we have

$$S_v = \frac{1}{d} \frac{\partial v}{\partial p} \tag{15.54}$$

where d denotes the crystal thickness. Now, since

$$\delta q = C \delta v \tag{15.55}$$

by using Equation 15.43 for a capacitor element, the following relationship between charge sensitivity and voltage sensitivity is obtained:

$$S_q = k S_v \tag{15.56}$$

Note that k is the dielectric constant of the crystal capacitor, as defined by Equation 15.43.

Example 15.3

A barium titanate crystal has a charge sensitivity of 150.0 picocoulombs per newton (pC/N). (*Note:* 1 pC = 1×10^{-12} coulombs; coulombs = farads \times volts.) The dielectric constant for the crystal is 1.25×10^{-8} farads per meter (F/m). What is the voltage sensitivity of the crystal?

Solution

The voltage sensitivity of the crystal is given by

$$S_v = \frac{150.0 \text{ pC/N}}{1.25 \times 10^{-8} \text{ F/m}} = \frac{150.0 \times 10^{-12} \text{ C/N}}{1.25 \times 10^{-8} \text{ F/m}}$$

or

$$S_v = 12.0 \times 10^{-3} \text{ V}\cdot\text{m/N} = 12.0 \text{ mV}\cdot\text{m/N}$$

The sensitivity of a piezoelectric element depends on the direction of loading. This is because the sensitivity depends on the crystal axis. Sensitivities of several piezoelectric materials along their most sensitive crystal axis are listed in Table 15.2.

15.5.10.2 Piezoelectric Accelerometer

Next we will discuss a piezoelectric motion transducer or vibration sensor, the piezoelectric accelerometer, in more detail. A piezoelectric velocity transducer is simply a piezoelectric accelerometer with a built-in integrating amplifier in the form of a miniature integrated circuit.

Accelerometers are acceleration-measuring devices. It is known from Newton's Second Law that a force (f) is necessary to accelerate a mass (or inertia element), and its magnitude is given by the

TABLE 15.2 Sensitivities of Several Piezoelectric Materials

Material	Charge Sensitivity S_q (pC/N)	Voltage Sensitivity S_v (mV m/N)
Lead zirconate titanate (PZT)	110	10
Barium titanate	140	6
Quartz	2.5	50
Rochelle salt	275	90

product of mass (M) and acceleration (a). This product (Ma) is commonly termed *inertia force*. The rationale for this terminology is that if a force of magnitude Ma were applied to the accelerating mass in the direction opposing the acceleration, then the system could be analyzed using static equilibrium considerations. This is known as *d'Alembert's principle*. The force that causes acceleration is itself a measure of the acceleration (mass is kept constant). Accordingly, mass can serve as a front-end element to convert acceleration into a force. This is the principle of operation of common accelerometers. There are many different types of accelerometers, ranging from strain gage devices to those that use electromagnetic induction. For example, force that causes acceleration can be converted into a proportional displacement using a spring element, and this displacement may be measured using a convenient displacement sensor. Examples of instruments of which operate this way are differential-transformer accelerometers, potentiometer accelerometers, and variable-capacitance accelerometers. Alternatively, the strain at a suitable location of a member that was deflected due to inertia force may be determined using a strain gage. This method is used in strain gage accelerometers. Vibrating-wire accelerometers use the accelerating force to create tension in a wire. The force is measured by detecting the natural frequency of vibration of the wire (which is proportional to the square root of tension). In servo force-balance (or null-balance) accelerometers, the inertia element is restrained from accelerating by detecting its motion and feeding back a force (or torque) to exactly cancel out the accelerating force (torque). This feedback force is determined, for instance, by knowing the motor current, and it is a measure of the acceleration.

The advantages of piezoelectric accelerometers (also known as *crystal accelerometers*) over other types of accelerometers are their light weight and high-frequency response (up to about 1 MHz). However, piezoelectric transducers are inherently high-output-impedance devices that generate small voltages (on the order of 1 mV). For this reason, special impedance-transforming amplifiers (e.g., charge amplifiers) have to be employed to condition the output signal and to reduce loading error.

A schematic diagram for a compression-type piezoelectric accelerometer is shown in Figure 15.30. The crystal and the inertia mass are restrained by a spring of very high stiffness. Consequently, the fundamental natural frequency or resonant frequency of the device becomes high (typically 20 kHz). This gives a reasonably wide, useful range (typically up to 5 kHz). The lower limit of the useful range (typically 1 Hz) is set by factors such as the limitations of the signal-conditioning systems, the mounting methods, the charge leakage in the piezoelectric element, the time constant of the charge-generating dynamics, and the signal-to-noise ratio. A typical frequency response curve for a piezoelectric accelerometer is shown in Figure 15.31.

In compression-type crystal accelerometers, the inertia force is sensed as a compressive normal stress in the piezoelectric element. There are also piezoelectric accelerometers that sense the inertia force as a shear strain or tensile strain. For an accelerometer, acceleration is the signal that is being measured (the measurand). Hence, accelerometer sensitivity is commonly expressed in terms of electrical charge per unit acceleration or

FIGURE 15.30 A compression-type piezoelectric accelerometer.

FIGURE 15.31 A typical frequency-response curve for a piezoelectric accelerometer.

voltage per unit acceleration (compare this with Equation 15.53 and Equation 15.54). Acceleration is measured in units of acceleration due to gravity (g), and charge is measured in picocoulombs (pC), which are units of 10^{-12} coulombs (C). Typical accelerometer sensitivities are 10 pC/g and 5 mV/g. Sensitivity depends on the piezoelectric properties and on the mass of the inertia element. If a large mass is used, the reaction inertia force on the crystal will be large for a given acceleration, thus generating a relatively large output signal. A large accelerometer mass results in several disadvantages, however. In particular:

1. The accelerometer mass distorts the measured motion variable (mechanical loading effect).
2. A heavier accelerometer has a lower resonant frequency and, hence, a lower useful frequency range (Figure 15.31).

For a given accelerometer size, improved sensitivity can be obtained by using the shear-strain configuration. In this configuration, several shear layers can be used (e.g., in a *delta arrangement*) within the accelerometer housing, thereby increasing the effective shear area and, hence, the sensitivity in proportion to the shear area. Another factor that should be considered in selecting an accelerometer is its *cross-sensitivity* or transverse sensitivity. Cross-sensitivity primarily results from manufacturing irregularities in the piezoelectric element, such as material unevenness and incorrect orientation of the sensing element. Cross-sensitivity should be less than the maximum error (a percentage) that is allowed for the device (typically 1%).

The technique employed to mount the accelerometer to an object can significantly affect the useful frequency range of the accelerometer. Some common mounting techniques are:

1. Screw-in base
2. Glue, cement, or wax
3. Magnetic base
4. Spring-base mount
5. Hand-held probe

Drilling holes in the object can be avoided by using the second to fifth methods, but the useful range can decrease significantly when spring-base mounts or hand-held probes are used (giving a typical upper limit of 500 Hz). The first two methods usually maintain the full useful range, whereas the magnetic attachment method reduces the upper frequency limit to some extent (typically 1.5 kHz).

Piezoelectric signals cannot be read using low-impedance devices. The two primary reasons for this are:

1. High output impedance in the sensor results in small output signal levels and large loading errors.
2. The charge can quickly leak out through the load.

15.5.10.3 Charge Amplifier

The charge amplifier, which has a very high input impedance and a very low output impedance, is the commonly used signal-conditioning device for piezoelectric sensors. Clearly, the impedance at the charge amplifier output is much smaller than the output impedance of the piezoelectric sensor. These impedance characteristics of a charge amplifier virtually eliminate loading error. Also, by using a charge amplifier circuit with a large time constant, charge leakage speed can be decreased. For example, consider a piezoelectric sensor and charge amplifier combination, as represented by the circuit in Figure 15.32. Let us examine how the charge leakage rate is slowed down by using this arrangement. Sensor capacitance, feedback capacitance of the charge amplifier, and feedback resistance of the charge amplifier are denoted by C , C_f , and R_f , respectively. The capacitance of the cable that connects the sensor to the charge amplifier is denoted by C_c .

For an opamp of gain, K , the voltage at its negative input is $-v_o/K$, where v_o is the voltage at the amplifier output. Note that the positive input of the opamp is grounded (zero potential). Current balance

at point A gives

$$\dot{q} + C_c \frac{\dot{v}_o}{K} + C_f \left(\dot{v}_o + \frac{\dot{v}_o}{K} \right) + \frac{v_o + v_o/K}{R_f} = 0 \quad (15.57)$$

Since gain, K , is very large (typically 10^5 to 10^9) compared to unity, this differential equation may be approximated to

$$R_f C_f \frac{dv_o}{dt} + v_o = -R_f \frac{dq}{dt} \quad (15.58)$$

Alternatively, instead of using Equation 15.57 it is possible to directly obtain Equation 15.58 from the two common assumptions (equal inverting and noninverting lead potentials and zero lead currents) for an opamp. In accordance with these assumptions the potential at the negative (inverting) lead is zero, as the positive lead is grounded. Also, as a result, the voltage across C_c is zero. Hence, the current balance at point A gives

$$\dot{q} + \frac{v_o}{R_f} + C_f \dot{v}_o = 0$$

This is identical to Equation 15.58. The corresponding transfer function is

$$\frac{v_o(s)}{q(s)} = -\frac{R_f s}{[R_f C_f s + 1]} \quad (15.59)$$

where s is the Laplace variable. Now, in the frequency domain ($s = j\omega$), we have

$$\frac{v_o(j\omega)}{q(j\omega)} = -\frac{R_f j\omega}{[R_f C_f j\omega + 1]} \quad (15.60)$$

Note that the output is zero at zero frequency ($\omega = 0$). Hence, a piezoelectric sensor cannot be used for measuring constant (DC) signals. At very high frequencies, on the other hand, the transfer function approaches the constant value $-1/C_f$ which is the calibration constant for the device.

From Equation 15.58 or Equation 15.59, which represent a first-order system, it is clear that the time constant τ_c of the sensor-amplifier unit is

$$\tau_c = R_f C_f \quad (15.61)$$

Suppose that the charge amplifier is properly calibrated (by the factor $-1/C_f$) so that the frequency transfer function (Equation 15.60) can be written as

$$G(j\omega) = \frac{j\tau_c \omega}{[j\tau_c \omega + 1]} \quad (15.62)$$

Magnitude M of this transfer function is given by

$$M = \frac{\tau_c \omega}{\sqrt{\tau_c^2 \omega^2 + 1}} \quad (15.63)$$

As $\omega \rightarrow \infty$, note that $M \rightarrow 1$. Hence, at infinite frequency, there is no error. Measurement accuracy depends on the closeness of M to 1. Suppose that we want the accuracy to be better than a specified value M_0 . Accordingly, we must have

$$\frac{\tau_c \omega}{\sqrt{\tau_c^2 \omega^2 + 1}} > M_0 \quad (15.64)$$

FIGURE 15.32 A piezoelectric sensor and charge amplifier combination.

or

$$\tau_c \omega > \frac{M_0}{\sqrt{1 - M_0^2}} \quad (15.65)$$

If the required lower frequency limit is ω_{\min} , the time constant requirement is

$$\tau_c > \frac{M_0}{\omega_{\min} \sqrt{1 - M_0^2}} \quad (15.66)$$

or

$$R_f C_f > \frac{M_0}{\omega_{\min} \sqrt{1 - M_0^2}} \quad (15.67)$$

It follows that a specified lower limit on the frequency of operation, for a specified level of accuracy, may be achieved by increasing the charge-amplifier time constant (i.e., by increasing R_f , C_f , or both). For instance, an accuracy better than 99% is obtained if

$$\frac{\tau_c \omega}{\sqrt{\tau_c^2 \omega^2 + 1}} > 0.99; \quad \text{or} \quad \tau_c \omega > 7.0$$

The minimum frequency of a transient signal that can tolerate this level of accuracy is $\omega_{\min} = 7.0/\tau_c$. Now ω_{\min} can be set by adjusting the time constant.

15.6 Torque, Force, and Other Sensors

The forced vibrations in a mechanical system depend on the forces and torques (excitations) applied to the system. Also, the performance of the system may be specified in terms of forces and torques that are generated, as for machine-tool operations such as grinding, cutting, forging, extrusion, and rolling. Performance monitoring and evaluation, failure detection and diagnosis, and vibration testing may depend considerably on the accurate measurement of associated forces and torques. In mechanical applications such as parts assembly, slight errors in motion can generate large forces and torques. These observations highlight the importance of measuring forces and torques. The strain gage is a sensor that is commonly used in this context. There are numerous other types of sensors and transducers that are useful in the context of mechanical vibration. In this section, we will outline several of these sensors.

15.6.1 Strain Gage Sensors

Many types of force and torque sensors, as well as motion sensors such as accelerometers, are based on strain gage measurements. Hence, strain gages are very useful in vibration instrumentation. Although strain gages measure strain, the measurements can be directly related to stress and force. Note, however, that strain gages may be used in a somewhat indirect manner, using auxiliary front-end elements, to measure other types of variables, including displacement and acceleration.

15.6.1.1 Equations for Strain Gage Measurements

The change of electrical resistance in material when it is mechanically deformed is the property used in resistance-type strain gages. The resistance R of a conductor that has length ℓ and area of cross section A , is given by

$$R = \rho \frac{\ell}{A} \quad (15.68)$$

where ρ denotes the resistivity of the material. Taking the logarithm of Equation 15.68, we attain $\log R = \log \rho + \log(\ell/A)$. Now, taking the differential, we obtain

$$\frac{dR}{R} = \frac{d\rho}{\rho} + \frac{d(\ell/A)}{\ell/A} \quad (15.69)$$

The first term on the right-hand side of Equation 15.69 depends on the change in resistivity, and the second term represents deformation. It follows that the change in resistance comes from the change in shape as well as from the change in the resistivity of the material. For linear deformations, the two terms on the right-hand side of Equation 15.69 are linear functions of strain, ϵ ; the proportionality constant of the second term, in particular, depends on Poisson's ratio of the material. Hence, the following relationship can be written for a strain gage element:

$$\frac{\delta R}{R} = S_s \epsilon \quad (15.70)$$

The constant S_s is known as the *sensitivity* or *gage factor* of the strain gage element. The numerical value of this constant ranges from 2 to 6 for most *metallic strain gage* elements and from 40 to 200 for *SC strain gages*. These two types of strain gage will be discussed later. The change in resistance of a strain gage element, which determines the associated strain (Equation 15.70), is measured using a suitable electrical circuit.

Resistance strain gages are based on resistance change due to strain, or the *piezoresistive* property of materials. Early strain gages were fine metal filaments. Modern strain gages are manufactured primarily as metallic foil (for example, using the copper–nickel alloy known as constantan) or SC elements (e.g., silicon with trace impurity boron). They are manufactured by first forming a thin film (foil) of metal or a single crystal of SC material and then cutting it into a suitable grid pattern, either mechanically or by using photoetching (chemical) techniques. This process is much more economical and is more precise than making strain gages with metal filaments. The strain gage element is formed on a backing film of electrically insulated material (e.g., plastic). This element is cemented onto the member whose strain is to be measured. Alternatively, a thin film of insulating ceramic substrate is melted onto the measurement surface, on which the strain gage is mounted directly. The direction of sensitivity is the major direction of elongation of the strain gage element (Figure 15.33(a)). To measure strains in more than one direction, multiple strain gages (e.g., various rosette configurations) are available as single units. These units have more than one direction of sensitivity. Principal strains in a given plane (the surface of the object on which the strain gage is mounted) can be determined by using these multiple strain gage units. Typical foil-type strain gages produce a relatively large output signal. A large accelerometer mass results in several disadvantages, however. In particular:

1. The accelerometer mass distorts the measured motion variable (mechanical loading effect).
2. A heavier accelerometer has a lower resonant frequency and, hence, a lower useful frequency range (Figure 15.31).

A direct way to obtain strain gage measurement is to apply a constant DC voltage across a series-connected strain gage element and a suitable resistor, and to measure the output voltage v_o across the strain gage under open-circuit conditions using a voltmeter with high input impedance. It is known as a *potentiometer circuit* or *ballast circuit* (see Figure 15.34(a)). This arrangement has several weaknesses. Any ambient temperature variation will directly introduce some error because of associated change in the strain gage resistance and the resistance of the connecting circuitry. Also, measurement accuracy will be affected by possible variations in the supply voltage v_{ref} . Furthermore, the electrical loading error will be significant unless the load impedance is very high. Perhaps, the most serious disadvantage of this circuit is that the change in signal due to strain is usually a very small percentage of the total signal level in the circuit output.

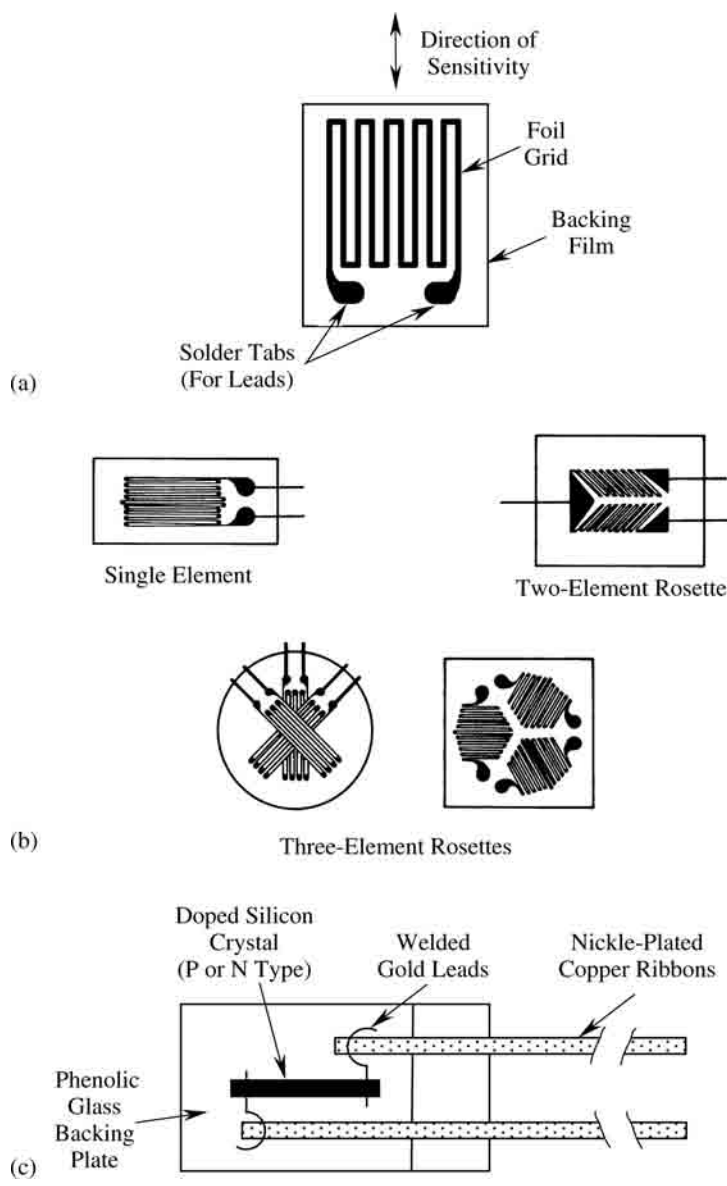

FIGURE 15.33 (a) Strain gage nomenclature; (b) typical foil-type strain gages; (c) a SC strain gage.

A more favorable circuit for use in strain gage measurements is the *Wheatstone bridge*, shown in Figure 15.34(b). One or more of the four resistors R_1 , R_2 , R_3 , and R_4 in the circuit may represent strain gages. To obtain the output relationship for the Wheatstone bridge circuit, assume that the load impedance R_L is very high. Hence, the load current, i , is negligibly small. Then, the potentials at nodes A and B are

$$v_A = \frac{R_1}{(R_1 + R_2)} v_{\text{ref}} \quad \text{and} \quad v_B = \frac{R_3}{(R_3 + R_4)} v_{\text{ref}}$$

and the output voltage $v_o = v_A - v_B$ is given by

$$v_o = \left[\frac{R_1}{(R_1 + R_2)} - \frac{R_3}{(R_3 + R_4)} \right] v_{\text{ref}} \tag{15.71}$$

By using straightforward algebra, we obtain

$$v_o = \frac{(R_1 R_4 - R_2 R_3)}{(R_1 + R_2)(R_3 + R_4)} v_{\text{ref}} \quad (15.72)$$

When this output voltage is zero, the bridge is said to be “balanced.” It follows from Equation 15.72 that, for a balanced bridge

$$\frac{R_1}{R_2} = \frac{R_3}{R_4} \quad (15.73)$$

Note that Equation 15.73 is valid for any value of R_L , not just for large R_L , because when the bridge is balanced, current i will be zero, even for small R_L .

15.6.1.2 Bridge Sensitivity

Strain gage measurements are calibrated with respect to a balanced bridge. When the strain gages in the bridge deform, the balance is upset. If one of the arms of the bridge has a variable resistor, it can be changed to restore the balance. The amount of this change corresponds to the amount by which the resistance of the strain gages changed, thereby measuring the applied strain. This is known as the *null-balance method* of strain measurement. This method is inherently slow because of the time required to balance the bridge each time a reading is taken. Hence, the null-balance method is generally not suitable for dynamic (time-varying) measurements. This approach to strain measurement can be sped up by using servo balancing, whereby the output error signal is fed back into an actuator that automatically adjusts the variable resistance so as to restore the balance.

A more common method, which is particularly suitable for making dynamic readings from a strain gage bridge, is to measure the output voltage resulting from the imbalance caused by the deformation of active strain gages in the bridge. To determine the *calibration constant* of a strain gage bridge, the sensitivity of the bridge output to changes in the four resistors in the bridge should be known. For small changes in resistance, this may be determined using the differential relation (or, equivalently, the first-order approximation for the Taylor series expansion):

$$\delta v_o = \sum_{i=1}^4 \frac{\partial v_o}{\partial R_i} \delta R_i \quad (15.74)$$

The partial derivatives are obtained directly from Equation 15.71. Specifically,

$$\frac{\partial v_o}{\partial R_1} = \frac{R_2}{(R_1 + R_2)^2} v_{\text{ref}} \quad (15.75)$$

$$\frac{\partial v_o}{\partial R_2} = \frac{R_1}{(R_1 + R_2)^2} v_{\text{ref}} \quad (15.76)$$

$$\frac{\partial v_o}{\partial R_3} = \frac{R_4}{(R_1 + R_4)^2} v_{\text{ref}} \quad (15.77)$$

FIGURE 15.34 (a) A potentiometer circuit (ballast circuit) for strain gage measurements; (b) a Wheatstone bridge circuit for strain gage measurements.

$$\frac{\partial v_o}{\partial R_4} = \frac{R_3}{(R_3 + R_4)^2} v_{\text{ref}} \quad (15.78)$$

The required relationship is obtained by substituting the equations from Equation 15.75 to Equation 15.78 into Equation 15.74; thus

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{(R_2 \delta R_1 - R_1 \delta R_2)}{(R_1 + R_2)^2} - \frac{(R_4 \delta R_3 - R_3 \delta R_4)}{(R_3 + R_4)^2} \quad (15.79)$$

This result is subject to Equation 15.73, because changes are measured from the balanced condition. Note that, from Equation 15.79, if all four resistors are identical (in value and material), resistance changes due to ambient effects cancel out among the first-order terms ($\delta R_1, \delta R_2, \delta R_3, \delta R_4$), producing no net effect on the output voltage from the bridge. Closer examination of Equation 15.79 will reveal that only the adjacent pairs of resistors (e.g., R_1 with R_2 and R_3 with R_4) have to be identical in order to achieve this environmental compensation. Even this requirement can be relaxed. Compensation is achieved if R_1 and R_2 have the same temperature coefficient and if R_3 and R_4 have the same temperature coefficient.

15.6.1.3 The Bridge Constant

Numerous activating combinations of strain gages are possible in a bridge circuit. For example, there might be tension in R_1 and compression in R_2 , as in the case of two strain gages mounted symmetrically at 45° about the axis of a shaft in torsion. In this manner, the overall sensitivity of a strain gage bridge can be increased. It is clear from Equation 15.79 that, if all four resistors in the bridge are active, the best sensitivity is obtained if all four differential terms have the same sign, for example, when R_1 and R_4 are in tension and R_2 and R_3 are in compression. If more than one strain gage is active, the bridge output may be expressed as

$$\frac{\delta v_o}{v_{\text{ref}}} = k \frac{\delta R}{4R} \quad (15.80)$$

where

$$k = \frac{\text{bridge output in the general case}}{\text{bridge output if only one strain gage is active}}$$

This constant is known as the *bridge constant*. The larger the bridge constant is, the better the sensitivity of the bridge.

Example 15.4

A strain gage load cell (force sensor) consists of four identical strain gages, which form a Wheatstone bridge and are mounted on a rod that has a square cross section. One opposite pair of strain gages is mounted axially and the other pair is mounted in the transverse direction, as shown in Figure 15.35(a). To maximize the bridge sensitivity, the strain gages are connected to the bridge as shown in Figure 15.35(b). Determine the bridge constant k in terms of *Poisson's ratio* ν of the rod material.

FIGURE 15.35 A strain-gage force sensor: (a) mounting configuration; (b) bridge circuit.

Solution

Suppose that $\delta R_1 = \delta R$. Then, for the given configuration, we have

$$\delta R_2 = -\nu \delta R$$

$$\delta R_3 = -\nu \delta R$$

$$\delta R_4 = \delta R$$

Note that, from the definition of Poisson's ratio, transverse strain $= (-\nu) \times$ longitudinal strain. Now, it follows from Equation 15.79 that

$$\frac{\delta v_o}{v_{\text{ref}}} = 2(1 + \nu) \frac{\delta R}{4R} \quad (15.81)$$

according to which the bridge constant is given by

$$k = 2(1 + \nu)$$

15.6.1.4 The Calibration Constant

The calibration constant, C , of a strain gage bridge relates the strain that is measured to the output of the bridge. Specifically,

$$\frac{\delta v_o}{v_{\text{ref}}} = C\varepsilon \quad (15.82)$$

Now, in view of Equation 15.70 and Equation 15.80, the calibration constant may be expressed as

$$C = \frac{k}{4} S_s \quad (15.83)$$

where k is the *bridge constant* and S_s is the *sensitivity* or *gage factor* of the strain gage. Ideally, the calibration constant should remain constant over the measurement range of the bridge (i.e., independent of strain ε and time t) and should be stable with respect to ambient conditions. In particular, there should not be any creep, non-linearities such as hysteresis, or thermal effects.

Example 15.5

A schematic diagram of a strain gage accelerometer is shown in Figure 15.36(a). A point mass of weight W is used as the acceleration sensing element, and a light cantilever with a rectangular cross section, which is mounted inside the accelerometer casing, converts the inertia force of the mass into a strain. The maximum bending strain at the root of the cantilever is measured using four identical active SC strain gages. Two of the strain gages (A and B) are mounted axially on the top surface of the cantilever, and the remaining two (C and D) are mounted on the bottom surface, as shown in Figure 15.36(b). In order to maximize the sensitivity of the accelerometer, indicate the

FIGURE 15.36 A strain gage accelerometer: (a) schematic diagram; (b) strain gage mounting configuration; (c) bridge connections.

manner in which the four strain gages (A, B, C, and D) should be connected to a Wheatstone bridge circuit. What is the bridge constant of the resulting circuit?

Obtain an expression relating the applied acceleration a (in units of g , which denotes acceleration due to gravity) to the bridge output δv_o (measured using a bridge balanced at zero acceleration) in terms of the following parameters:

W = weight of the seismic mass at the free end of the cantilever element

E = Young's modulus of the cantilever

ℓ = length of the cantilever

b = cross-sectional width of the cantilever

h = cross-sectional height of the cantilever

S_s = sensitivity (gage factor) of each strain gage

v_{ref} = supply voltage to the bridge

If $W = 0.02$ lb, $E = 10 \times 10^6$ lbf/in.², $\ell = 1$ in., $b = 0.1$ in., $h = 0.05$ in., $S_s = 200$, and $v_{\text{ref}} = 20$ V, determine the sensitivity of the accelerometer in mV/ g .

If the yield strength of the cantilever element is 10×10^3 lbf/in.², what is the maximum acceleration that could be measured using the accelerometer?

Is the cross-sensitivity (i.e., the sensitivity in the two directions orthogonal to the direction of sensitivity shown in Figure 15.36(a)) small given your arrangement of the strain gage bridge? Explain.

Note: For a cantilever subjected to force F at the free end, the maximum stress at the root is given by

$$\sigma = \frac{6F\ell}{bh^2} \quad (15.84)$$

with the present notation.

Solution

The bridge sensitivity is maximized by connecting the strain gages A, B, C, and D to the bridge as shown in Figure 15.36(c). This follows from Equation 15.79, noting that the contributions from all four strain gages are positive when δR_1 and δR_4 are positive and δR_2 and δR_3 are negative. The bridge constant for the resulting arrangement is $k = 4$. Hence, from Equation 15.80, we have

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{\delta R}{R}$$

or, from Equation 15.82 and Equation 15.83

$$\frac{\delta v_o}{v_{\text{ref}}} = S_s \varepsilon$$

Also,

$$\varepsilon = \frac{\sigma}{E} = \frac{6F\ell}{Eb h^2}$$

where F denotes the inertia force

$$F = \frac{W}{g} \ddot{x} = Wa$$

Note that \ddot{x} is the acceleration in the direction of sensitivity and $\ddot{x}/g = a$ is the acceleration in units of g . Thus,

$$\varepsilon = \frac{6W\ell}{Eb h^2} a \quad (15.85)$$

or

$$\delta v_o = \frac{6W\ell}{Ebh^2} S_s v_{\text{ref}} a \quad (15.86)$$

Now, with the given values

$$\begin{aligned} \frac{\delta v_o}{a} &= \frac{6 \times 0.02 \times 1 \times 200 \times 20}{10 \times 10^6 \times 0.1 \times (0.05)^2} \text{ V/g} = 0.192 \text{ V/g} = 192 \text{ mV/g} \\ \frac{\varepsilon}{a} &= \frac{1}{S_s v_{\text{ref}}} \frac{\delta v_o}{a} = \frac{0.192}{200 \times 20} \text{ strain/g} \\ \text{yield strain} &= \frac{\text{yield strength}}{E} = \frac{10 \times 10^3}{10 \times 10^6} = 1 \times 10^{-3} \text{ strain} \end{aligned}$$

Hence,

$$\text{number of gs to yielding} = \frac{1 \times 10^{-3}}{48 \times 10^{-6}} g = 20.8g$$

Cross-sensitivity comes from accelerations in the two directions (y and z) orthogonal to the direction of sensitivity (x). In the lateral (y) direction, the inertia force causes lateral bending. This will produce equal tensile (or compressive) strains in B and D , and equal compressive (or tensile) strains in A and C . According to the bridge circuit, we see that these contributions cancel each other. In the axial (z) direction, the inertia force causes equal tensile (or compressive) stresses in all four strain gages. These also will cancel out, as is clear from the following relationship for the bridge:

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{(R_C \delta R_A - R_A \delta R_C)}{(R_A + R_C)^2} - \frac{(R_B \delta R_D - R_D \delta R_B)}{(R_D + R_B)^2} \quad (15.87)$$

with

$$R_A = R_B = R_C = R_D = R$$

which gives

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{(\delta R_A - \delta R_C - \delta R_D + \delta R_B)}{4R} \quad (15.88)$$

It follows that this arrangement is good with respect to cross-sensitivity problems.

15.6.1.5 Data Acquisition

As noted earlier, the two common methods of measuring strains using a Wheatstone bridge circuit are (1) the null-balance method and (2) the imbalance output method. One possible scheme for using the first method is shown in [Figure 15.37\(a\)](#). In this particular arrangement, two bridge circuits are used. The *active bridge* contains the active strain gages, dummy gages, and bridge-completion resistors. The *reference bridge* has four resistors, one of which is micro-adjustable, either manually or automatically. The output from the each of the two bridges is fed into a difference amplifier, which provides an amplified difference of the two signals. This error signal is indicated on a null detector, such as a galvanometer. Initially, both bridges are balanced. When the measurement system is in use, the active gages are subjected to the strain that is being measured. This upsets the balance, giving a net output that is indicated on the null detector. In manual operation of the null-balance mechanism, the resistance knob in the reference bridge is adjusted carefully until the galvanometer indicates a null reading. The knob can be calibrated to indicate the measured strain directly. In servo operation, which is much faster than the manual method, the error signal is fed into an actuator that automatically adjusts the variable resistor in the reference bridge until the null balance is achieved. Actuator movement measures the strain.

For measuring dynamic strains in vibrating systems, either the servo null-balance method or the imbalance output method should be employed. A schematic diagram for the imbalance output method is

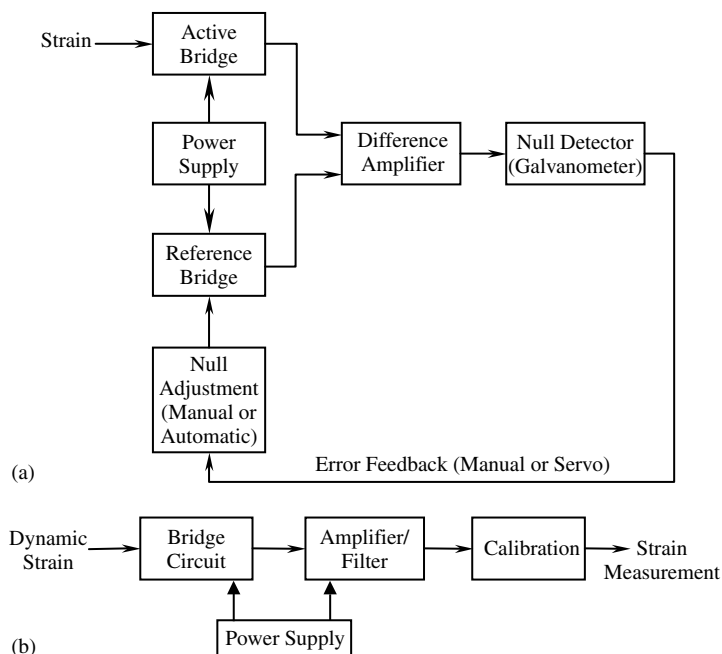

FIGURE 15.37 Strain gage bridge measurement: (a) null-balance method; (b) imbalance output method.

shown in Figure 15.37(b). In this method, the output from the active bridge is directly measured as a voltage signal and calibrated to provide the measured strain. An AC bridge may be used, where the bridge is powered by an AC voltage. The supply frequency should be about ten times the maximum frequency of interest in the dynamic strain signal (bandwidth). A supply frequency on the order of 1 kHz is typical. This signal is generated by an oscillator and is fed into the bridge. The transient component of the output from the bridge is very small (typically less than 1 mV and sometimes a few microvolts). This signal must be amplified, demodulated (especially if the signals are transient), and filtered to provide the strain reading. The calibration constant of the bridge should be known in order to convert the output voltage to strain.

Strain gage bridges powered by DC voltages are very common. They have the advantages of portability and simplicity with regard to necessary circuitry. The advantages of AC bridges include improved stability (reduced drift), improved accuracy, and reduced power consumption.

15.6.1.6 Accuracy Considerations

Foil gages are available with resistances as low as 50 Ω and as high as several kilohms. The power consumption of the bridge decreases with increased resistance. This has the added advantage of decreased heat generation. Bridges with a high range of measurement (e.g., a maximum strain of 0.01 m/m) are available. The accuracy depends on the linearity of the bridge, environmental (particularly temperature) effects, and mounting techniques. For example, a calibration error occurs in the case of zero shift, due to the strains produced when the cement that is used to mount the strain gage dries. Creep will introduce errors during static and low-frequency measurements. Flexibility and hysteresis of the bonding cement will bring about errors during high-frequency strain measurements. Resolutions on the order of 1 $\mu\text{m/m}$ (i.e., one *microstrain*) are common. The cross-sensitivity should be small (say, less than 1% of the direct sensitivity). Manufacturers usually provide the values of the cross-sensitivity factors for their strain gages. This factor, when multiplied by the cross strain present in a given application, gives the error in the strain reading due to cross-sensitivity.

Often, measurements of strains in moving members are needed, for example, in real-time monitoring and failure detection in machine tools. If the motion is small or the device has a limited stroke, strain gages mounted on the moving member can be connected to the signal-conditioning circuitry and the power source using coiled flexible cables. For large motions, particularly in rotating shafts, some form of commutating arrangement must be used. Slip rings and brushes are commonly used for this purpose. When AC bridges are used, a mutual-induction device (rotary transformer) can be used, with one coil located on the moving member and the other coil stationary. To accommodate and compensate for errors caused by commutation (e.g., losses and glitches in the output signal), it is desirable to place all four arms of the bridge, rather than just the active arms, on the moving member.

15.6.1.7 Semiconductor Strain Gages

In some low-strain applications (e.g., dynamic torque measurement), the sensitivity of foil gages is not adequate to produce an acceptable strain gage signal. SC strain gages are particularly useful in such situations. The strain element of a SC strain gage is made of a single crystal of *piezoresistive* material such as silicon, doped with a trace impurity such as boron. A typical construction is shown in Figure 15.38. The sensitivity (gage factor) of a SC strain gage is about two orders of magnitude higher than that of a metallic foil gage (typically, 40 to 200). The resistivity is also higher, providing reduced power consumption and heat generation. Another advantage of SC strain gages is that they deform elastically until fracture. In particular, mechanical hysteresis is negligible. Furthermore, they are smaller and lighter, providing less cross-sensitivity, reduced distribution error (i.e., improved spatial resolution), and negligible error due to mechanical loading. The maximum strain that is measurable using a SC strain gage is typically 0.003 m/m (i.e., 3000 $\mu\epsilon$). Strain gage resistance can be several hundred ohms (typically, 120 Ω or 350 Ω).

FIGURE 15.38 Details of a semiconductor strain gage.

There are several disadvantages associated with SC strain gages, however, which can be interpreted as advantages of foil gages. Undesirable characteristics of SC gages include the following:

1. The strain–resistance relationship is more nonlinear.
2. They are brittle and difficult to mount on curved surfaces.
3. The maximum strain that can be measured is an order of magnitude smaller (typically, less than 0.01 m/m).
4. They are more costly.
5. They have a much higher temperature sensitivity.

The first disadvantage is illustrated in Figure 15.39. There are two types of SC strain gages: the P-type and the N-type. In P-type strain gages, the direction of sensitivity is along the (1, 1, 1) crystal axis, and the element produces a “positive” (P) change in resistance in response to a positive strain. In N-type strain gages, the direction of sensitivity is along the (1, 0, 0) crystal axis, and the element responds with a “negative” (N) change in resistance to a positive strain. In both types, the response is nonlinear and can be approximated by the quadratic relationship

$$\frac{\delta R}{R} = S_1 \epsilon + S_2 \epsilon^2 \quad (15.89)$$

The parameter S_1 represents the *linear sensitivity*, which is positive for P-type gages and negative for N-type gages. Its magnitude is usually somewhat larger for P-type gages, thereby providing

better sensitivity. The parameter S_2 represents the degree of nonlinearity, which is usually positive for both types of gage. Its magnitude, however, is typically a little smaller for P-type gages. It follows that P-type gages are less nonlinear and have higher strain sensitivities. The nonlinear relationship given by Equation 15.89 or the nonlinear characteristic curve (Figure 15.39) should be used when measuring moderate to large strains with SC strain gages. Otherwise, the nonlinearity error will be excessive.

15.6.1.8 Force and Torque Sensors

Torque and force sensing is useful in vibration applications, including the following:

1. In vibration control of machinery where a small motion error can cause large damaging forces or performance degradation.
2. In high-speed vibration control when motion feedback alone is not fast enough (here, force feedback and feedforward force control can be used to improve the accuracy and bandwidth).
3. In vibration testing, monitoring, and diagnostic applications, where torque and force sensing can detect, predict, and identify abnormal operation, malfunction, component failure, or excessive wear (e.g., in monitoring machine tools such as milling machines and drills).
4. In experimental modal analysis where both excitation forces and response motioning may be needed to experimentally determine the system model.

In most applications, torque (or force) is sensed by detecting either an effect or the cause of torque (or force). There are also methods for measuring torque (or force) directly. Common methods of torque sensing include the following:

1. Measuring the strain in a sensing member between the drive element and the driven load, using a strain gage bridge.
2. Measuring the displacement in a sensing member (as in the first method), either directly, using a displacement sensor, or indirectly, by measuring a variable, such as magnetic inductance or capacitance, that varies with displacement.
3. Measuring the reaction in the support structure or housing (by measuring a force) and the associated lever arm length.
4. In electric motors, measuring the field or armature current that produces motor torque; in hydraulic or pneumatic actuators, measuring the actuator pressure.
5. Measuring the torque directly, for example, using piezoelectric sensors.
6. Employing the servo method to balance the unknown torque with a feedback torque generated by an active device (say, a servomotor) whose torque characteristics are known precisely.
7. Measuring the angular acceleration in a known inertia element when the unknown torque is applied.

FIGURE 15.39 Nonlinear behavior of a semiconductor (silicon/boron) strain gage: (a) a P-type gage; (b) an N-type gage.

Note that force sensing may be accomplished by essentially the same techniques. Some types of force sensor (e.g., the strain gage force sensor) have been introduced before. Now, we will limit our discussion primarily to torque sensing. The extension of torque-sensing techniques to the task of force sensing is somewhat straightforward.

15.6.1.9 Strain Gage Torque Sensors

The most straightforward method of torque sensing is to connect a torsion member between the drive unit and the load-in series, and to measure the torque in the torsion member. If a circular shaft (solid or hollow) is used as the torsion member, the torque–strain relationship is relatively simple. A complete development of the relationship is found in standard textbooks on elasticity, solid mechanics, or strength of materials. With reference to Figure 15.40, it can be shown that the torque, T , may be expressed in terms of the direct strain, ϵ , on the shaft surface along a principal stress direction (i.e., at 45° to the shaft axis) as

$$T = \frac{2GJ}{r} \epsilon \quad (15.90)$$

where G = shear modulus of the shaft material, J = polar moment of area of the shaft, and r = shaft radius (outer). This is the basis of torque sensing using strain measurements.

Using the general bridge Equation 15.82 along with Equation 15.83 in Equation 15.90, we can obtain torque, T , from bridge output, δv_o :

$$T = \frac{8GJ}{kS_s r} \frac{\delta v_o}{v_{ref}} \quad (15.91)$$

where S_s is the gage factor (or sensitivity) of the strain gages. The bridge constant, k , depends on the number of active strain gages used. Strain gages are assumed to be mounted along a principal direction.

FIGURE 15.40 (a) Linear distribution of shear stress in a circular shaft under pure torsion; (b) pure shear state of stress and principal directions x and y ; (c) Mohr's circle.

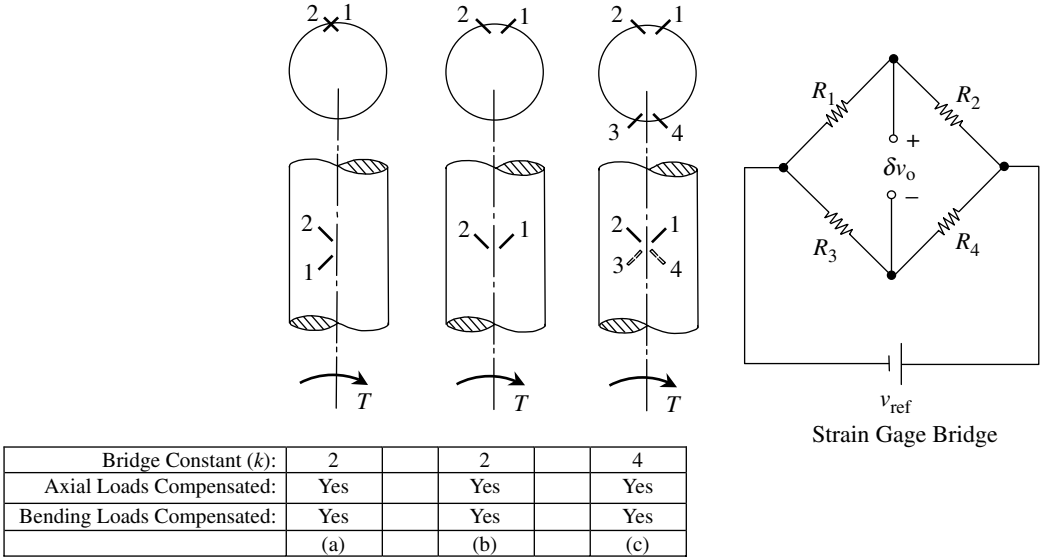

FIGURE 15.41 Strain gage configurations for a circular shaft torque sensor.

Three possible configurations are shown in Figure 15.41. In configurations (a) and (b), only two strain gages are used, and the bridge constant, k , is equal to 2. Note that both axial loads and bending are compensated with the given configurations because resistance in both gages will be changed by the same amount (the same sign and same magnitude) that cancels out, up to first order, for the bridge circuit connection shown in Figure 15.41. Configuration (c) has two pairs of gages, mounted on the two opposite surfaces of the shaft. The bridge constant is doubled in this configuration, and here again, the sensor clearly selfcompensates for axial and bending loads up to first order [$O(\delta R)$].

For a circular-shaft torque sensor that uses SC strain gages, design criteria for obtaining a suitable value for the polar moment of area (J) are listed in Table 15.3. Note that ϕ is a safety factor.

Although the manner in which strain gages are configured on a torque sensor can be exploited to compensate for cross-sensitivity effects arising from factors such as tensile and bending loads, it is advisable to use a torque-sensing element that inherently possesses low sensitivity to these factors that cause error in a torque measurement. A tubular torsion element is convenient for analytical purposes because of the simplicity of the associated expressions for design parameters. Unfortunately, such an

TABLE 15.3 Design Criteria for a Strain Gage Torque-Sensing Element

Criterion	Specification	Governing Formula for the Polar Moment of Area (J)
Strain capacity of strain gage element	ϵ_{\max}	$\geq \frac{\phi r}{2G} \frac{T_{\max}}{\epsilon_{\max}}$
Strain gage nonlinearity	$N_p = \frac{\text{Max strain error}}{\text{Strain range}} \times 100\%$	$\geq \frac{25\phi r S_2}{G S_1} \frac{T_{\max}}{N_p}$
Sensor sensitivity (output voltage)	$v_o = K_a \delta v_o$ where K_a = transducer gain	$\leq \frac{K_a k S_s r v_{\text{ref}}}{8G} \frac{T_{\max}}{v_o}$
Sensor stiffness (system bandwidth and gain)	$K = \frac{\text{Torque}}{\text{Twist angle}}$	$\geq \frac{L}{G} K$

element is not very rigid to bending and tensile loading. Alternative shapes and structural arrangements have to be considered if inherent rigidity (insensitivity) to cross-loads is needed. Furthermore, a tubular element has the same strain at all locations on the element surface. This does not provide a choice with respect to mounting locations of strain gages in order to maximize the torque sensor sensitivity. Another disadvantage of the basic tubular element is that the surface is curved; therefore, much care is needed in mounting fragile SC gages, which could be easily damaged by even slight bending. Hence, a sensor element that has flat surfaces to mount the strain gages would be desirable. A torque-sensing element that has the aforementioned desirable characteristics (i.e., inherent insensitivity to cross-loading, nonuniform strain distribution on the surface, and the availability of flat surfaces to mount strain gages) is shown in Figure 15.42. Note that two sensing elements are connected radially between the drive unit and the driven member. The sensing elements undergo bending while transmitting a torque between the driver and the driven member. Bending strains are measured at locations of high sensitivity and are taken to be proportional to the transmitted torque. Analytical determination of the calibration constant is not easy for such complex sensing elements, but experimental determination is straightforward. Note that the strain gage torque sensor measures the direction as well as the magnitude of the torque transmitted through it.

15.6.1.10 Deflection Torque Sensors

Instead of measuring strain in the sensor element, the actual deflection (twisting or bending) can be measured and used to determine torque, through a suitable calibration constant. For a circular-shaft (solid or hollow) torsion element, the governing relationship is given by

$$T = \frac{GJ}{L} \theta \quad (15.92)$$

The calibration constant GJ/L must be small in order to achieve high sensitivity. This means that the element stiffness should be low. This will limit the bandwidth (which measures speed of response) and gain (which determines steady-state error) of the overall system. The twist angle, θ , is very small (e.g., a fraction of a degree) in systems with high bandwidth. This requires very accurate measurement of θ in order to determine the torque T . A type of displacement sensor that could be used is described as follows. Two ferromagnetic gear wheels are splined at two axial locations of the torsion element. Two stationary proximity probes of the magnetic induction type (selfinduction or mutual induction) are placed radially, facing the gear teeth, at the two locations. As the shaft rotates, the gear teeth change the flux linkage of the proximity sensor coils. The resulting output signals of the two probes are pulse sequences, shaped somewhat like sine waves. The phase shift of one signal with respect to the other determines the relative angular deflection of one gear wheel with respect to the other, assuming that the two probes are synchronized under no-torque conditions. Both the magnitude and the direction of the transmitted torque are determined using this method. A 360° phase shift corresponds to a relative deflection by an integer multiple of the gear pitch. It follows that deflections less than half the pitch can be measured

FIGURE 15.42 Use of a bending element in torque sensing: (a) sensing element; (b) element configuration.

without ambiguity. Assuming that the output signals of the two probes are sine waves (narrow-band filtering can be used to achieve this), the phase shift will be proportional to the angle of twist, θ .

15.6.1.11 Variable-Reluctance Torque Sensor

A torque sensor that is based on the sensor element deformation and that does not require a contacting commutator is a variable-reluctance device that operates like a differential transformer (RVDT or LVDT). The torque-sensing element is a ferromagnetic tube that has two sets of slits, typically oriented along the two principal stress directions of the tube (45°) under torsion. When a torque is applied to the torsion element, one set of gaps closes and the other set opens as a result of the principal stresses normal to the slit axes. Primary and secondary coils are placed around the slitted tube, and they remain stationary. One segment of the secondary coil is placed around one set of slits, and the second segment is placed around the other, perpendicular, set. The primary coil is excited by an AC supply, and the induced voltage, v_o , in the secondary coil is measured. As the tube deforms, it changes the magnetic reluctance in the flux linkage path, thus changing the induced voltage. The two segments of the secondary coil should be connected so that the induced voltages are absolutely additive (algebraically subtractive), because one voltage increases and the other decreases, to obtain the best sensitivity. The output signal should be demodulated, by removing the carrier frequency component, to measure transient torques effectively. Note that the direction of torque is given by the sign of the demodulated signal.

15.6.1.12 Reaction Torque Sensors

The foregoing methods of torque sensing use a sensing element that is connected between the drive member and the driven member. A major drawback of such an arrangement is that the sensing element modifies the original system in an undesirable manner, particularly by decreasing the system stiffness and adding inertia. Not only will the overall bandwidth of the system decrease, but the original torque will also be changed (mechanical loading) because of the inclusion of an auxiliary sensing element. Furthermore, under dynamic conditions, the sensing element will be in motion, thereby making the torque measurement more difficult. The reaction method of torque sensing eliminates these problems to a large degree. This method can be used to measure torque in a rotating machine. The supporting structure (or housing) of the rotating machine (e.g., a motor, pump, compressor, turbine, or generator) is cradled by releasing its fixtures, and the effort necessary to keep the structure from moving is measured. A schematic representation of the method is shown in [Figure 15.43\(a\)](#). Ideally, a lever arm is mounted on the cradled housing, and the force required to fix the housing is measured using a force sensor (load cell). The reaction torque on the housing is given by

$$T_R = F_R \cdot L \quad (15.93)$$

where

F_R = reaction force measured using load cell

L = lever arm length

Alternatively, strain gages or other types of force sensors could be mounted directly at the fixture locations (e.g., at the mounting bolts) of the housing to measure the reaction forces without cradling the housing. Then, the reaction torque is determined with a knowledge of the distance of the fixture locations from the shaft axis.

The reaction-torque method of torque sensing is widely used in dynamometers (reaction dynamometers) that determine the transmitted power in rotating machinery through torque and shaft speed measurements. A drawback of reaction-type torque sensors can be explained using [Figure 15.43\(b\)](#). A motor with rotor inertia, J , which rotates at angular acceleration, $\ddot{\theta}$, is shown. By Newton's Third Law (action equals reaction), the electromagnetic torque generated at the rotor of the motor, T_m , and the frictional torques, T_{f1} and T_{f2} , will be reacted back onto the stator and housing. By applying

FIGURE 15.43 (a) Schematic representation of a reaction torque sensor setup (reaction dynamometer); (b) various torque components.

Newton's Second Law to the motor rotor and the housing combination, we obtain

$$T_L = T_R - J\ddot{\theta} \quad (15.94)$$

Note that T_L is the variable which must be measured. Under accelerating or decelerating conditions, the reaction torque, T_R , is not equal to the actual torque, T_L , that is transmitted. One method of compensating for this error is to measure the shaft acceleration, compute the inertia torque, and adjust the measured reaction torque using this inertia torque. Note that the frictional torque in the bearings does not enter the final Equation 15.94. This is an advantage of this method.

15.6.2 Miscellaneous Sensors

Motion and force/torque sensors of the types described thus far are widely used in vibration instrumentation. Several other types of sensors are also useful. A few of them are indicated now.

15.6.2.1 Stroboscope

Consider an object that executes periodic motions such as vibrations or rotations in a fairly dark environment. Suppose that a light is flashed at the object at the same frequency as the moving object. Since the object completes a full cycle of motion during the time period between two adjacent flashes,

the object will appear to be stationary. This is the principle of operation of a stroboscope. The main components of a stroboscope are a high-intensity strobe lamp and circuitry to vary the frequency of the electrical pulse signal that energizes the lamp. The flashing frequency may be varied either manually using a knob or according to the frequency of an external periodic signal (trigger signal) that is applied to the stroboscope.

It is clear that by synchronizing the stroboscope with a moving (vibrating, rotating) object so that the object appears stationary, and then noting the flashing (strobe) frequency, the frequency of vibration or speed of rotation of the object can be measured. In this sense, the stroboscope is a noncontacting vibration frequency sensor or a tachometer (rotating speed sensor). Note that the object appears stationary for any integer multiple of the synchronous flashing frequency. Hence, once the strobe is synchronized with the moving object, it is good practice to check whether the strobe also synchronizes at an integer fraction of that flashing frequency. (Typically, trying $1/2$, $1/3$, $1/5$, and $1/7$ the original synchronous frequency is adequate.) The lowest synchronous frequency thus obtained is the correct speed (frequency) of the object. Since the frequency of visual persistence of a human is about 15 Hz, the stationary appearance will not be possible using a stroboscope below this frequency. Hence, the low-frequency limit for a stroboscope is about 15 Hz.

In addition to serving as a sensor for vibration frequency and rotating speed, the stroboscope has many other applications. For example, by maintaining the strobe (flashing) frequency close (but not equal) to the object frequency, the object will appear to move very slowly. In this manner, visual inspection of objects that execute periodic motions at high speed is possible. Also, stroboscopes are widely used in dynamic balancing of rotating machinery. In this case, it is important to measure the phase angle of the resultant imbalance force with respect to a coordinate axis (direction) that is fixed to the rotor. Suppose that a radial line is marked on the rotor. If we synchronize a stroboscope with the rotor such that the marked line appears not only stationary but also oriented in a fixed direction (e.g., horizontal or vertical), we in effect make the strobe signal in phase with the rotation of the rotor. Then by comparing the imbalance force signal of the rotor (obtained, for example, by an accelerometer or a force sensor at the bearings of the rotor) with the synchronized strobe signal (with a fixed reference), by means of an oscilloscope or a phase meter, it is possible to determine the orientation of the imbalance force with respect to a fixed body reference of the rotating machine.

15.6.2.2 Fiber Optic Sensors and Lasers

The characteristic component in a fiber optic sensor is a bundle of glass fibers (typically a few hundred) that can carry light. Each optical fiber may have a diameter on the order of 0.01 mm. There are two basic types of fiber optic sensors. In one type, the “indirect” or the *extrinsic* type, the optical fiber acts only as the medium in which the sensed light is transmitted. In this type, the sensing element itself does not consist of optical fibers. In the second type, the “direct” or the *intrinsic* type, the optical fiber bundle itself acts as the sensing element. When the conditions of the sensed medium change, the light-propagation properties of the optical fibers change, providing a measurement of the change in the conditions. Examples of the first (extrinsic) type of sensor include fiber optic position sensors and tactile (distributed touch) sensors. The second (intrinsic) type of sensor is found, for example, in fiber optic gyroscopes, fiber optic hydrophones, and some types of micro-displacement or force sensors.

A schematic representation of a fiber optic position sensor (or proximity sensor or displacement sensor) is shown in [Figure 15.44\(a\)](#). The optical fiber bundle is divided into two groups: transmitting fibers and receiving fibers. Light from the light source is transmitted along the first bundle of fibers to the target object whose position is being measured. Light reflected onto the receiving fibers by the surface of the target object is carried to a photodetector. The intensity of the light received by the photodetector will depend on the position, x , of the target object. In particular, if $x = 0$, the transmitting bundle will be completely blocked off and the light intensity at the receiver will be zero. As x is increased, the received light intensity will increase, because more light will be

FIGURE 15.44 (a) A fiber-optic proximity sensor; (b) nonlinear characteristic curve.

reflected onto the receiving bundle tip. This will reach a peak at some value of x . When x is increased beyond that value, more light will be reflected outside the receiving bundle; hence, the intensity of the received light will decrease. Hence, in general, the proximity–intensity curve for an optical proximity sensor will be nonlinear and will have the shape shown in Figure 15.44(b). Using this (calibration) curve, we can determine the position (x) once the intensity of the light received at the photosensor is known. The light source could be a *laser* (or light amplification by stimulated emission of radiation; structured light), infrared light-source, or some other type, such as a light-emitting diode (LED). The light sensor (photodetector) could be some light-sensitive discrete SC element such as a photodiode or a photo field effect transistor (photo FET). Very fine resolutions, better than 1×10^{-6} cm, can be obtained using a fiber optic position sensor. An *optical encoder* is a digital (or pulse-generating) motion transducer. Here, a light beam is intercepted by a moving disk that has a pattern of transparent windows. The light that passes through, as detected by a photosensor, provides the transducer output. These sensors may also be considered in the extrinsic category.

The advantages of fiber optics include insensitivity to electrical and magnetic noise (due to optical coupling), safe operation in explosive, high-temperature, hazardous environments and high sensitivity. Furthermore, mechanical loading and wear problems do not exist because fiber optic position sensors are noncontacting devices with stationary sensor heads. The disadvantages include direct sensitivity to variations in the intensity of the light source and dependence on ambient conditions (ambient light, dirt, moisture, smoke, etc.).

As an example of an *intrinsic* application of fiber optics in sensing, consider a straight optical fiber element that is supported at each end. In this configuration almost 100% of the light at the source end will transmit through the optical fiber and will reach the detector (receiver) end. Then, suppose that a slight load is applied to the optical fiber segment at its mid span. The fiber will deflect slightly due to the

load, and as a result the amount of light received at the detector can significantly drop. For example, a deflection of just $50\text{ }\mu\text{m}$ can result in a drop in intensity at the detector by a factor of 25. Such an arrangement may be used in deflection, force, and tactile sensing. Another intrinsic application is the fiber optic gyroscope, as described below.

15.6.2.3 Fiber-Optic Gyroscope

This is an angular speed sensor that uses fiber optics. Contrary to the implication of its name, however, it is not a gyroscope in the conventional sense. Two loops of optical fibers wrapped around a cylinder are used in this sensor. One loop carries a monochromatic light (or laser) beam in the clockwise direction, and the other loop carries a beam from the same light (or laser) source in the counterclockwise direction. Since the laser beam traveling in the direction of rotation of the cylinder has a higher frequency than that of the other beam, the difference in frequencies of the two laser beams received at a common location will measure the angular speed of the cylinder. This may be accomplished through interferometry, as the light and dark patterns of the detected light will measure the frequency difference. Note that the length of the optical fiber in each loop can exceed 100 m. Angular displacements can be measured with the same sensor simply by counting the number of cycles and clocking the fractions of cycles. Acceleration can be determined by digitally determining the rate of change of speed.

15.6.2.4 Laser Doppler Interferometer

The laser produces electromagnetic radiation in the ultraviolet, visible, or infrared bands of the spectrum. A laser can provide a single-frequency (*monochromatic*) light source. Furthermore, the electromagnetic radiation in a laser is *coherent* in the sense that all waves generated have constant phase angles. The laser uses oscillations of atoms or molecules of various elements. The helium–neon (HeNe) laser and the SC laser are commonly used in industrial applications.

As noted earlier, the laser is useful in fiber optics, but it can also be used directly in sensing and gaging applications. The laser Doppler interferometer is one such sensor. It is useful in the accurate measurement of small displacements, for example, in strain measurements. To explain the operation of this device, we should explain two phenomena: the Doppler effect and light wave interference. Consider a wave source (e.g., a light source or sound source) that is moving with respect to a receiver (observer). If the source moves toward the receiver, the frequency of the received wave appears to have increased; if the source moves away from the receiver, the frequency of the received wave appears to have decreased. The change in frequency is proportional to the velocity of the source relative to the receiver. This phenomenon is known as the *Doppler effect*. Now consider a monochromatic (single-frequency) light wave of frequency, f (say, 5×10^{14} Hz), emitted by a laser source. If this ray is reflected by a target object and received by a light detector, the frequency of the received wave is

$$f_2 = f + \Delta f \quad (15.95)$$

The frequency increase Δf will be proportional to the velocity, v , of the target object, which is assumed to be positive when moving toward the light source. Hence,

$$\Delta f = cv \quad (15.96)$$

Now by comparing the frequency, f_2 , of the reflected wave, with the frequency

$$f_1 = f \quad (15.97)$$

of the original wave, we can determine Δf and, hence, the velocity, v , of the target object.

The change in frequency Δf due to the Doppler effect can be determined by observing the fringe pattern due to light wave interference. To understand this, consider the two waves

$$v_1 = a \sin 2\pi f_1 t \quad (15.98)$$

and

$$v_2 = a \sin 2\pi f_2 t \quad (15.99)$$

If we add these two waves, the resulting wave is

$$v = v_1 + v_2 = a(\sin 2\pi f_1 t + \sin 2\pi f_2 t)$$

which can be expressed as

$$v = 2a \sin \pi(f_2 + f_1)t \cos \pi(f_2 - f_1)t \quad (15.100)$$

It follows that the combined signal will beat at the beat frequency $\Delta f/2$. When f_2 is very close to f_1 (i.e., when Δf is small compared with f), these beats will appear as dark and light lines (fringes) in the resulting light wave. This is known as *wave interference*. Note that Δf can be determined by two methods:

1. By measuring the spacing of the fringes
2. By counting the beats in a given time interval or by timing successive beats using a high-frequency clock signal

The velocity of the target object is determined in this manner. Displacement can be obtained simply by digital integration or by accumulating the count. A schematic diagram for the laser Doppler interferometer is shown in Figure 15.45. Industrial interferometers usually employ a HeNe laser that has waves of two frequencies close together. In that case, the arrangement shown in Figure 15.45 has to be modified to take into account the two frequency components.

Note that there are laser interferometers that directly measure *displacement* rather than speed. They are based on measuring *phase difference* between the direct and the returning laser, not the Doppler effect (frequency difference). In this case, integration is not needed to obtain displacement from a measured velocity.

15.6.2.5 Ultrasonic Sensors

Audible sound waves have frequencies in the range of 20 Hz to 20 kHz. Ultrasound waves are pressure waves, just like sound waves, but their frequencies are higher than the audible frequencies. Ultrasonic sensors are used in many applications, including displacement and vibration sensing, medical imaging, ranging for cameras with autofocusing capability, level sensing, machine monitoring, and speed sensing. For example, in medical applications, ultrasound probes of frequencies 40 kHz, 75 kHz, 7.5 MHz and 10 MHz are commonly used. Ultrasound can be generated according to several principles. For example, high-frequency (gigahertz) oscillations in piezoelectric crystals subjected to electrical potentials are used to generate very high-frequency ultrasound. Another method is to use the magnetostrictive property of ferromagnetic material. Ferromagnetic materials deform when subjected to magnetic fields. Respondent oscillations generated by this principle can produce ultrasonic waves. Another method of generating ultrasound is to apply a high-frequency voltage to a metal-film capacitor. A microphone can serve as an ultrasound detector (receiver).

Analogous to the case of fiber-optic sensing, there are two common ways of employing ultrasound in a sensor. In one approach, the *intrinsic* method, the ultrasound signal undergoes change as it passes through an object, due to acoustic impedance and the absorption characteristics of the object. The resulting signal (image) may be interpreted to determine properties of the object, such as texture, firmness, and deformation. This approach is utilized, for example, in machine monitoring and object

FIGURE 15.45 A laser Doppler interferometer for measuring velocity and displacement.

firmness sensing. In the other approach, the *extrinsic* method, the time for an ultrasound burst to travel from its source to some object and then back to a receiver is measured. This approach is used in distance, position, and vibration measurement and in dimensional gauging.

In distance (vibration, proximity, displacement) measurement using ultrasound, a burst of ultrasound is projected at the target object, and the time taken for the echo to be received is clocked. A signal processor computes the position of the target object, possibly compensating for environmental conditions. This configuration is shown in Figure 15.46. Alternatively, the velocity of the target object can be measured, using the Doppler effect, by measuring (clocking) the change in frequency between the transmitted wave and the received wave. The “beat” phenomenon may be employed here. Position measurements with fine resolution (e.g., a fraction of a millimeter) can be achieved using the ultrasonic method. Since the speed of ultrasonic wave propagation depends on the temperature of the medium (typically air), errors will enter into the ultrasonic readings unless the sensor is adjusted to compensate for temperature variations.

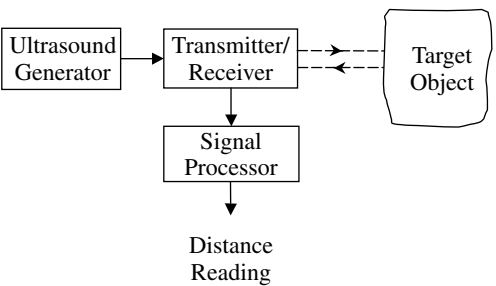

FIGURE 15.46 An ultrasonic position sensor.

15.6.2.6 Gyroscopic Sensors

Consider a rigid body spinning about an axis at angular speed, ω . If the moment of inertia of the body about that axis is J , the angular momentum H about the same axis is given by

$$H = J\omega \tag{15.101}$$

Newton’s Second Law (torque = rate of change of angular momentum) tells us that to rotate (precess) the spinning axis slightly, a torque has to be applied, because precession causes a change in the spinning angular momentum vector (the magnitude remains constant but the direction changes), as shown in Figure 15.47(a). This is the principle of operation of a gyroscope. Gyroscopic sensors are commonly used in control systems for stabilizing vehicle systems.

FIGURE 15.47 (a) Illustration of the gyroscopic torque needed to change the direction of an angular momentum vector; (b) a simple single-axis gyroscope for sensing angular displacements.

TABLE 15.4 Rating Parameters of Several Sensors and Transducers

Transducer	Measurand	Measurand Frequency Max/Min	Output Impedance	Typical Resolution	Accuracy	Sensitivity
Potentiometer	Displacement	10 Hz/DC	Low	0.1 mm	0.1%	200 mV/mm
LVDT	Displacement	2500 Hz/DC	Moderate	0.001 mm or less	0.3%	50 mV/mm
Resolver	Angular displacement	500 Hz/DC (limited by excitation frequency)	Low	2 min	0.2%	10 mV/deg
Tachometer	Velocity	700 Hz/DC	Moderate (50 Ω)	0.2 mm/sec	0.5%	5 mV/mm/sec; 75 mV/rad/sec
Eddy current proximity sensor	Displacement	100 kHz/DC	Moderate	0.001 mm 0.05% full scale	0.5%	5 V/mm
Piezoelectric accelerometer	Acceleration (and velocity, etc.)	25 kHz/1 Hz	High	1 mm/sec ²	1%	0.5 mV/m/sec ²
Semiconductor strain gage	Strain (displacement, acceleration, etc.)	1 kHz/DC (limited by fatigue)	200	1 to 10 μ sec (1 μ sec = 10^{-6} unity strain)	1%	1 V/ ϵ , 2000 μ sec max
Loadcell	Force (10–1000 N)	500 Hz/DC	Moderate	0.01 N	0.05%	1 mV/N
Laser	Displacement/shape	1 kHz/DC	100 Ω	1.0 μ m	0.5%	1 V/mm
Optical encoder	Motion	100 kHz/DC	500 Ω	10 bit	\pm 1/2 bit	10 ⁴ /rev

Consider the gyroscope shown in [Figure 15.47\(b\)](#). The disk is spun about frictionless bearings using a torque motor. Since the gimbal (the framework on which the disk is supported) is free to turn about the frictionless bearings on the vertical axis, it will remain fixed with respect to an inertial frame, even if the bearing housing (the main structure in which the gyroscope is located) rotates. Hence, the relative angle between the gimbal and the bearing housing (angle θ in the figure) can be measured, and this gives the angle of rotation of the main structure. In this manner, angular displacements in systems such as aircraft, space vehicles, ships, and land vehicles can be measured and stabilized with respect to an inertial frame. Note that bearing friction introduces an error that must be compensated for, perhaps by recalibration before a reading is taken.

The *rate gyro*, which has the same arrangement as shown in [Figure 15.47\(b\)](#), except with a slight modification, can be used to measure angular speeds. In this case, the gimbal is not free but is restrained by a torsional spring. A viscous damper is provided to suppress any oscillations. By analyzing this gyro as a mechanical tachometer, we will note that the relative angle of rotation, θ , gives the angular speed of the structure about the gimbal axis.

Several areas can be identified where new developments and innovations are being made in sensor technology:

1. Microminiature sensors: IC-based, with built-in signal processing.
2. Intelligent sensors: built-in reasoning or information preprocessing to provide high-level knowledge.
3. Integrated and distributed sensors: sensors are integral with the components and agents of the overall multiagent system that communicate with each other.
4. Hierarchical sensory architectures: low level sensory information is preprocessed to match higher level requirements.

These four areas of activity are also representative of future trends in sensor technology development. To summarize, rating parameters of a selected set of sensors/transducers are listed in [Table 15.4](#).

Summary

The proper acquisition, analysis, and presentation of shock and vibration data demand careful configuration and execution of the measurement system. This Appendix provides a review of the fundamental considerations, which have to be made when acquiring, analyzing, and presenting shock as vibration data. Additionally, the Appendix indicates some tips and techniques for programming such tests using modern software packages. Specifically, this Appendix refers to the graphical programming environment LabVIEW and the Sound and Vibration Toolkit, and supplements the material presented in Chapter 10 and in Chapter 15 to Chapter 18.

15A.1 Dynamic Signals

This Appendix introduces how to properly obtain data to analyze with the LabVIEW Sound and Vibration Toolkit, as well as issues that can affect the quality of the data. One can simulate data with the generation Virtual Instruments (VIs) located on the Generation palette as well as with other VIs. The Appendix particularly supplements the material presented in [Chapter 10](#) and in Chapter 15 to [Chapter 18](#), on vibration instrumentation, testing, data acquisition, and analysis.

15A.1.1 Acquiring and Simulating Dynamic Signals

This section discusses obtaining data and some key issues when acquiring or simulating dynamic signals to ensure valid measurement results. The three techniques that allow one to obtain data

are as follows:

- Acquisition of data with a data acquisition (DAQ) device or system
- Reading of data from a file
- Simulation of data with a generation VI (LabVIEW Virtual Instrument) or other source

It is important that you keep certain considerations in mind when you obtain your data. Measurement and analysis software such as the LabVIEW Sound and Vibration Toolkit does not compensate for inaccurate data. Therefore, the test equipment and test procedure should be calibrated to ensure accurate results. Generally, the test equipment should have specifications at least ten times better than those of the device under test (DUT). Use a verifiable and repeatable test procedure to get accurate results.

Whether one is obtaining the data from a DAQ system, reading the data from a file, or simulating the data, aliasing and time continuity are common issues, which should be considered in the measurement analysis.

15A.1.1.1 Aliasing

When a dynamic signal is discretely sampled, aliasing is the phenomenon in which frequency components greater than the Nyquist frequency are erroneously shifted to lower frequencies (see [Chapter 10](#)). The Nyquist frequency is calculated with the following formula:

$$f_{\text{Nyquist}} = \text{sample rate}/2$$

When acquiring data with an NI Dynamic Signal Acquisition (DSA) device, aliasing protection is automatic in any acquisition. The sharp antialiasing filters on DSA devices track the sample rate and filter out (attenuate) all frequencies above the Nyquist frequency.

When performing frequency measurements with an NI E Series DAQ device, you must take steps to eliminate aliasing. These antialiasing steps can include the following actions:

- Increasing the sample rate
- Applying an external low-pass filter
- Using an inherently band-limited DUT

FIGURE 15A.1 Simulated data aliasing.

Simulated data also can exhibit aliasing. The signals often are generated according to a time-domain expression and, therefore, have high-frequency components that are aliased in the discretely sampled data. [Figure 15A.1](#) shows an example of this aliasing for a simulated square wave.

The only way to protect data from aliasing is to apply appropriate aliasing protection before the data are generated or acquired. Aliasing occurs when the data are generated or sampled, and it is not possible to remove aliased components from the data without detailed knowledge of the original signal. In general, it is not possible to distinguish between true frequency components and aliased frequency components. Therefore, accurate frequency measurements require adequate alias protection.

15A.1.1.2 Time Continuity

When you acquire data in a continuous acquisition, you can use the t_0 parameter in the waveform data-type to ensure there are no gaps between successive blocks of waveforms returned by sequential calls to the DAQmx Read VI or AI Read VI. When signals are generated with one of the waveform generation VIs, in the Generation palette or the Waveform Generation palette, the t_0 of the current waveform is one sample period later than the timestamp of the last sample in the previous waveform. Continuity is enforced in this way until the generation is reset.

The waveform data type is integral for testing time continuity in the Sound and Vibration Toolkit. If you read data from a file or simulate a signal using one of the VIs in the Signal Generation palette, wire a t_0 that meets the continuous timestamp condition to the waveform data type connected to the measurement analysis VIs. This action prevents unexpected resets of the measurement analysis due to detected discontinuities in the input signal.

15A.2 Measurement Configuration Considerations

This section describes how the analog input (AI), analog output (AO), timing, and triggering configuration affect your measurements.

15A.2.1 Input Signal Considerations

One must consider the following configuration before acquiring dynamic signals and performing shock and vibration measurements.

15A.2.1.1 Input Pseudodifferential and Differential Configuration

DSA devices such as the National Instruments PXI-4461 supports two terminal configurations for AI, differential and pseudodifferential. The term pseudodifferential refers to the fact that there is a 50 Ω resistance between the outer BNC shell and chassis ground. One can configure the NI PXI-4461 input channels on a per-channel basis. Therefore, you can have one channel configured for differential mode and the other channel configured for pseudodifferential mode. Configure the channels based on how the signal source or DUT is referenced. Refer to [Table 15A.1](#) to determine how to configure the channel based on the source reference.

If the signal source is floating, use the pseudodifferential channel configuration. A floating signal source does not connect to the building ground system. Instead, the signal source has an isolated ground-reference point. Some examples of floating signal sources are outputs of transformers without grounded center taps, battery-powered devices, nongrounded accelerometers, and most instrumentation

TABLE 15A.1 Input Channel Configuration

Source Reference	Channel Configuration
Floating, ground referenced	Pseudodifferential
Ground referenced	Differential

microphones. An instrument or device that has an isolated output is considered to be a floating signal source. It is important to provide a ground reference for a floating signal. If no ground-reference point is provided — for example, in selecting differential mode with a floating microphone — the microphone outputs can drift outside the NI PXI-4461 common-mode range.

If the signal source is ground-referenced, use either the differential or pseudodifferential channel configurations. A ground-referenced signal source connects in some way to the building system ground. Therefore, it is already connected to a ground-reference point with respect to the NI PXI-4461, assuming the PXI or CompactPCI chassis and controller are plugged into the same power system. Nonisolated outputs of instruments and devices that plug into the building power system fall into this category.

Provide only one ground-reference point for each channel by properly selecting differential or pseudodifferential configuration. If you provide two ground-reference points — for example, if you select pseudodifferential mode with a grounded accelerometer — the difference in ground potential results in currents in the ground system that can cause measurement errors. The 50 W resistor on the signal ground is usually sufficient to reduce this current to negligible levels, but results can vary depending on the system setup.

The NI PXI-4461 is automatically configured for differential mode when powered on or when power is removed from the device. This configuration protects the 50 W resistor on the signal ground.

15A.2.1.2 Gain

DSA devices such as the NI PXI-4461 often offer variable gain settings for each AI channel. Each gain setting corresponds to a particular AI range, and each range is centered on 0 V. The gain settings are specified in decibels (dB), where the 0 dB reference is the default input range of ± 10 V.

Positive gain values amplify the signal before the analog-to-digital converter (ADC) digitizes it. This signal amplification reduces the range of the measurement. However, amplifying the signal before digitization allows better resolution by strengthening weak signal components before they reach the ADC. Conversely, negative gains attenuate the signal before they reach the ADC. This attenuation increases the effective measurement range though it sacrifices some resolution for weak signal components.

In general, select the voltage range that provides the greatest dynamic range and the least distortion. For example, consider an accelerometer with a 100 mV/g sensitivity rating with an absolute maximum output voltage of 5 V_{pk}. In this case, the ± 10 V_{pk} is appropriate, corresponding to 0 dB gain. However, the ± 3.16 V_{pk} setting maximizes the dynamic range if one knows the stimulus is limited, for example, to 20 g or 2 V_{pk}.

15A.2.1.3 Input Coupling

One can configure each AI channel for either alternating current (AC) or direct current (DC) coupling. If you select DC coupling, any DC offset present in the source signal is passed to the ADC. The DC-coupling configuration is usually best if the signal source has only small amounts of offset voltage or if the DC content of the acquired signal is important.

If the source has a significant amount of unwanted offset, select AC coupling to take full advantage of the input dynamic range.

15A.2.1.4 Integrated Electronic Piezoelectric Excitation

If you attach an Integrated Electronic Piezoelectric Excitation (IEPE) accelerometer or microphone to an AI channel that requires excitation from your DSA device, you must enable the IEPE excitation circuitry for that channel to generate the required current.

One can independently configure IEPE signal conditioning on a per-channel basis. It is common to set the excitation from 0 to 20 mA with 20 mA resolution.

A DC voltage offset is generated equal to the product of the excitation current and sensor impedance when IEPE signal conditioning is enabled. To remove the unwanted offset, enable AC coupling. Using DC coupling with IEPE excitation enabled is appropriate only if the offset does not exceed the voltage range of the channel.

15A.2.1.5 Nyquist Frequency and Bandwidth

Further discussion of DSA measurement configuration requires a brief introduction of two concepts:

- Nyquist frequency
- Nyquist bandwidth

Any sampling system, such as an ADC, is limited in the bandwidth of the signals it can represent. Specifically, a sampling rate of f_s can only represent signals with a maximum frequency of $f_s/2$. This maximum frequency is known as the Nyquist frequency. The bandwidth from 0 Hz to the Nyquist frequency is the Nyquist bandwidth.

15A.2.1.6 Analog-to-Digital Conversion

ADC is discussed in [Chapter 16](#). DSA devices commonly use a conversion method known as delta–sigma modulation. If the data rate is 51.2 kS/sec, each ADC actually samples its input signal at 6.5536 MS/sec, 128 times the data rate, and produces one-bit samples that are applied to the digital filter. This filter then expands the data to 24 bits, rejects signal components greater than the Nyquist frequency of 25.6 kHz, and digitally resamples the data at 51.2 kS/sec.

The one-bit, 6.5536 MS/sec data stream from the ADC contains all of the information necessary to produce 24-bit samples at 51.2 kS/sec. The delta–sigma ADC achieves this conversion from high speed to high resolution by adding a large amount of random noise to the signal so that the resulting quantization noise, although large, is restricted to frequencies above the Nyquist frequency, 25.6 kHz in this case. This noise is not correlated with the input signal and is almost completely rejected by the digital filter.

The resulting output of the filter is a band-limited signal with a large dynamic range. One of the advantages of a delta–sigma ADC is that it uses a one-bit digital-to-analog converter (DAC) as an internal reference. As a result, the delta–sigma ADC is free from the kind of differential nonlinearity (DNL) and associated noise that is inherent in most high-resolution ADCs.

15A.2.1.7 Antialias Filters

A digitizer may sample signals containing frequency components above the Nyquist limit. The process by which the digitizer modulates out-of-band components, returning them to the Nyquist bandwidth, is known as aliasing. The greatest danger of aliasing is that there is no straightforward way to know whether it has happened by looking at the ADC output. If an input signal contains several frequency components or harmonics, some of these components may be represented correctly while others are aliased.

Low-pass filtering to eliminate components above the Nyquist frequency, either before or during the digitization process, can guarantee that the digitized data set is free of aliased components. The NI PXI-4461 employs both digital and analog low-pass filters to achieve this protection.

In addition to the ADC built-in digital filtering, DSA devices may also feature a fixed-frequency analog filter. The analog filter removes high-frequency components in the analog signal path before they reach the ADC. This filtering addresses the possibility of high-frequency aliasing from the narrow-bands that are not covered by the digital filter.

15A.2.1.8 Input Filter Delay

The input filter delay is the time required for digital data to propagate through the ADC digital filter. For example, a signal experiences a delay equal to 6.3 msec at 10 kS/sec. This delay is an important factor for stimulus–response measurements, control applications, or any application where loop time is critical. In this case, it is often advantageous to maximize the sample rate and minimize the time required for 63 sample clock cycles to elapse.

The input filter delay also makes an external digital trigger appear to occur 63 sample clocks later than expected. Alternatively, the acquired buffer appears to begin 63 samples earlier than expected. This delay occurs because external digital triggering is a predigitization event.

15A.2.1.9 **Overload Detection**

It is desirable to ensure that the DSA device includes overload detection in both the analog domain (predigitization) and digital domain (postdigitization). An analog overrange can occur independently from a digital overrange, and *vice versa*. For example, an IEPE accelerometer might have a resonant frequency that, when stimulated, can produce an overrange in the analog signal. However, because the delta-sigma technology of the ADC uses very sharp antialiasing filters, the overrange is not passed into the digitized signal. Conversely, a sharp transient on the analog side might not overrange, but the step response of the delta-sigma antialiasing filters might result in clipping in the digital data.

Modern DSA devices allow you to programmatically poll the digital and analog overload detection circuitry on a per-channel basis to monitor for an overload condition. If an overload is detected, consider any data acquired at that time corrupt.

15A.2.2 **Output Signal Considerations**

This section describes the theory of operation of the output components of DSA devices such as the NI PXI-4461.

15A.2.2.1 **Output Pseudodifferential and Differential Configuration**

The output channel terminal configuration options are very similar to those for the input channels. The NI PXI-4461 output channels are configurable on a per-channel basis. As with the input channels, you should configure the output channel based on how the DUT is referenced. Refer to Table 15A.2 to determine how to configure the output channel based on the DUT reference.

If the DUT inputs are floating, use the pseudodifferential channel configuration. The term pseudodifferential refers to the fact that there is a 50 W resistance between the outer BNC shell and chassis ground. A floating DUT does not connect in any way to the building ground system. Instead, the DUT has an isolated ground-reference point. Transformer inputs without center ground taps, battery-powered devices, or any instruments that have an isolated input are all examples of floating DUTs. One should provide a ground-reference for a floating DUT input. If no ground-reference point is provided — for example, in selecting differential mode with a floating shaker table input amplifier — the outputs can float outside the common-mode range of the amplifier input.

If the DUT input is ground referenced, use the differential channel configuration. A single-ended DUT connects in some way to the building system ground. Therefore, it is already connected to a ground-reference point with respect to the NI PXI-4461, assuming the PXI or CompactPCI chassis and controller are plugged into the same power system. Nonisolated inputs of instruments that plug into the building power system fall into this category.

You should provide only one ground-reference point for each channel by properly selecting the differential or pseudodifferential configuration. If you provide two ground-reference points — for example, by selecting the pseudodifferential output mode for a single-ended amplifier as the DUT — the difference in ground potential results in currents in the ground system that can cause errors in the output signal. The 50 W resistor on the signal ground is usually sufficient to reduce this current to negligible levels, but results can vary depending on the system setup.

The NI PXI-4461 is automatically configured for the differential mode when powered on or when power is removed from the device. Using the differential mode by default protects the 50 W resistor on the signal ground.

TABLE 15A.2 Output Channel Configuration

DUT Reference	Output Channel Configuration
Floating	Pseudodifferential
Ground referenced	Differential

TABLE 15A.3 NI PXI-4461 Gain Ranges

Gain (Referenced to $\pm 10 V_{pk}$) (dB)	Voltage Range (V_{pk})
0	± 10
-20	± 1
-40	± 0.1

15A.2.2.2 Attenuation

Modern DSA devices offer variable gain settings for AO. Most gain settings correspond to a particular AO range, always centered at 0 V. These gain settings can be specified in dB, where the 0 dB reference corresponds to the default output range.

Table 15A.3 summarizes the three output gain options available on the NI PXI-4461.

In general, select the gain that provides the greatest dynamic range and the least distortion. The $\pm 1 V_{pk}$ setting maximizes the dynamic range if you know the stimulus is limited to, for example, $0.5 V_{pk}$. You can minimize system distortion by providing sufficient headroom between the stimulus setting ($0.5 V_{pk}$) and the range setting ($\pm 1 V_{pk}$). In some cases in which distortion performance is critical, you can reduce the overall dynamic range to improve the distortion characteristics by selecting the $\pm 10 V_{pk}$ setting.

15A.2.2.3 Digital-to-Analog Conversion

Digital-to-analog conversion (DAC) is discussed in [Chapter 16](#). The delta-sigma DACs on the NI PXI-4461 function in a way analogous to delta-sigma ADCs. The digital data first passes through a digital interpolation filter, then the resampling filter of the DAC, and finally goes to the delta-sigma modulator.

In the ADC, the delta-sigma modulator is an analog circuit that converts high-resolution analog signals to high-rate, 1-bit digital data, whereas in the DAC the delta-sigma modulator is a digital circuit that converts high-resolution digital data to high-rate, 1-bit digital data. As in the ADC, the modulator frequency shapes the quantization noise so that almost all of its energy is above the Nyquist frequency.

The digital 1-bit data is then sent directly to a 1-bit DAC. This DAC can have only one of two analog values, and therefore is inherently perfectly linear.

15A.2.2.4 Anti-imaging and Interpolation Filters

A sampled signal repeats itself throughout the frequency spectrum. These repetitions begin above one half the sample rate, f_s , and, theoretically, continue up through the spectrum to infinity. Images remain in the sample data because the data actually represent only the frequency components below one half f_s (the baseband).

15A.2.2.5 Output Filter Delay

Output filter delay, or the time required for digital data to propagate through the DAC and interpolation digital filters, varies depending on the sample rate. This delay is an important factor for stimulus-response measurements, control applications, and every application where loop time is critical.

15A.3 Scaling and Calibration

This Appendix discusses using the SVL Scale Voltage to EU VI located on the Scaling palette to scale a signal to engineering units (EU) and using the Calibration VIs located on the Calibration palette.

15A.3.1 Scaling to Engineering Units

This section discusses scaling data to the appropriate EU so one can perform measurement analysis.

Typically, scaling a signal to the appropriate EU occurs before any analysis is performed. Use the SVL Scale Voltage to EU VI to scale the signal to the appropriate EU. All measurement VIs in the Sound and

Vibration Toolkit expect input signals and return results with the appropriate units, such as time-domain signals in the correct EU, frequency spectra in decibels with the proper reference, phase information in degrees or radians, and so on. To handle units properly, the high-level VIs need the signal to be scaled to the appropriate EU.

If you use any method outside of the Sound and Vibration Toolkit to apply scaling to a waveform, do not use the SVL Scale Voltage to EU VI. NI provides several tools and methods to apply scaling to a waveform. These include, but are not limited to, NI-DAQmx tasks or global channels created with Measurement and Automation Explorer (MAX), the DAQ Assistant, or the DAQmx Create Virtual Channel VI.

15A.3.2 Performing System Calibration

One typically performs system calibration with a dedicated calibrator, such as a pistonphone for microphones or a handheld shaker for accelerometers. If you are calibrating a microphone, consider using the SVL Calibrate Microphone VI. If you are calibrating an accelerometer, consider using the SVL Calibrate Accelerometer VI. These VIs are very similar to the general-purpose SVL Calibrate Sensor VI, but they offer the advantage of having default values commonly found for pistonphones or hand-held shakers. All of the Calibration VIs use the characteristics of the calibrator, such as reference calibration value and frequency, to perform the calibration.

15A.3.2.1 Propagation Delay Calibration

The Sound and Vibration Toolkit provides VIs for calibrating the propagation delay of the measurement system. National Instruments DSA devices like the NI PXI-4461 and NI PCI-4451 can acquire and generate signals on the same device. The input and output channels have analog and digital circuitry, such as antialiasing and anti-imaging filters, that introduce a certain delay to the signal. The propagation delay is the number of samples ranging from the time a sample is first written to the output channel, to the time when that sample is digitized on the input channel, assuming there is no delay from the output channel to the input channel. This delay varies by DSA device.

There are two ways to determine the propagation delay of the DSA device. You can refer to the documentation for the DSA device to find the propagation delay specifications, also referred to as group delay. You also can measure the propagation delay in samples with the SVL Measure Propagation Delay VIs. The SVL Measure Propagation Delay VIs allow you to measure the delay introduced in the input and output circuitry for a specific device at the desired sample rate. Connect the DSA device output channel directly to the input channel, as displayed in Figure 15A.2, to measure the device propagation delay.

Note: Do not put a DUT in the signal path when measuring the propagation delay for a DAQ device.

For an E or S Series DAQ device from NI, you should expect to measure a one-sample propagation delay due to the time required for the signal to traverse the signal path between the DAC on the analog output channel and the ADC on the analog input channel. Figure 15A.3 shows the time domain data for the propagation delay measurement of an NI PCI-6052E.

FIGURE 15A.2 15A.2 Measuring the device propagation delay.

FIGURE 15A.3 Propagation delay measurement of an NI PCI-6052E.

FIGURE 15A.4 NI PXI-4461 propagation delay with a 204.8 kHz sample rate.

For DSA devices, or any other device which has onboard filtering on either the input, output, or both channels, you should expect to measure a propagation delay consistent with the sum of the delays specified for the onboard filters on the input and output channels. Figure 15A.4 shows the delay of a smooth pulse generated and acquired by an NI PXI-4461 with a 204.8 kHz sample rate.

Not all DSA devices have a constant propagation delay across the entire range of supported sample rates. For example, the NI PXI-4461 propagation delay is dependent on the output update rate. Figure 15A.5 shows the total propagation delay vs. sample rate relationship for the NI PXI-4461 from output to input as a function of the sample rate.

As illustrated by Figure 15A.3, Figure 15A.4, and Figure 15A.5, the propagation delay can vary significantly with different sample rates and devices. To ensure measurement accuracy in your I/O applications, determine and account for the propagation delay of the DAQ device at the same sample rate used in your application.

It is important to remove the effects of the delay due to the data acquisition system for two reasons. First, there is always a delay between the generated output signal and the acquired input on the device even when the output and input channels are hardware synchronized. Second, the anti-imaging and antialiasing filters of the device introduce additional delays. You must account for this delay to perform accurate dynamic measurements. Use the *device propagation delay [samples]* input on the examples found in the LabVIEW program directory under “\examples\Sound” and “Vibration\Audio Measurements\” to remove the delay due to the DAQ device.

The anti-imaging and antialiasing filters have a low-pass filter effect on the data. This effect results in a transient response at sharp transitions in the data. These transitions are common at the start and stop of a

FIGURE 15A.5 NI PXI-4461 propagation delay vs. sample rate.

generation, at a change in frequency (swept sine), and when the amplitude changes (amplitude sweep). The swept-sine analysis and audio measurements examples in the Sound and Vibration Toolkit account for this transient behavior in the device response to achieve the highest degree of accuracy.

The propagation delay of the DUT is also an important specification in some applications. For example, the propagation delay for the DUT is a required input when performing audio measurements and when measuring the frequency response using swept sine. If the DUT and the propagation medium can successfully pass the pulse signal used by the SVL Measure Propagation Delay VIs without excessive attenuation, then this measurement also applies when measuring the propagation delay of the DUT and the propagation medium. Figure 15A.6 shows the wiring diagram for this configuration.

The DUT propagation delay is the delay of the entire system minus the device delay. Remember to measure the device delay without the DUT connected.

The propagation delay for an analog DUT is a constant time delay rather than a delay of samples. Use the following equation to convert the measured delay in samples to the equivalent delay in seconds:

$$\text{delay}[\text{sec}] = \text{delay}[\text{samples}] / \text{sample rate}[\text{Hz}]$$

FIGURE 15A.6 Measuring the DUT propagation delay.

15A.4 Limit Testing Analysis

This Appendix discusses using the polymorphic SVT Limit Testing VI located on the Limit Testing palette.

You can use Limit Testing to perform analysis on any type of measured result produced by the Sound and Vibration Toolkit, including the following measurements:

- Waveform
- Spectrum
- Peak
- Octave
- Swept sine
- Scalar

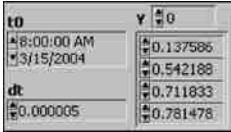

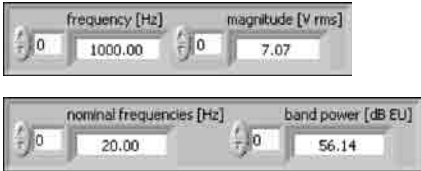

15A.4.1 Limit Testing Overview

You can use the SVT Limit Testing VI to analyze almost any measured result produced by the Sound and Vibration Toolkit. Refer to [Table 15A.4](#) for examples of data-types supported by the SVT Limit Testing VI and VIs that generate supported data-types.

15A.4.2 Using the SVT Limit Testing VI

Limit testing allows one to specify an envelope around the data to define a pass range. You can enter a scalar to the upper limit, lower limit, or both to specify a constant ceiling and floor for the data to perform tests such as range detection. You can enter an upper limit mask, lower limit mask, or both to the SVT Limit Testing VI to define a pass range that varies in shape and level based on acceptable results at any given point in the measurement. You also can create a discontinuous mask which allows you to perform limit testing on only a part of the results while ignoring the rest.

TABLE 15A.4 Compatible Data Types for SVT Limit Testing VI

Data-type		Output VIs
Waveform measurement		AI read, DAQmx read, waveform generation, weighting, integration, vibration level, sound level
Frequency spectrum measurement		Baseband FFT, baseband subset FFT, zoom FFT, extended measurements
XY data		ANSI and IEC octave, swept sine
Peak measurement		Distortion, single-tone, extended measurements
Scalar measurement		Calibration, vibration level, sound level, ANSI and IEC octave, distortion, single-tone, extended measurements

You must enter at least one limit, or the SVT Limit Testing VI returns an error. You can visually display the input signal, failures, upper limit, and lower limit by creating an indicator from the *output values* terminal.

The upper limit and lower limit inputs to the SVT Limit Testing VI must be compatible with the input signal. Table 15A.5 lists the criteria that must be met for each input signal type that is compatible with the SVT Limit Testing VI.

In Table 15A.5, the following abbreviations apply:

- dt is the time spacing, in seconds, between elements.
- df is the frequency spacing, in hertz, between elements.
- N is the number of elements in the array.
- $f(i)$ is the i th frequency element.
- S is the signal.
- U is the upper mask limit.
- L is the lower mask limit.

Limit testing covers a broad range of data testing from range detection to discontinuous mask testing of a swept-sine frequency response spectrum. [Figure 15A.7](#), [Figure 15A.9](#), [Figure 15A.11](#), and

TABLE 15A.5 Criteria for Upper and Lower Limits

Input Signal Type	Criteria on Input Limit Masks
Waveform data type ($t0$, dt , [signal])	$dt > 0$, $dt_S = dt_U = dt_L$, $N_S = N_U = N_L$
Frequency spectrum ($f0$, df , [spectrum])	$f0_S = f0_U = f0_L$, $df_S = df_U = df_L$, $N_S = N_U = N_L$
Octave spectrum, swept-sine spectrum, XY data ([X], [Y])	$[X]_S = [X]_U = [X]_L$, $N_S = N_U = N_L$
Identified peaks, harmonic components, multitone phases ([frequency, amplitude])	$f(i)_S = f(i)_U = f(i)_L$, $N_S = N_U = N_L$

FIGURE 15A.7 Range detection performed in engineering units.

Figure 15A.13 illustrate some, but not all, of the different ways one can use the SVT Limit Testing VI in your application.

Figure 15A.7 illustrates a range-detection test. Scaled waveform data and upper and lower limits are input to the SVT Limit Testing VI. The VI checks that the data fall within the envelope specified by the upper and lower limits. Figure 15A.8 shows the output results for the range detection test.

Figure 15A.9 shows a pass/fail test on the measured THD. This test only checks the upper limit of the measurement, therefore, only the upper limit is wired to the VI. The upper limit should have the same units as the input measurement. In this case, both the THD and the upper limit are expressed as percentages. Figure 15A.10 shows the THD test output results.

Figure 15A.11 shows a continuous mask test on a power spectrum. Formula nodes define both the upper and lower limits in this VI, making this a more complex test than the one in Figure 15A.9. Figure 15A.12 shows the output graph for the power spectrum continuous mask test.

Figure 15A.13 shows a discontinuous mask test on a swept-sine frequency response. A discontinuous mask test can track and test the results at different magnitudes and ranges, as well as stop testing at defined intervals. For example, one might use the envelope defined by the upper and lower limit masks in this example for a DUT such as a notch filter. Figure 15A.14 shows the output graph for the discontinuous mask test.

FIGURE 15A.8 Range detection test on a time-domain signal.

15A.5 Integration

This Appendix discusses the integration process, including basic theory and implementation in the time and frequency domains.

FIGURE 15A.9 Test scalar measurement.

The Sound and Vibration Toolkit contains the following integration VIs:

- SVT Integration VI located on the Integration palette for time-domain integration
- SVT Integration (frequency) VI located on the Frequency Analysis >> Extended Measurements palette for frequency-domain integration

15A.5.1 Introduction to Integration

The conversion between acceleration, velocity, and displacement is based on one of the fundamental laws in Newtonian physics, represented by the following equations:

$$\dot{x} = \frac{d}{dt}(x)$$

$$\ddot{x} = \frac{d}{dt}(\dot{x}) = \frac{d^2}{dt^2}(x)$$

Velocity is the first derivative of displacement with respect to time. *Acceleration* is the first derivative of velocity and the second derivative of displacement with respect to time. Therefore, given acceleration, perform a single integration with respect to time to compute the velocity or perform a double integration with respect to time to compute the displacement.

When representing the acceleration of a point by a simple sinusoid, the velocity and the displacement of the point are well known and represented by the following equations:

$$a = A \sin(\omega t) \tag{15A.1}$$

$$v = -\frac{A}{\omega} \cos(\omega t) = \frac{A}{\omega} \sin\left(\omega t - \frac{\pi}{2}\right) \tag{15A.2}$$

$$d = -\frac{A}{\omega^2} \sin(\omega t) = \frac{A}{\omega^2} \sin(\omega t - \pi)$$

Note: The initial condition is arbitrarily set to zero in Equation 15A.1 and Equation 15A.2. The amplitude of the velocity is inversely proportional to the frequency of vibration. The amplitude of the displacement is inversely proportional to the square of the frequency of vibration. Furthermore, the phase of the velocity lags the acceleration by 90°. The phase of the displacement lags the acceleration by 180°. Figure 15A.15 illustrates the relationship between acceleration, velocity, and displacement.

The integration of a sinusoid is known in closed form. Integration of an arbitrary waveform typically requires a numerical approach. You can use several numerical integration schemes to evaluate an integral in the time domain.

FIGURE 15A.10 Limit testing on THD measurements.

FIGURE 15A.11 Continuous mask test on power spectrum.

In the frequency domain, you can define any arbitrary band-limited waveform as a sum of sinusoids. Because the amplitude and phase relationships are known for sinusoids, you can carry out the integration in the frequency domain.

15A.5.2 Implementing Integration

If you need to perform measurements on velocity or displacement data when you have only acquired acceleration or velocity data, respectively, integrate the measured signal to yield the desired data. You can perform integration either in the time domain as a form of signal conditioning or in the frequency domain as a stage of analysis. When performed in the frequency domain, integration is one of the extended measurements for frequency analysis.

FIGURE 15A.12 Continuous mask test on a power spectrum.

15A.5.2.1 Challenges when Integrating Vibration Data

Converting acceleration data to velocity or displacement data presents a pair of unique challenges. First, measured signals typically contain some unwanted DC components. The second challenge is the fact that many transducers, especially vibration transducers, have lower-frequency limits. A transducer cannot accurately measure frequency components below the lower-frequency limit of the transducer.

15A.5.2.1.1 DC Component

Even though a DC component in the measured signal might be valid, the presence of a DC component indicates that the DUT has a net acceleration along the axis of the transducer. For a typical vibration measurement, the DUT is mounted or suspended in the test setup. The net acceleration of the DUT is zero. Therefore, any DC component in the measured acceleration is an artifact and should be ignored.

15A.5.2.1.2 Transducers

Most acceleration and velocity transducers are not designed to accurately measure frequency components close to DC (see Chapter 15). Closeness to DC is relative and depends on the specific transducer. A typical accelerometer can accurately measure components down to about 10 Hz. A typical velocity probe can accurately measure components down to 2 to 3 Hz. Inaccurately measured low-frequency vibrations can dominate the response when the signal is integrated because integration attenuates low-frequency components less than high-frequency components.

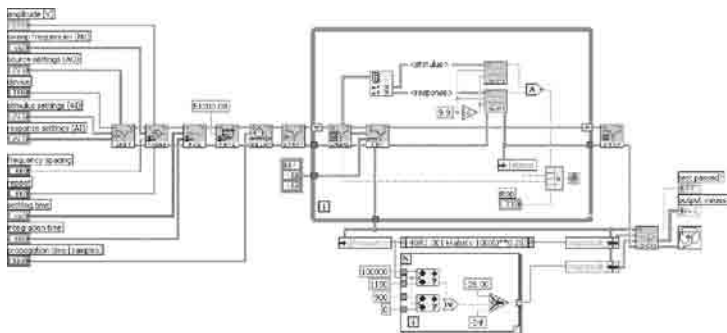

FIGURE 15A.13 Discontinuous mask test on swept-sine frequency response.

15A.5.2.1.3 Implementing Integration Using the Sound and Vibration Toolkit

Both the SVT Integration VI and the SVT Integration (frequency) VI address the challenges of converting acceleration data to velocity or displacement data.

15A.5.3 Time-Domain Integration

This section presents examples of and discussion about time-domain integration.

15A.5.3.1 Single-Shot Acquisition and Integration

The following example shows how one can use integration to convert acceleration data into displacement data in a single-shot acquisition and integration. In this example, the acquired waveform is sampled at 51.2 kHz and is double integrated. Figure 15A.16 shows the block diagram for the VI.

Because the integration is implemented with filters, there is a transient response associated with integration while the filters settle. You should take care to avoid the transient region when making further measurements. Figure 15A.17 shows the results of a single-shot acquisition and integration of a 38 Hz sine wave. You can see the transient response in the first 200 msec of the integrated signal.

15A.5.3.2 Continuous Acquisition and Integration

The more common case for time-domain integration occurs with continuous acquisition. Figure 15A.18 shows the block diagram for a VI designed for continuous acquisition and integration.

In this example, the high-pass cut-off frequency used for the integration is 10 Hz. Additionally, the integration is explicitly reset in the first iteration of the VI and performed continuously thereafter. In this example, this additional wiring is optional because the SVT Integration VI automatically resets the first time it is called and runs continuously thereafter.

If you use the block diagram in Figure 15A.18 in a larger application that requires starting and stopping the data acquisition process more than once, NI suggests setting the *reset filter* control to “TRUE” for the first iteration of the while loop. Setting the reset filter control to TRUE causes the filter to reset every time the data acquisition process starts. Set the reset filter control to “FALSE” for subsequent iterations of the while loop.

FIGURE 15A.14 Discontinuous mask test on a swept-sine frequency response.

FIGURE 15A.15 Integration of a 0.5 Hz sine wave.

FIGURE 15A.16 Block diagram for single-shot acquisition and integration.

Figure 15A.19 shows the results of the continuous acquisition and integration of the same 38 Hz sinusoid used in the single-shot acquisition and integration example.

As in single-shot acquisition and integration, continuous acquisition and integration has an initial transient response. Take care to avoid making additional measurements until the response of the filters settles. Once the filters settle, you can use the integrated signals for additional analysis.

Figure 15A.20 shows the frequency response for time-domain single integration. Figure 15A.21 shows the frequency response for time-domain double integration.

In Figure 15A.20, one can see the characteristic 20 dB per decade roll-off of the magnitude response of the single integration. In Figure 15A.21, one can see the characteristic 40 dB per decade roll-off of the magnitude response of the double integration.

Upper and lower frequency limits exist for which you can obtain a specified degree of accuracy in the magnitude response. For example, sampling at a rate of 51.2 kHz, the magnitude response of the integrator is accurate to within 1 dB from 1.17 to 9.2 kHz for single integration and from 1.14 to 6.6 kHz for double integration. The accuracy ranges change with the sampling frequency and the high-pass cut-off frequency. The attenuation of the single integration filter at 9.2 kHz is -95 dB. The attenuation of the double integration filter at 6.6 kHz is -185 dB. Accuracy at high frequencies usually is not an issue.

15A.5.4 Frequency-Domain Integration

You can use the following strategies to obtain the spectrum of an integrated signal:

- Perform the integration in the time domain before computing the spectrum.
- Compute the spectrum before performing the integration in the frequency domain.

The following example demonstrates the implementation of the strategies used to obtain the spectrum of an integrated signal. Figure 15A.22 shows the block diagram for the example VI.

The *high-pass cutoff frequency* parameter of the SVT Integration VI is wired with a constant of 10 Hz. The SVT Integration (frequency) VI does not have a high-pass cutoff frequency parameter. Instead, the SVT Integration (frequency) VI sets the DC component of the integrated signal to zero if the spectrum scale is linear or to negative infinity (-Inf) if the spectrum scale is in decibels.

Figure 15A.23 shows the results of integrating in the time and frequency domains.

FIGURE 15A.17 Transient response in single-shot acquisition and integration.

FIGURE 15A.18 Continuous acquisition and integration.

FIGURE 15A.19 Settled response of continuous acquisition and integration.

The power spectrum is computed after the time-domain integration filters settle. The frequency-domain integration scales the spectrum at each frequency line. No settling time is necessary for the frequency-domain integration because integration filters are not involved in the frequency-domain integration.

Perform frequency-domain integration in the following situations to maximize performance:

- When the integrated signal is not needed in the time domain
- When spectral measurements are made

15A.6 Vibration-Level Measurements

This Appendix briefly discusses the analysis concepts associated with performing vibration-level measurements and how one can use the Vibration Level VIs located on the Vibration Level palette to perform vibration-level measurements.

15A.6.1 Measuring the Root Mean Square Level

A basic requirement of vibration measurements is measuring the level of the signal returned by an accelerometer. The level of the accelerometer signal generally is expressed in root-mean-square (RMS) acceleration (g_{rms}).

15A.6.1.1 Single-Shot Buffered Acquisition

The block diagram in Figure 15A.24 illustrates a VI designed to perform a single-shot acquisition and compute the RMS levels.

The sampling frequency is 10 kS/sec. A buffer containing 1 sec of data is returned by the read VI.

FIGURE 15A.20 Frequency response for single integration.

FIGURE 15A.21 Frequency response for double integration.

FIGURE 15A.22 Integration in the time domain and in the frequency domain.

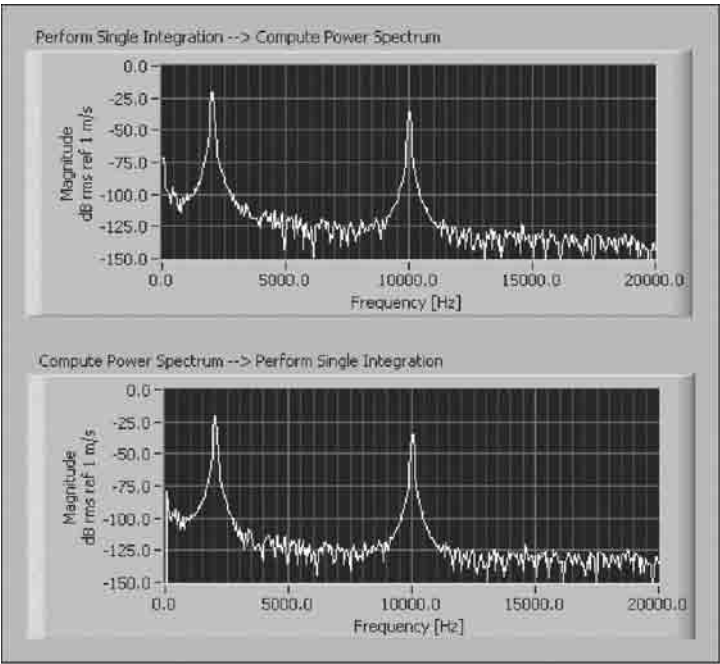

FIGURE 15A.23 Power spectra of the integrated signal.

FIGURE 15A.24 Single-shot buffered acquisition and RMS level VI.

FIGURE 15A.25 Continuous data acquisition and RMS level VI.

15A.6.1.2 Continuous Signal Acquisition

One can use the block diagram in Figure 15A.24 with a while loop to continuously acquire signals from an accelerometer and display the vibration level in a chart. The block diagram in Figure 15A.25 illustrates how to measure the RMS value once every 100 msec and display the results in a strip chart. In this example, the RMS value is computed based on the last 100 msec of acquired data.

FIGURE 15A.26 Running RMS VI.

Note: Set the *restart averaging* control on the SVT RMS Level VI to TRUE. Otherwise, the SVT RMS Level VI accumulates intermediate results to compute the RMS vibration level over the entire data acquisition instead of just over the last block of data.

15A.6.2 Performing a Running RMS Level Measurement

The SVT Running RMS Level VI returns the RMS value computed over the last N seconds, which is the integration time. The block diagram in Figure 15A.26 illustrates an application using the SVT Running RMS Level VI. The sampling frequency is 10 kS/sec. The read VI reads 1000 samples at a time.

15A.6.3 Computing the Peak Level

Use the SVT Peak Level VI to compute the peak level of a signal. In peak-hold averaging, the largest measured level value of all previous values is computed and returned until a new value exceeds the current maximum. The new value becomes the new maximum value and is the value returned until a new value exceeds it.

15A.6.4 Computing the Crest Factor

The crest factor is the ratio of the peak value over the RMS value of a given signal and indicates the shape of the waveform. The crest factor is defined by the following equation:

$$F_c = \frac{V_{pk}}{V_{rms}}$$

where

F_c is the crest factor.

V_{pk} is the peak value of the signal.

V_{rms} is the RMS value of the signal.

The block diagram in Figure 15A.27 illustrates an application using the SVT Crest Factor VI. Along with the crest factors, the SVT Crest Factor VI also returns the peak and RMS levels.

FIGURE 15A.27 Crest factor VI.

15A.7 Frequency Analysis

This Appendix discusses methods used by the Frequency Analysis VIs located on the Frequency Analysis palette for windowing, averaging, and performing frequency-domain measurements.

The Frequency Analysis VIs offer various frequency measurements based on the discrete Fourier transform (DFT).

For simplicity, the remainder of this document uses the term FFT to denote both the FFT and the DFT.

15A.7.1 FFT Fundamentals

The FFT resolves the time waveform into its sinusoidal components. The FFT takes a block of time-domain data and returns the frequency spectrum of that data. The FFT is a digital implementation of the Fourier transform. Thus, the FFT does not yield a continuous spectrum. Instead, the FFT returns a discrete spectrum where the frequency content of the waveform is resolved into a finite number of frequency lines, or bins.

15A.7.1.1 Number of Samples

The computed spectrum is completely determined by the sampled time waveform input to the FFT. If an arbitrary signal is sampled at a rate equal to f_s over an acquisition time, T , N samples are acquired. Compute T with the following equation:

$$T = \frac{N}{f_s}$$

where

T is the acquisition time.

N is the number of samples acquired.

f_s is the sampling frequency.

Compute N with the following equation:

$$N = Tf_s$$

where

N is the number of samples acquired.

T is the acquisition time.

f_s is the sampling frequency.

15A.7.1.2 Frequency Resolution

Because of the properties of the FFT, the spectrum computed from the sampled signal has a frequency resolution, d_f . Calculate the frequency resolution with the following equation:

$$d_f = \frac{1}{T} = \frac{f_s}{N}$$

where

d_f is the frequency resolution.

T is the acquisition time.

f_s is the sampling frequency.

N is the number of samples.

Note: The frequency resolution is determined solely by the acquisition time. The frequency resolution improves as the acquisition time increases.

15A.7.1.3 Maximum Resolvable Frequency

The sampling rate of the time waveform determines the maximum resolvable frequency. According to the Shannon Sampling Theorem, the maximum resolvable frequency must be half the sampling frequency. To calculate the maximum resolvable frequency, use the following equation:

$$f_{\max} = f_{\text{Nyquist}} = \frac{f_s}{2}$$

where

f_{\max} is the maximum resolvable frequency

f_{Nyquist} is the Nyquist frequency

f_s is the sampling frequency

15A.7.1.4 Minimum Resolvable Frequency

The minimum resolvable frequency is 0 (DC). The term *baseband analysis* is often used to describe analysis from 0 to f_{Nyquist} .

15A.7.1.5 Number of Spectral Lines

The number of lines in the spectrum is half the number of samples, N , in the waveform. Directly specify the number of lines in the spectrum for the Zoom FFT VIs, in the Sound and Vibration Toolkit. Specify the number of data samples to control the number of spectral lines for the Baseband FFT and the Baseband Subset VIs.

15A.7.1.6 Relationship between Time-Domain and Frequency-Domain Specifications and Parameters

Table 15A.6 summarizes the relationship of time-domain specifications to frequency-domain parameters.

Use the information in Table 15A.7 if you prefer to specify the spectrum parameters and determine the required data-acquisition parameters from these specifications.

TABLE 15A.6 Time-Domain Specifications to Frequency-Domain Parameters

Time Domain	Frequency Domain			
	f_{Nyquist}	f_{\max}	Number of Lines	df
f_s	$\frac{f_s}{2}$	$f_s \cdot E_b$	$E_b \cdot N$	$\frac{1}{T} = \frac{f_s}{N}$
N				
T				

f_s is the sampling frequency, E_b is the effective bandwidth, N is the number of samples acquired, and T is the acquisition time.

TABLE 15A.7 Frequency-Domain Specifications to Time-Domain Parameters

Frequency Domain	Time Domain		
	f_s	N	T
f_{\max}	$\frac{f_{\max}}{E_b}$	Number of lines	$\frac{1}{df} = \frac{\text{Number of lines}}{f_{\max}}$
Number of lines in the spectrum			
df			

f_{\max} is the maximum resolvable frequency, E_b is the effective bandwidth, and df is the frequency resolution.

In Table 15A.6 and Table 15A.7, E_b is the ratio of the alias-free bandwidth to the sampling frequency. In traditional instruments, E_b is typically 1/256. However, the alias-free bandwidth depends on the hardware used to acquire the dynamic signal. E_b can have a maximum value of 0.5. This maximum value corresponds to a perfect antialiasing filter. For example, if 1024 samples are input to the FFT algorithm, the computed spectrum has 512 nonDC spectral lines. The computed spectrum has a total of 513 lines including the DC component. Acquire these same 1024 samples on an instrument with a standard 1/256 effective bandwidth, then use the equation in Table 15A.6 to find the expected number of alias-free lines in the computed spectrum. Complete the necessary calculations with the following equations:

$$\begin{aligned} \text{Number of lines} &= E_b N \\ \text{Number of lines} &= \frac{1}{2.56} \times 1024 = 400 \text{ lines} \end{aligned}$$

E_b is entirely a hardware property. However, mathematically, you can use the FFT to compute the frequency spectrum up to the Nyquist frequency. Remember to account for the presence or absence of an antialiasing filter when performing the frequency analysis. The Frequency Analysis VIs compute every spectral line, alias-free or not. Use the frequency range to limit the analysis to the alias-free region of the spectrum with FFT subset and zoom FFT measurements. Use the SVT Get Spectrum Subset VI to limit the analysis to the alias-free region of the spectrum with baseband FFT measurements.

Note: Table 15A.6 shows that the sampling frequency and the block size acquired during each cycle of a continuous acquisition completely determine the frequency-domain parameters in baseband FFT analysis. However, many stand-alone instruments are operated by specifying the frequency range of interest and the number of lines in the FFT. Table 15A.7 shows how a stand-alone instrument uses the frequency range of interest and the number of lines in the FFT to determine an appropriate sampling frequency and block size.

15A.7.2 Increasing Frequency Resolution

Increasing the frequency resolution helps one to distinguish two individual tones that are close together. For example, if you analyze a signal that contains two tones at 1000 and 1100 Hz, use a sampling frequency of 10,000 Hz. Acquire data for 10 msec and the frequency resolution is 100 Hz. Figure 15A.28 shows the results of this analysis. In this particular case, you cannot distinguish one tone from the other.

Increase the acquisition time to 1 sec to achieve a frequency resolution of 1 Hz. Figure 15A.29 shows the results obtained with a 1 sec acquisition time. You can distinguish the individual tones with the increased acquisition time.

The following strategies achieve a finer frequency resolution:

- Decrease the sampling frequency, f_s . Decreasing f_s usually is not practical because decreasing f_s reduces the frequency range.
- Increase the number of samples, N . Increasing N yields an increased number of lines over the original frequency range.

Implement the decreased f_s strategy with zoom FFT analysis. Use baseband FFT and FFT-subset analyses to implement the increased N strategy. Baseband FFT analysis and FFT-subset analysis both achieve the same frequency resolution. However, FFT subset analysis only computes a narrow subset of the spectrum.

FIGURE 15A.28 Power spectrum obtained with an acquisition time of 10 msec.

Refer to Section 15A.7.2.1 and Section 15A.7.2.5 for examples that demonstrate the importance of frequency resolution in frequency analysis. The examples illustrate how to achieve a finer frequency resolution with the frequency analysis tools in the Sound and Vibration Toolkit.

15A.7.2.1 Zoom FFT Analysis

In some applications, it is necessary to obtain the spectral information with a very fine frequency resolution over a limited portion of the baseband span. In other words, you must zoom in on a spectral region to observe the details of that spectral region. Use the zoom FFT to obtain spectral information over a limited portion of the baseband span and with greater resolution. Just as in baseband analysis, the acquisition time determines the frequency resolution of the computed spectrum. The number of samples used in the transform determines the number of lines computed in the spectrum.

Zoom FFT analysis achieves a finer frequency resolution than the baseband FFT. The Zoom FFT VI acquires multiple blocks of data and downsamples to simulate a lower sampling frequency. The block size is decoupled from the achievable frequency resolution because the Zoom FFT VI accumulates the decimated data until you acquire the required number of points. Because the transform operates on a decimated set of data, you only need to compute a relatively small spectrum. The data are accumulated, so do not think of the acquisition time as the time required to acquire one block of samples. Instead, the acquisition time is the time required to accumulate the required set of decimated samples.

The Zoom FFT VIs complete the following steps to process the sampled data:

1. Modulate the acquired data to center the analysis band at 0 frequency.
2. Filter the modulated data in the time domain to isolate the analysis band and prevent aliasing when the data are resampled at a lower sampling frequency.
3. Decimate the filtered data to reduce the effective sampling frequency.
4. Accumulate the decimated data until sufficient samples are available to compute the spectrum.
5. Use the Discrete Zak Transform (DZT) to efficiently compute the desired spectral lines.
6. Demodulate, or shift, the computed spectrum.

15A.7.2.2 Frequency Resolution of the Zoom FFT VIs

Use the Zoom FFT VIs to compute the spectrum of a signal over a narrow frequency range with an arbitrarily fine frequency resolution. To get an approximation of the frequency resolution seen with the Zoom FFT VIs, use the following formula:

$$\text{frequency resolution} \approx \frac{\text{stop frequency} - \text{start frequency}}{\text{number of lines}}$$

Note: The exact frequency resolution is returned as d_f in the spectrum computed by the Zoom FFT VIs.

15A.7.2.3 Zoom Measurement

The following example demonstrates a zoom measurement of the power spectrum.

Acquire a sine wave at 1390 Hz with a National Instruments DSA device and the VI displayed in Figure 15A.30.

Acquire the signal at 51.2 kHz. The VI reads the data in blocks of 2048 samples. Compute the frequency resolution of this measurement using baseband analysis with the following equation:

$$\frac{51,200 \text{ Hz}}{2048} = 25 \text{ Hz}$$

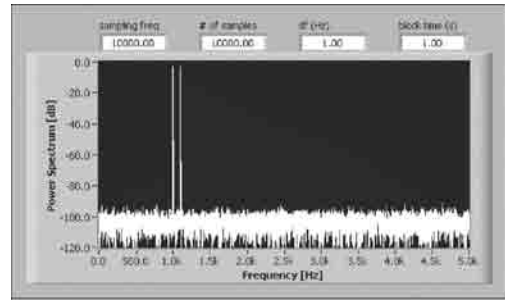

FIGURE 15A.29 Power spectrum obtained with an acquisition time of 1 sec.

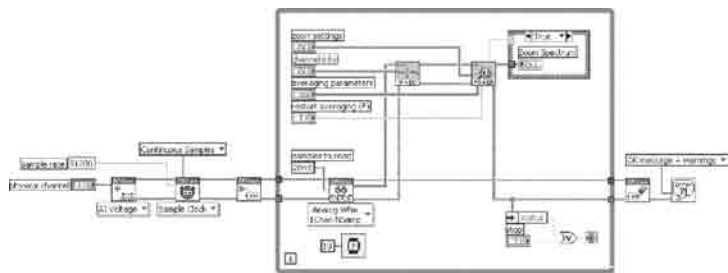

FIGURE 15A.30 Performing a zoom power spectrum measurement.

Use the SVT Zoom Power Spectrum VI located on the Zoom FFT palette to analyze a narrowband with a much finer frequency resolution. Figure 15A.31 shows the result of limiting the measurement to the frequency band between 1 and 2 kHz and computing 400 lines. Derive the frequency resolution of the computed spectrum with the following equation:

$$\frac{2000 - 1000 \text{ Hz}}{400 \text{ lines}} = 2.5 \text{ Hz}$$

FIGURE 15A.31 Zoom power spectrum measurement results.

15A.7.2.4 Zoom Settings

Figure 15A.32 shows the *zoom settings* control used to acquire the zoom measurement results displayed in Figure 15A.31. Use this control to specify the frequency range, window, number of lines, and percent overlap used in the zoom analysis.

FIGURE 15A.32 Zoom settings control.

15A.7.2.5 Subset Analysis

The Baseband Subset VIs located on the Baseband Subset palette allow one to compute a subset of the baseband FFT measurement. Subset analysis uses the DZT to compute a subset of the baseband FFT. The frequency resolution for spectral measurements computed with the Baseband Subset VIs equals the frequency resolution for measurements made with the Baseband FFT VIs. The acquisition time determines the frequency resolution. The only way to achieve a finer frequency resolution is to increase the length of the time record. In the case of baseband or subset analysis, a longer time record implies a larger block size.

The Baseband Subset VIs algorithm computes only the desired spectral lines. The only programming difference between the Baseband Subset VIs and the Baseband FFT VIs is the additional parameter *frequency range*. The frequency range parameter specifies which spectral lines the Baseband Subset VI computes. The computed spectral lines are always inclusive of the start frequency and the stop frequency.

Note: Setting the start frequency to 0 Hz and the stop frequency to f_{max} yields the same spectrum as the corresponding Baseband FFT VI. If you set the stop frequency to -1 , the baseband subset VIs return the Nyquist frequency as the highest frequency in the computed spectrum.

The following consideration can help you decide when to use the Baseband Subset VIs instead of the Baseband FFT VIs:

- The required block size yields an acceptable frequency resolution.
- The analysis of a narrow subset of the baseband span requires better processing performance than the Baseband FFT VI can provide.

15A.8 Transient Analysis

This Appendix discusses performing transient analysis with the Transient Analysis VIs located on the Transient Analysis palette.

15A.8.1 Transient Analysis with the Sound and Vibration Toolkit

Transient analysis is the analysis of nonstationary signals. The Transient Analysis VIs offer two different techniques for extracting information about transient signals. Use the short-time Fourier transform (STFT) for signals in which the frequency content changes relatively slowly with time. Use the shock-response spectrum (SRS) for shock signals.

You can use the STFT VIs to extract frequency information as a function of time directly from the signal of interest. Additionally, in the case of a rotating machine where a tachometer signal is simultaneously acquired with the signal of interest, the STFT VIs can extract frequency information as a function of the rotational speed.

The results generated by the STFT are typically displayed on a waterfall display or on a colormap. The STFT VIs return the information needed to properly scale the axes of the displays. You can pass the information directly to a Waterfall Display VI. Use property nodes for the colormap display.

You can use the SVT SRS VI to evaluate the severity of a shock signal. The results generated by the SRS are typically displayed on an X–Y graph.

Note: Other LabVIEW toolkits are available that provide additional transient analysis capabilities. The Order Analysis Toolkit is designed for rotating machinery analysis and monitoring. The Signal Processing Toolkit has tools, such as wavelets and joint time-frequency analysis (JTFA), for the analysis of fast transients.

15A.8.2 Performing an STFT vs. Time

The STFT available in the Sound and Vibration Toolkit can compute multiple Fourier transforms on the time-domain signal with or without overlapping.

For example, analyze a waveform containing 10 sec of data acquired at 51.2 kS/sec. The signal is a chirp signal with the following attributes:

- Start frequency = 10 Hz
- End frequency = 10,000 Hz

Figure 15A.33 shows the signal corresponding to the first 200 msec of the waveform.

Figure 15A.34 shows the result of applying a baseband FFT on the entire waveform.

Note: No window is applied on the signal.

FIGURE 15A.33 Chirp signal.

FIGURE 15A.34 Baseband FFT on a chirp signal.

The spectrum is flat from 10 Hz to 10 kHz. Only noise is measured at frequencies above 10 kHz. Unfortunately, this measurement does not provide any information about how the frequency content of the signal changes with time. However, the STFT can reveal useful information about the time dependence of the frequency content.

Instead of computing a single FFT on the whole data set, you can divide the data set into smaller blocks and compute FFTs on these smaller data blocks. For example, divide the signal into 100 msec blocks and perform an FFT on each of the blocks with the SVT STFT vs. Time VI.

Subdivide the time-domain signal by configuring the *time segment* control displayed in Figure 15A.35.

Leave *from [s]* and *to [s]* each equal to -1.00 to ensure that the entire signal is used in the STFT computation. In this particular example, the -1.00 setting in both *from [s]* and *to [s]* is equivalent to setting *from [s]* to 0 and *to [s]* to 10.

Create a 100 msec time increment by setting *time increment* to 100.00 and *time increment units (%)* to msec. The 100 msec time increment causes the SVT STFT vs. Time VI to compute one FFT every 100 msec. Setting time increment is independent from selecting the FFT block size.

FIGURE 15A.35 Time segment control.

15A.8.2.1 Selecting the FFT Block Size

In addition to the time segment, one can adjust the FFT block size. For example, analyze a chirp signal having the following attributes:

- Start frequency = 10 Hz
- End frequency = 10,000 Hz

The measurement is performed using the following settings:

- Acquisition time = 10 sec
- Sampling frequency = 51.2 kS/sec
- FFT block size = 1024 samples or 512 lines (400 alias-free lines)
- Time increment = 100 msec.

Based on the sampling frequency of 51,200 Hz, a 1024 sample FFT requires a 20 msec block of data, leading to a frequency resolution of 50 Hz.

Because the time increment is 100 msec and a 1024 sample FFT only requires a 20 msec block, only one block out of five is used for computation. Figure 15A.36 shows the result obtained with a 1024 sample FFT.

FIGURE 15A.36 STFT using a 1024 sample block size.

FIGURE 15A.37 STFT using a 4096 sample block size.

If you select an FFT Block size of 4096 samples, or 1600 alias-free lines, the resolution improves, as illustrated in Figure 15A.37. However, the increased resolution comes with the expense of extra processing.

15A.8.2.2 Overlapping

Overlapping is a method that uses a percentage of the previous data block to compute the FFT of the current data block. When combined with windowing, overlapping maximizes the use of the entire data set. If no overlapping is used, the part of the signal close to the window edges becomes greatly attenuated. The attenuation of the signal near the window edges could result in the loss of information in the region near the window edges.

Note: Set the desired overlapping rate by specifying % in the time increment units (%) in the time increment control. Refer to [Figure 15A.35](#) for the location of this control. No overlapping, or 0%, corresponds to a time increment of 100%. An overlapping of 75% corresponds to a time increment of 25%. An overlapping of 50% corresponds to a time increment of 50%, and so forth. The advantage of using the time increment control is that one can specify values greater than 100%. For example, a time increment of 200% corresponds to computing an FFT on every other block of data.

Figure 15A.38 and [Figure 15A.39](#) illustrate the overlapping process. Figure 15A.38 shows a 50% overlap.

FIGURE 15A.38 50% overlap.

Figure 15A.39 shows the resulting subdivisions when one uses a 50% overlap and a Hamming window.

15A.8.2.3 Using the SVT STFT vs. Time VI

The following example illustrates how to use the SVT STFT vs. Time VI. [Figure 15A.40](#) shows the block diagram.

The example in Figure 15A.40 acquires 10 sec of data at a sample rate of 51.2 kHz. After scaling, the signal is sent to the SVT STFT vs. Time VI. The result is displayed on the intensity graph in [Figure 15A.41](#).

Note: Use the X scale and Y scale offset and multiplier properties to properly scale the axes of the intensity graph. In this example, the X scale range is 0 to 10 sec. The Y scale range is 0 to 25,600 Hz. The Nyquist frequency is 25,600 Hz. You can adjust the Z scale so that only the relevant part of the signal is displayed. In other words, you can hide noise in the displayed signal by increasing the minimum limit of the Z-axis. Refer to the *LabVIEW Help* for information about the offset and multiplier properties for graph controls.

FIGURE 15A.39 Subdivisions of the time-domain waveform.

FIGURE 15A.40 Use of the SVT STFT vs. Time VI.

FIGURE 15A.41 STFT vs. time graph.

15A.8.3 Performing an STFT vs. Rotational Speed

Analyzing the frequency content as a function of the rotational speed is helpful when dealing with measurements on rotating machinery. Use the SVT STFT vs. RPM (analog) VI to analyze the frequency content as a function of the rotational speed.

15A.8.3.1 Converting the Pulse Train to Rotational Speed

Use the SVT Convert to RPM (analog) VI to convert a pulse train acquired by a tachometer or encoder to the rotational speed expressed in rotations per minute (RPM).

Note: For simplicity, the remainder of this Appendix uses the term tachometer to denote both a tachometer and an encoder.

In this example, an accelerometer is mounted at the test location for an engine run-up. A tachometer is used to measure the speed of the shaft and returns one pulse per revolution as a transistor–transistor logic (TTL) signal. Use the *tach info* control to specify the characteristics of the pulses generated by the tachometer. Figure 15A.42 shows the settings for the tachometer info control.

Figure 15A.43 shows a simulated tachometer signal.

You can use the SVT Convert to RPM (analog) VI to measure the rotational speed in RPM as a function of time. Figure 15A.44 shows the result obtained with the SVT Convert to RPM (analog) VI and a simulated tachometer signal.

15A.8.3.2 STFT vs. RPM

You also can display the STFT of an input signal as a function of the rotational speed based on the tachometer signal. Two input signals are needed, the signal of interest and the signal from the tachometer. Again, an engine run-up serves as a good example of computing an STFT as a function of the rotational speed.

During an engine run-up, the sound pressure close to the engine is measured with a microphone. Figure 15A.45 shows the signal acquired by the microphone.

The signal from the tachometer is also acquired. The measured tachometer signal is converted to RPM with the SVT Convert to RPM (analog) VI. Figure 15A.46 shows the rotational speed as a function of time, as computed by the SVT Convert to RPM (analog) VI.

Using the SVT STFT vs. RPM (analog) VI allows you to measure the frequency content of the signal as a function of the rotational speed of the engine. Figure 15A.47 displays the results obtained with the SVT STFT vs. RPM (analog) VI on an intensity graph.

FIGURE 15A.42 Tachometer info control.

FIGURE 15A.43 Tachometer signal.

FIGURE 15A.44 Result from SVT convert to RPM (analog) VI.

FIGURE 15A.45 Microphone signal obtained during engine run-up.

15A.8.4 Measuring a Shock Response Spectrum

Obtain the SRS by applying the acquired shock pulse to a series of single degree of freedom (SDOF) systems. Plot the system maximum response as resonance frequency of the system.

An SDOF mechanical system consists of the following components:

- Mass, whose value is represented with the variable m
- Spring, whose stiffness is represented with the variable k
- Damper, whose damping coefficient is represented with the variable c

The resonance frequency f_N , and the critical damping factor, z , characterize an SDOF system, where

$$f_N = \frac{1}{2\pi} \sqrt{\frac{k}{m}}$$
$$\zeta = \frac{c}{2\sqrt{km}}$$

For light damping, where z is less than or equal to 0.05, the peak value of the frequency response occurs in the immediate vicinity of f_N and is given by the following equation, where Q is the resonant gain:

$$Q = \frac{1}{2\zeta}$$

Figure 15A.48 illustrates the response of an single-DoF system to a half-sine pulse with a 10g acceleration amplitude and 10 msec duration. The top graph shows the time-domain acceleration. The middle graph is the single-DoF system response with a 50 Hz resonance frequency. The bottom graph is the single-DoF system response with a 150 Hz resonance frequency. In both cases, z is 0.05.

Use the signals shown in Figure 15A.48 to construct the SRS. For example, the *maximax*, the absolute maximum response of the calculated shock response over the entire signal duration, uses the absolute maximum system response as a function of the system natural frequency. Figure 15A.49 illustrates the maximax SRS for the same half-sine pulse.

Note: Each computed SRS is specific to the pulse used to perform the measurement.

You can use other types of shock spectra depending on the application. These spectra include the initial shock response from the system response over the pulse duration or from the residual shock

FIGURE 15A.46 Rotational speed as a function of time during engine run-up.

FIGURE 15A.47 Intensity graph of sound pressure level for an engine run-up.

FIGURE 15A.48 Single-DoF system response to a half-sine shock.

spectrum from the system response after the pulse. You can use the positive maximum, the negative maximum, or the absolute maximum response signal value.

The Sound and Vibration Toolkit uses the Smallwood algorithm to compute the SRS. The SVT Shock Response Spectrum VI also offers the ability to preprocess the time-domain signal to improve SRS results. You can remove any DC component or apply a low-pass filter with a selectable cut-off frequency.

The SVT Shock Response Spectrum VI can compute the SRS from the absolute acceleration response or from the relative displacement response. Use the *model* control on the SVT Shock Response Spectrum VI to select the appropriate response.

Figure 15A.50 shows how to use the SVT Shock Response Spectrum VI. The example in Figure 15A.50 acquires 1000 samples of data from an accelerometer during a shock. The shock signal triggers the acquisition. The program stores 100 samples before the trigger to properly capture the entire shock signal.

Figure 15A.51 displays the acquired time-domain signal and the computed SRS.

FIGURE 15A.49 Half-sine pulse SRS (Maximax).

15A.9 Waterfall Display

This Appendix discusses using the Waterfall Display VIs located on the Waterfall Display palette.

15A.9.1 Using the Display VIs

Waterfall display is a visualization technique that permits the visual representation of various analyses of nonstationary signals, such as machine run-up, coast down, transients, and others.

Use the Waterfall Display VIs to display FFT spectra from frequency analysis or transient analysis and octave spectra from octave analysis in waterfall graphs. Refer to *Front Panel Displays* in the *LabVIEW Help* for more information about displaying octave results.

Specific Waterfall Display VIs display the results of frequency analysis and octave analysis in a waterfall graph. The waterfall display opens in an external window called the *Waterfall* window.

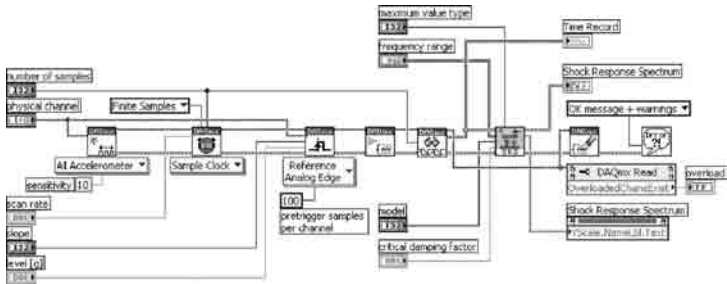

FIGURE 15A.50 Using the SVT shock response spectrum VI.

Complete the following basic steps to display results on a waterfall graph:

- 1. Initialize the display.
- 2. Send data to the display.
- 3. Close the waterfall display.

Figure 15A.52 shows the Waterfall window.

15A.9.1.1 Initializing the Display

Use the SVL Initialize Waterfall Display VI to create a reference to a waterfall display. If you are displaying octave spectra, use the SVT Initialize Waterfall Display for Octave VI. Both of the initializing VIs also enable one to define graph properties, including the window title, the bounds of the external window, and the colors used in the waterfall display.

15A.9.1.2 Sending Data to the Display

The Waterfall window does not open until it receives data sent to it. Use the SVL Send Data to Waterfall VI to send data to a waterfall display. Use the SVT Send Data to Waterfall for Octave VI to send octave data to a waterfall display.

The SVL Send Data to Waterfall VI is polymorphic and accepts an array of spectra, such as that returned by a power spectrum, a two-dimensional (2D) array, or a STFT.

15A.9.1.3 Waterfall Display for Frequency Analysis

The following example shows how to accumulate 20 spectra and display them in a waterfall graph. Figure 15A.53 shows the block diagram for the VI.

Twenty data blocks of 1024 samples are acquired. The power spectrum is computed on each block. The autoindexing capability of the For Loop is used to build an array of 20 spectra. The array of spectra is sent to the waterfall display. Refer to the *LabVIEW Help* for information about autoindexing.

15A.9.1.4 Waterfall Display for Transient Analysis

This example illustrates how to use the waterfall display in conjunction with the Transient Analysis VIs. Figure 15A.54 shows the block diagram for the example VI.

FIGURE 15A.51 Acquired SRS (Maximax).

FIGURE 15A.52 Waterfall display for frequency analysis.

FIGURE 15A.53 Waterfall display for frequency analysis VI block diagram.

FIGURE 15A.54 STFT VI block diagram.

The data are scaled and sent to the SVT STFT vs. Time VI. The SVT STFT vs. Time VI returns a 2D array. You can use the results in the 2D array in an intensity graph or connect the 2D array directly to the SVL Send Data to Waterfall VI. Figure 15A.54 shows the 2D array connected directly to the Waterfall VI. The while loop keeps the waterfall display open until the *Stop* control is set to TRUE.

Note: Connect f_0 and Δf and y_0 and Δy on the SVL Send Data to Waterfall VI to ensure the graph shows the proper scales.

Figure 15A.55 shows the result obtained with the STFT VI illustrated in Figure 15A.54.

FIGURE 15A.55 STFT waterfall display.

15A.9.1.5 Waterfall Display for Octave Spectra

To display octave spectra in a waterfall display, use the SVT Initialize Waterfall Display for Octave and SVT Send Data to Waterfall for Octave VIs. Figure 15A.56 shows the block diagram for a VI displaying octave spectra in a waterfall display.

Figure 15A.57 shows the waterfall display created by the VI in Figure 15A.56.

15A.10 Swept-Sine Measurements

This Appendix discusses using the swept-sine VIs located on the Swept Sine palette (see Chapter 17). The swept-sine measurements include dynamic measurements for stimulus level, response level, frequency response (gain and phase), THD, and individual harmonic distortion.

15A.10.1 Swept-Sine Overview

Swept sine is a technique for characterizing the frequency response of the DUT. Two techniques are commonly used in swept-sine measurements. The first technique slowly sweeps through a range of

FIGURE 15A.56 Block diagram for VI displaying octave spectra.

frequencies in a manner similar to a chirp. Figure 15A.58 shows an example of the excitation signal for this form of swept-sine measurement.

The second technique steps through a range of frequencies. Figure 15A.59 shows an example of the excitation signal for this form of swept-sine measurement. The swept sine implemented in the Sound and Vibration Toolkit generates an excitation signal that steps through a range of test frequencies, similar to the signal in Figure 15A.59. Both techniques can yield similar results. However, they require very different measurement analysis processes.

Swept-sine frequency-response measurements compare a response signal to the stimulus tone in order to compute the FRF of the DUT. The magnitude of the FRF is equivalent to gain and represents the ratio of the output level to the input level for each test frequency. The phase of the FRF is equivalent to the phase lag introduced by the DUT for each test frequency.

Swept-sine measurements require a signal source. The stimulus signal is always a single tone that excites the DUT at the test frequency. Since the stimulus is a single tone, swept-sine analysis can measure the harmonic distortion while simultaneously measuring the linear response.

FIGURE 15A.57 Waterfall display for octave spectra analysis.

15A.10.2 Choosing Swept-Sine vs. FFT Measurements

The frequency response of the DUT is a useful tool. The Sound and Vibration Toolkit provides two distinct techniques to measure the frequency response. The swept-sine technique performs single-tone

FIGURE 15A.58 Sweeping swept sine example.

FIGURE 15A.59 Stepping swept sine example.

TABLE 15A.8 Swept Sine and FFT Differences

Swept-Sine Frequency Response	FFT-Based Frequency Response
Single-tone excitation	Broadband excitation
Can measure harmonics	Cannot measure harmonics
Arbitrary test frequencies	Linearly spaced frequency resolution
Longer test time for many test frequencies	
Better dynamic range possibility	

measurements at each test frequency. The FFT-based technique measures the response over the entire acquisition bandwidth. Table 15A.8 lists the basic differences between swept-sine and FFT-based techniques for measuring frequency response.

Swept-sine measurements offer superior dynamic range over FFT-based measurements because you can optimize the signal level and input ranges at each test frequency. FFT-based techniques must specify a signal level and input ranges appropriate for the maximum broadband response.

Figure 15A.60 shows the simulated frequency response function for a four-DoF system. The peak at 17.6 Hz has a magnitude roughly 1000 times larger than the peak at 5.8 Hz. To use an FFT-based technique, use broadband excitation to excite the entire frequency range of interest, to measure the frequency response. This situation forces one to set the input range so that the overall response does not overload the DUT or the acquisition device. Therefore, when you measure the response at 5.8 Hz, you lose 60 dB of measurement dynamic range. The swept-sine technique allows you to tailor the excitation amplitude to the specific test frequency, preserving the full measurement dynamic range.

FFT-based measurements are limited to a linearly spaced frequency resolution determined by the sample rate and the block size. Refer to [Appendix 15A.7](#) for more information on FFT-based measurements. When the response changes rapidly, this frequency resolution may not yield enough information about the dynamic response. Also, a linear resolution may yield an excessive amount of information in frequency regions where the dynamic response is relatively constant. Swept-sine analysis has the ability to test arbitrary frequency resolutions that are linear, logarithmic, or adapted to the dynamic response of the DUT. When the frequency resolution is adapted to the DUT dynamic response, you can test more frequencies in regions where the dynamic response is of interest to your application and fewer where it is not.

The main benefit of swept-sine analysis is the ability to measure harmonic distortion simultaneously with linear response. FFT-based analysis offers a speed advantage for broadband measurements with many test frequencies.

15A.10.3 Taking a Swept-Sine Measurement

Use the SVT Initialize Swept Sine VI to create a new swept-sine task for the designated device, source channel settings, and acquisition channel settings. Swept sine in the Sound and Vibration Toolkit only supports measurements on a single device with output and input capabilities.

Use configure swept sine VIs in the configure swept sine palette to configure the scaling, test frequencies, averaging, delays, and other measurement settings. These configuration VIs allow control over basic and advanced measurement parameters. The order in which you place the configuration VIs is important, as it allows you to customize a swept-sine measurement. For example, you can easily generate

FIGURE 15A.60 Swept-sine and FFT measurements.

FIGURE 15A.61 Customizing a swept-sine measurement.

100 logarithmically spaced test frequencies in the audio range, then apply inverse A-weighted scaling to the excitation level by adding code similar to that in Figure 15A.61 into your swept-sine application.

You can use the swept-sine configuration VIs to customize your swept-sine application. For example, to speed up a swept-sine measurement, reduce the settling or integration time specified by the SVT Set Swept Sine Averaging VI. You also can configure the device IEPE with the SVT Set Swept Sine Coupling and IEPE Excitation (DAQmx) VI. You also can reduce the *block duration* input to SVT Set Swept Sine Block Duration VI.

Note: The minimum block duration is limited by the capabilities of the computer processing the measurement. A very small block duration can result in a loss of continuous processing, causing the swept-sine measurement to stop and return an error.

Use the SVT Start Swept Sine VI to begin the generation and acquisition. The VI fills the device output buffer with zeros before writing the first test frequency excitation.

The SVT Swept Sine Engine VI continually acquires data and processes it to remove samples acquired during delays, transitions, and settling periods. The SVT Swept Sine Engine VI performs measurement analysis on samples acquired during integration periods. The SVT Swept Sine Engine VI updates the excitation to excite the DUT at the next test frequency after it integrates sufficient data at the current test frequency.

Note: The transition to the next excitation tone, both frequency and amplitude, always occurs at a zero crossing to minimize transients introduced to the DUT.

Use the Read Swept Sine Measurements VIs in the Read Swept Sine Measurements palette to read the raw measurements, scale the measurements, and perform additional conversions to display and report the data in the desired format.

Use the SVT Close Swept Sine VI to stop the generation and acquisition, and clear the swept-sine task.

15A.10.4 Swept-Sine Measurement Example

This example of a swept-sine application measures the frequency response and harmonic distortion of a notch filter. In this example, a NI PXI-4461 generates the excitation signal and acquires the stimulus and response signals.

Figure 15A.62 illustrates the connection scheme used in this example to measure the dynamic response of the DUT using a swept-sine measurement. The acquired stimulus signal on the analog input channel 0, the AI0, is the generated excitation signal from the analog output channel 0, AO0.

The NI PXI-4461 converts the desired stimulus signal from digital data to an analog signal and outputs that signal on AO0. The excitation signal is

FIGURE 15A.62 Swept-sine measurement connection diagram.

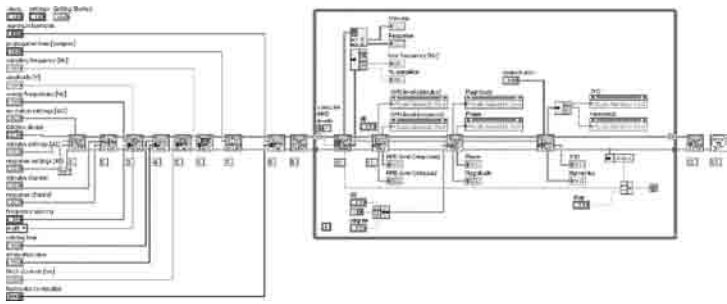

FIGURE 15A.63 Block diagram of SVXMPL_swept sine FRF DAQmx VI.

TABLE 15A.9 Swept Sine Measurement Steps

Step Number	Description	Optional or Required
1	Initialize a swept-sine measurement by specifying the hardware device and channel settings	Required
2	Specify the scaling that will be applied to the acquired stimulus and response data.	Optional
3	Configure the source by specifying the test frequencies, amplitude, and whether or not the sweep automatically restarts after completion	Required
4	Set the settling and integration parameters to allow sufficient time for the DUT to settle before the measurement is performed at the new test frequency and that there is sufficient integration time to achieve the desired level of accuracy	Required
5	Set the block duration input terminal for the measurement to be small enough to give a reasonable test time and large enough so that it does not put the test computer at risk of being unable to continuously generate and read the signals. The smaller the block size, the faster the swept sine can transition from one test frequency to the next	Optional
6	Explicitly set the sample rate for the measurement. The rate is automatically selected if this VI is not used. The same rate is used for input and output channels	Optional
7	Specify the <i>propagation time</i> terminal input specific to the DAQ device being used for the measurement. You can measure the device propagation time using the SVL Measure Propagation Delay VI. Refer to Appendix 3, <i>Scaling and Calibration</i> , for more information	Optional
8	Configure the harmonic distortion measurement by specifying the maximum harmonic to use in the computation of the THD. Only those harmonics specified in the <i>harmonics to visualize</i> array return individual harmonic components	Required if performing distortion measurements
9	Start the swept sine to perform the hardware configuration and start the output and input tasks. Channel synchronization is performed internally in this VI	Required
10	Generate the excitation and acquire the stimulus and response data at each test frequency	Required
11	Convert the raw data to the specified format in order to display and report measurement results	Required
12	Stop the swept-sine measurement and clear the output and input tasks to release the device	Required

connected to both the stimulus input channel AI0 and the input terminal of the DUT. The response signal is connected from the output terminal of the DUT to the response input channel AI1.

The DUT for this example is a notch filter centered at 1 kHz.

Figure 15A.63 shows the block diagram of the example SVXMPL_swept sine FRF DAQmx VI, which ships with the Sound and Vibration Toolkit.

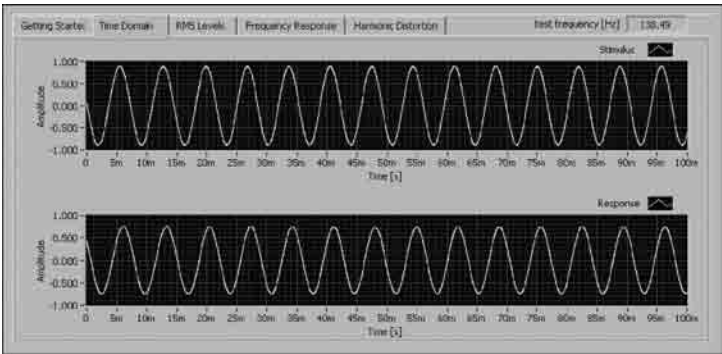

FIGURE 15A.64 Time-domain results.

FIGURE 15A.65 Magnitude and phase response of a 1 kHz notch filter.

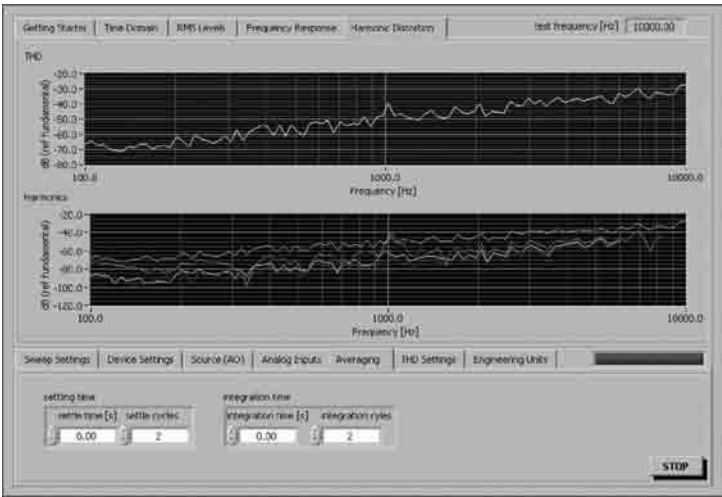

FIGURE 15A.66 THD vs. frequency.

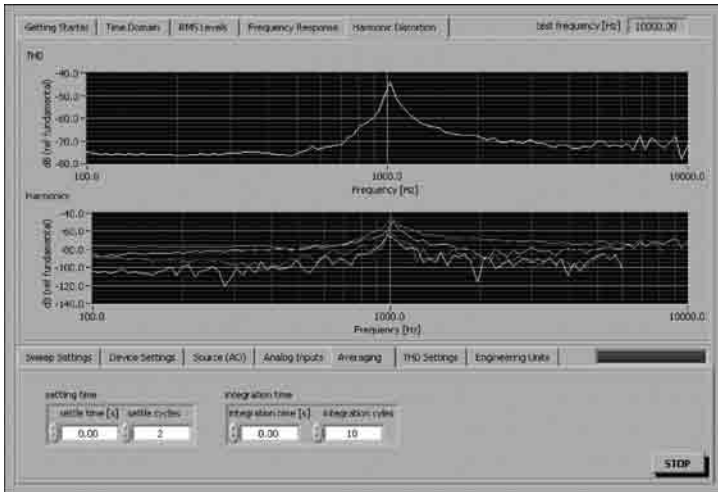

FIGURE 15A.67 THD vs. frequency results.

Table 15A.9 documents the actions performed by the VIs in Figure 15A.63. Some steps are required and must be done for the VI to function correctly. The optional steps allow you to customize your measurement.

The while loop in Figure 15A.63 controls the synchronized generation and acquisition. Display controls and measurement indicators are updated inside the while loop. This loop allows for the monitoring of intermediate results.

Many of the steps in Table 15A.9 are configuration steps. Through the Sound and Vibration Toolkit swept-sine configuration VIs, you can specify numerous configuration parameters to achieve fine control of the swept-sine measurement parameters. For many applications two or three configuration VIs are sufficient.

It is important to allow for the propagation delay of the DAQ or DSA device. This delay is specific to the device used to perform the measurement. To determine the device propagation delay, refer to the device documentation or measure the delay with the SVL Measure Propagation Delay VI.

Figures 15A.64 to 15A.67 display measurement results obtained with the SVXMPL_swept sine FRF DAQmx VI example program. Figure 15A.64 shows the time-domain stimulus and response signals for the 138.49 Hz test frequency. From the time-domain data, you can see that the notch filter has attenuated the signal and introduced a phase shift.

Figure 15A.65 shows the magnitude and phase responses of the notch filter at all the test frequencies in the magnitude and phase spectra in the Bode plot.

In addition to measuring the frequency response, this example simultaneously measures the harmonic distortion at each test frequency. Figure 15A.66 shows the graph of THD vs. frequency.

You expect to see a peak in the THD at the notch frequency. The peak occurs because the fundamental frequency is attenuated at the notch frequency. However, the graph indicates that this measurement has failed to accurately identify the power in the harmonic distortion components. For the example in Figure 15A.66, the number of *integration cycles* is two. More integration cycles must be specified to perform accurate harmonic distortion measurements. If you change the number of integration cycles to ten and rerun the example, you obtain the THD vs. frequency results displayed in Figure 15A.67.

Now, with a sufficient number of integration cycles specified, you can see the characteristic peak in the THD at the center frequency of the notch filter.

Summary

This chapter concerns the conditioning of signals in a vibrating system and the conversion of signals in one form to another as needed. Amplification, filtering, modulation, demodulation, analog/digital conversion, voltage/frequency conversion, voltage/current conversion, linearization, bridge circuits, and signal analysis and display devices are presented. Hardware, software, and techniques are considered. Issues of impedance and loading associated with the interconnection of components are addressed.

16.1 Introduction

Signal modification is an important function in many applications of vibration. The tasks of signal modification may include: *signal conditioning* (e.g., amplification, and analog and digital filtering); *signal conversion* (e.g., analog-to-digital conversion, digital-to-analog conversion, voltage-to-frequency conversion, and frequency-to-voltage conversion); *modulation* (e.g., amplitude modulation, frequency modulation, phase modulation, pulse-width modulation, pulse-frequency modulation, and pulse-code modulation); and *demodulation* (the reverse process of modulation). In addition, many other types of useful signal modification operations can be identified. For example, *sample and hold circuits* are used in digital data acquisition systems. Devices such as *analog and digital multiplexers* and *comparators* are needed in many applications of data acquisition and processing. Phase shifting, curve shaping, offsetting, and linearization can also be classified as signal modification. This chapter describes signal conditioning and modification operations that are useful in vibration applications. Signal modification plays a crucial role in component interfacing. When two devices are interfaced, it is essential to ensure that a signal leaving one device and entering the other will do so at proper signal levels (voltage, current, power), in the proper form (analog, digital), and without distortion (loading and impedance considerations). A signal should be properly modified for transmission by amplification, modulation, digitizing, and so on, so that the signal/noise ratio of the transmitted signal is sufficiently large at the receiver. The significance of signal modification is clear from these observations.

16.2 Amplifiers

The level of an electrical signal can be represented by variables such as voltage, current, and power. Analogous across variables, through variables, and power variables can be defined for other types of signals (e.g., mechanical) as well. Signal levels at various interface locations of components in a vibratory system have to be properly adjusted for proper performance of these components and of the overall system. For example, input to an actuator should possess adequate power to drive the actuator. A signal should maintain its signal level above some threshold during transmission so that errors due to signal weakening will not be excessive. Signals applied to digital devices must remain within the specified, logic levels. Many types of sensors produce weak signals that have to be upgraded before they can be fed into a monitoring system, data processor, controller, or data logger.

Signal amplification concerns the proper adjustment of a signal level for performing a specific task. Amplifiers are used to accomplish signal amplification. An amplifier is an active device that needs an external power source to operate. Even though active circuits, amplifiers in particular, can be developed in the monolithic form using an original integrated-circuit (IC) layout so as to accomplish a particular amplification task, it is convenient to study their performance using the *operational amplifier* (opamp) as the basic element. Of course, operational amplifiers are widely used not only for modeling and analyzing other types of amplifier but also as basic elements in building other kinds of amplifier. For these reasons, our discussion on amplifiers will revolve around the operational amplifier.

16.2.1 Operational Amplifier

The origin of the operational amplifier dates to the 1940s when the vacuum tube operational amplifier was introduced. The operational amplifier, or *opamp*, got its name due to the fact that originally it was used almost exclusively to perform mathematical operations; for example, it was used in analog computers. Subsequently, in the 1950s, the transistorized opamp was developed. It used discrete elements such as *bipolar junction transistors* and *resistors*. The opamp was still too large in size, consumed too much power, and was too expensive for widespread use in general applications. This situation changed in the late 1960s when IC opamp was developed in the monolithic form as a single IC chip. Today, the IC opamp, which consists of a large number of circuit elements on a *substrate*, typically of a single *silicon crystal* (the monolithic form), is a valuable component in almost any signal modification device.

An opamp could be manufactured in the discrete-element form using perhaps ten bipolar junction transistors and as many discrete resistors; alternatively (and preferably), it may be manufactured in the modern monolithic form as an IC chip that may be equivalent to over 100 discrete elements. In any form, the device has an *input impedance*, Z_i , an *output impedance*, Z_o , and a gain, K . Hence, a schematic model for an opamp can be given as in Figure 16.1(a). The conventional symbol of an opamp is shown in Figure 16.1(b). Typically, there are about six terminals (lead connections) to an opamp. For example, there may be two input leads (a *positive lead* with voltage v_{ip} and a *negative lead* with voltage v_{in}), an output lead (voltage v_o), two bipolar power supply leads ($+v_s$ and $-v_s$), and a ground lead.

Note from Figure 16.1(a) that, under open-loop (no feedback) conditions

$$v_o = K v_i \quad (16.1)$$

in which the input voltage, v_i , is the differential input voltage defined as the algebraic difference between the voltages at the positive and negative lead; thus

$$v_i = v_{ip} - v_{in} \quad (16.2)$$

The *open loop voltage gain* K is very high (10^5 to 10^9) for a typical opamp. Furthermore, the input impedance, Z_i , could be as high as $1 \text{ M}\Omega$ and the output impedance is low, of the order of 10Ω . Since v_o is typically 1 to 10 V, from Equation 16.1 it follows that $v_i \cong 0$ since K is very large. Hence, from Equation 16.2, we have $v_{ip} \cong v_{in}$. In other words, the voltages at the two input leads are nearly equal. Now, if we apply a large voltage differential v_i (say, 1 V) at the input then, according to Equation 16.1, the output voltage should be extremely high. This never happens in practice, however, since the device saturates quickly beyond moderate output voltages (of the order of 15 V).

From Equation 16.1 and Equation 16.2, it is clear that if the negative input lead is grounded (i.e., $v_{in} = 0$), then

$$v_o = K v_{ip} \quad (16.3)$$

and, if the positive input lead is grounded (i.e., $v_{ip} = 0$)

$$v_o = -K v_{in} \quad (16.4)$$

Accordingly, v_{ip} is termed *noninverting input* and v_{in} is termed *inverting input*.

Example 16.1

Consider an opamp having an open-loop gain of 1×10^5 . If the saturation voltage is 15 V, determine the output voltage in the following cases:

1. $5 \mu\text{V}$ at the positive lead and $2 \mu\text{V}$ at the negative lead.
2. $-5 \mu\text{V}$ at the positive lead and $2 \mu\text{V}$ at the negative lead.
3. $5 \mu\text{V}$ at the positive lead and $-2 \mu\text{V}$ at the negative lead.
4. $-5 \mu\text{V}$ at the positive lead and $-2 \mu\text{V}$ at the negative lead.
5. 1 V at the positive lead and negative lead grounded.
6. 1 V at the negative lead and positive lead grounded.

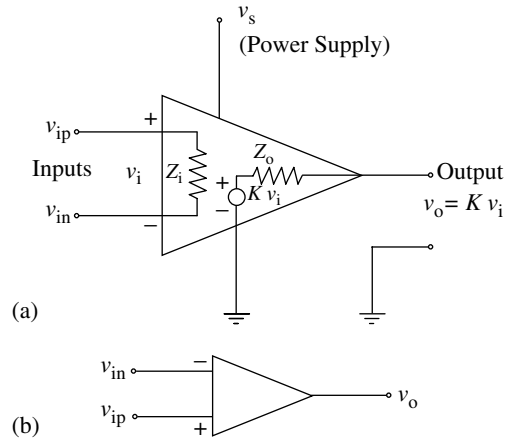

FIGURE 16.1 Operational amplifier: (a) a schematic model; (b) conventional symbol.

0	$1\ \text{V}$	$-1\ \text{V}$	$-15\ \text{V}$

Solution

This problem can be solved using Equation 16.1 and Equation 16.2. The results are given in Table 16.1. Note that, in the last two cases, the output will saturate and Equation 16.1 will no longer hold.

Field effect transistors (FET), for example, metal oxide semiconductor field effect transistors (MOSFET), could be used in the IC form of an opamp. The MOSFET type has advantages over many other types; for example, such opamps have higher input impedance and more stable output (almost equal to the power supply voltage) at saturation. This makes the MOSFET opamps preferable over bipolar junction transistor opamps in many applications.

In analyzing operational amplifier circuits under unsaturated conditions, we use the following two characteristics of an opamp:

1. Voltages of the two input leads should be (almost) equal.
2. Currents through each of the two input leads should be (almost) zero.

As explained earlier, the first property is credited to high open-loop gain and the second property to high input impedance in an operational amplifier. We shall repeatedly use these two properties to obtain input–output equations for amplifier systems.

16.2.2 Use of Feedback in Opamp

The operation amplifier is a very versatile device, primarily due to its very high input impedance, low output impedance, and very high gain. However, it cannot be used without modification as an amplifier because it is not very stable, as shown in Figure 16.1. Two factors that contribute to this problem are:

1. Frequency response
2. Drift

Stated in another way, opamp gain, K , does not remain constant; it can vary with the frequency of the input signal (i.e., frequency-response function is not flat in the operating range); also, it can vary with time (i.e., *drift*). The frequency-response problem arises due to circuit dynamics of an operational amplifier. This problem is usually not severe unless the device is operated at very high frequencies. The drift problem arises due to the sensitivity of gain, K , to environmental factors such as temperature, light, humidity, and vibration, and as a result of variation of K due to aging. Drift in an opamp can be significant and steps should be taken to remove that problem.

It is virtually impossible to avoid drift in gain and frequency-response error in an operational amplifier. However, an ingenious way has been found to remove the effect of these two problems at the amplifier output. Since gain K is very large, by using feedback we can virtually eliminate its effect at the amplifier output. This *closed loop* form of an opamp is preferred in almost every application. In particular, the *voltage follower* and *charge amplifier* are devices that use the properties of high Z_i , low Z_o , and high K of an opamp, along with feedback through a precision resistor, to eliminate errors due to nonconstant K . In summary, the operational amplifier is not very useful in its *open-loop* form, particularly because gain, K , is not steady. However, since K is very large, the problem can be removed by using feedback. It is this *closed-loop* form that is commonly used in the practical applications of an opamp.

In addition to the nonsteady nature of gain, there are other sources of error that contribute to the less than ideal performance of an operational amplifier circuit. Noteworthy are:

1. *offset current* present at input leads due to bias currents that are needed to operate the solid-state circuitry
2. *offset voltage* that might be present at the output even when the input leads are open
3. unequal gains corresponding to the two input leads (i.e., the *inverting gain* not equal to the *noninverting gain*)

Such problems can produce nonlinear behavior in opamp circuits, and they can be reduced by proper circuit design and through the use of compensating circuit elements.

16.2.3 Voltage, Current, and Power Amplifiers

Any type of amplifier can be constructed from scratch in the monolithic form as an IC chip, or in the discrete form as a circuit containing several discrete elements such as discrete bipolar junction transistors or discrete FETs, discrete diodes, and discrete resistors. However, almost all types of amplifiers can also be built using operational amplifier as the basic element. Since we are already familiar with opamps and since opamps are extensively used in general amplifier circuitry, we prefer to use the latter approach, which uses discrete opamps for the modeling of general amplifiers.

If an electronic amplifier performs a voltage amplification function, it is termed a *voltage amplifier*. These amplifiers are so common that, the term “amplifier” is often used to denote a voltage amplifier. A voltage amplifier can be modeled as

$$v_o = K_v v_i \quad (16.5)$$

in which

v_o = output voltage
 v_i = input voltage
 K_v = voltage gain

Voltage amplifiers are used to achieve voltage compatibility (or level shifting) in circuits.

Current amplifiers are used to achieve current compatibility in electronic circuits. A *current amplifier* may be modeled by

$$i_o = K_i i_i \quad (16.6)$$

in which

i_o = output current
 i_i = input current
 K_i = current gain

Note that voltage follower has $K_v = 1$ and, hence, it may be considered to be a current amplifier. Also, it provides impedance compatibility and acts as a buffer between a low-current (high-impedance) output device (the device that provides the signal) and a high-current (low-impedance) input device (the device that receives the signal) that are interconnected. Hence, the name *buffer amplifier* or *impedance transformer* is sometimes used for a current amplifier with unity voltage gain.

If the objective of signal amplification is to upgrade the associated power level, then a *power amplifier* should be used for that purpose. A simple model for a power amplifier is

$$p_o = K_p P_i \quad (16.7)$$

in which

p_o = output power
 P_i = input power
 K_p = power gain

It is easy to see from Equation 16.5 to Equation 16.7 that

$$K_p = K_v K_i \tag{16.8}$$

Note that all three types of amplification could be achieved simultaneously from the same amplifier. Furthermore, a current amplifier with unity voltage gain (for example, a voltage follower) is a power amplifier as well. Usually, voltage amplifiers and current amplifiers are used in the first stages of a signal path (e.g., sensing, data acquisition, and signal generation) where signal levels and power levels are relatively low. Power amplifiers are typically used in the final stages (e.g., actuation, recording, and display) where high signal levels and power levels are usually required.

Figure 16.2(a) shows an opamp-based voltage amplifier. Note the feedback resistor, R_f , that serves the purposes of stabilizing the opamp and providing an accurate voltage gain. The negative lead is grounded through an accurately known resistor, R . To determine the voltage gain, recall that the voltages at the two input leads of an opamp should be virtually equal. The input voltage, v_i , is applied to the positive lead of

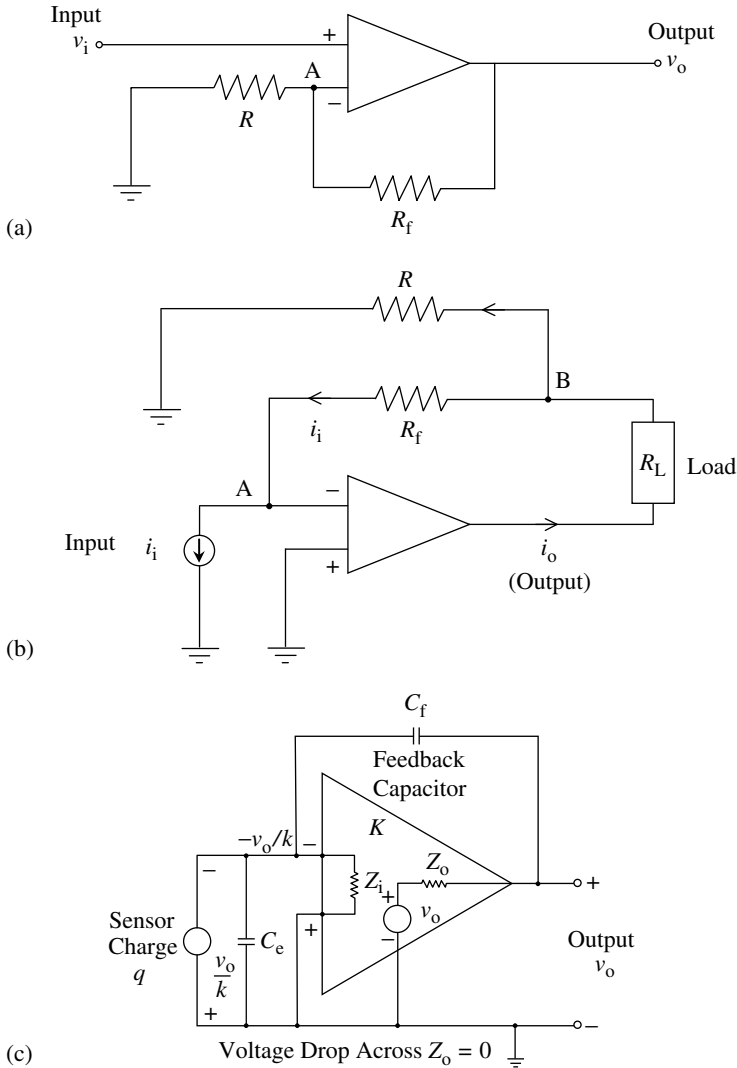

FIGURE 16.2 (a) A voltage amplifier; (b) a current amplifier; (c) a charge amplifier.

the opamp. Then the voltage at point A should also be equal to v_i . Next, recall that the current through the input lead of an opamp is virtually zero. Hence, by writing the current balance equation for the node point A, we have

$$\frac{v_o - v_i}{R_f} = \frac{v_i}{R}$$

This gives the amplifier equation

$$v_o = \left(1 + \frac{R_f}{R}\right)v_i \quad (16.9a)$$

Hence, the voltage gain is given by

$$K_v = 1 + \frac{R_f}{R} \quad (16.9b)$$

Note the K_v depends on R and R_f and not on the opamp gain. Hence, the voltage gain can be accurately determined by selecting the two resistors, R and R_f , precisely. Also note that the output voltage has the same sign as the input voltage. Hence, this is a *noninverting amplifier*. If the voltages are of the opposite sign, we will have an *inverting amplifier*.

A current amplifier is shown in Figure 16.2(b). The input current, i_i , is applied to the negative lead of the opamp as shown and the positive lead is grounded. There is a feedback resistor R_f connected to the negative lead through the load R_L . The resistor R_f provides a path for the input current since the opamp takes in virtually zero current. There is a second resistor R through which the output is grounded. This resistor is needed for current amplification. To analyze the amplifier, note that the voltage at point A (i.e., at the negative lead) should be zero because the positive lead of the opamp is grounded (zero voltage). Furthermore, the entire input current, i_i , passes through resistor, R_f , as shown. Hence, the voltage at point B is $R_f i_i$. Consequently, current through resistor R is $R_f i_i / R$, which is positive in the direction shown. It follows that the output current, i_o , is given by

$$i_o = i_i + \frac{R_f}{R} i_i$$

or

$$i_o = \left(1 + \frac{R_f}{R}\right)i_i \quad (16.10a)$$

The current gain of the amplifier is

$$K_i = 1 + \frac{R_f}{R} \quad (16.10b)$$

This gain can be accurately set using the high-precision resistors, R and R_f .

16.2.3.1 Charge Amplifiers

The principle of capacitance feedback is utilized in charge amplifiers. These amplifiers are commonly used for conditioning the output signals from piezoelectric transducers. A schematic diagram for the charge amplifier is shown in Figure 16.2(c). The feedback capacitance is denoted by C_f and the connecting cable capacitance by C_c . The charge amplifier views the sensor as a charge source (q), even though there is an associated voltage. Using the fact that charge = voltage \times capacitance, a charge balance equation can be written:

$$q + \frac{v_o}{K} C_c + \left(v_o + \frac{v_o}{K}\right) C_f = 0 \quad (16.11)$$

From this, we obtain

$$v_o = -\frac{K}{(K+1)C_f + C_c} q \quad (16.12a)$$

If the feedback capacitance is large in comparison with the cable capacitance, the latter can be neglected. This is desirable in practice. In any event, for large values of gain, K , we have the approximate relationship

$$v_o = -\frac{q}{C_f} \quad (16.12b)$$

Note that the output voltage is proportional to the charge generated at the sensor and depends only on the feedback parameter, C_f . This parameter can be appropriately chosen in order to obtain the required output impedance characteristics. Actual charge amplifiers also have a feedback resistor, R_f , in parallel with the feedback capacitor, C_f . Then, the relationship corresponding to Equation 16.12a becomes a first-order ordinary differential equation, which in turn determines the time constant of the charge amplifier. This time constant should be high. If it is low, the charge generated by the piezoelectric sensor will leak out quickly, giving erroneous results at low frequencies.

16.2.4 Instrumentation Amplifiers

An instrumentation amplifier is typically a special-purpose voltage amplifier dedicated to a particular instrumentation application. Examples include amplifiers used for producing the output from a bridge circuit (bridge amplifier) and amplifiers used with various sensors and transducers. An important characteristic of an instrumentation amplifier is the adjustable gain capability. The gain value can be adjusted manually in most instrumentation amplifiers. In more sophisticated instrumentation amplifiers, gain is *programmable* and can be set by means of digital logic. Instrumentation amplifiers are normally used with low-voltage signals.

16.2.4.1 Differential Amplifier

Usually, an instrumentation amplifier is also a *differential amplifier* (sometimes termed difference amplifier). Note that in a differential amplifier both input leads are used for signal input, whereas in a single-ended amplifier one of the leads is grounded and only one lead is used for signal input. Ground-loop noise can be a serious problem in single-ended amplifiers. Ground-loop noise can be effectively eliminated by using a differential amplifier, because noise loops are formed with both inputs of the amplifier using a differential amplifier allows that these noise signals are subtracted at the amplifier output. Since the noise level is almost the same for both inputs, it is canceled out. Note that any other noise (e.g., 60 Hz line noise) that might enter both inputs with the same intensity will also be canceled out in the output of a differential amplifier.

A basic differential amplifier that uses a single opamp is shown in Figure 16.3(a). The input–output equation for this amplifier can be obtained in the usual manner. For instance, since current through the opamp is negligible, current balance at point B gives

$$\frac{v_{i2} - v_B}{R} = \frac{v_B}{R_f} \quad (i)$$

in which v_B is the voltage at B. Similarly, current balance at point A gives

$$\frac{v_o - v_A}{R_f} = \frac{v_A - v_{i1}}{R} \quad (ii)$$

Now, we use the property

$$v_A = v_B \quad (iii)$$

for an operational amplifier to eliminate v_A and v_B from Equation i and Equation ii. This gives

$$\frac{v_{i2}}{(1 + R/R_f)} = \frac{(v_o R/R_f + v_{i1})}{(1 + R/R_f)}$$

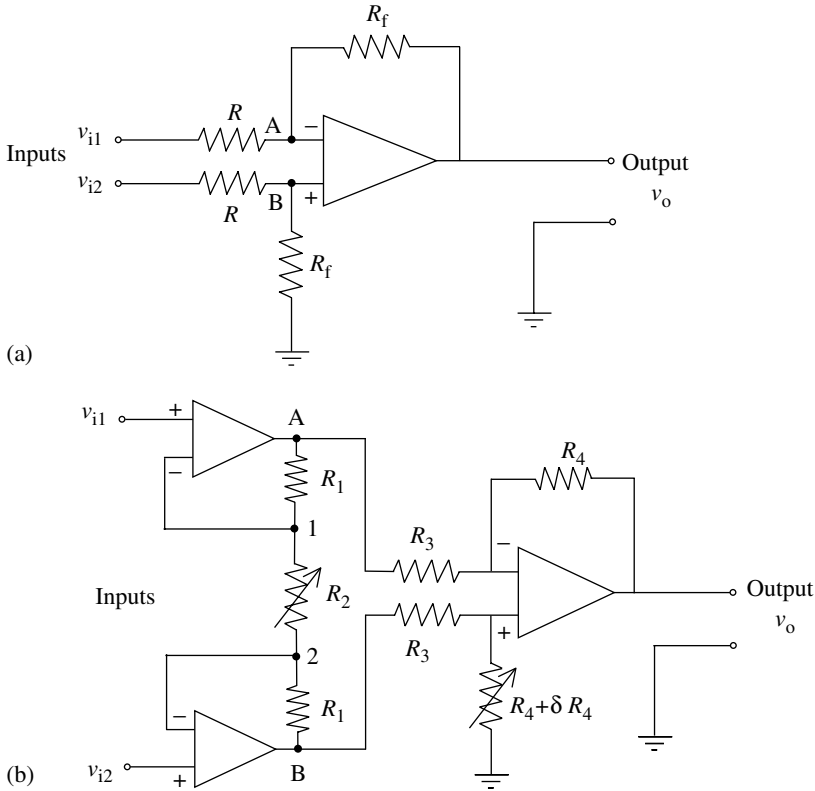

FIGURE 16.3 (a) A basic differential amplifier; (b) a basic instrumentation amplifier.

or

$$v_o = \frac{R_f}{R} (v_{i2} - v_{i1}) \quad (16.13)$$

Two things are clear from Equation 16.13. First, the amplifier output is proportional to the difference between, and not the absolute value of, the two inputs v_{i1} and v_{i2} . Second, voltage gain of the amplifier is R_f/R . This is known as the *differential gain*. Note that the differential gain can be accurately set by using high-precision resistors R and R_f .

The basic differential amplifier, shown in Figure 16.3(a) and discussed above, is an important component of an instrumentation amplifier. In addition, an instrumentation amplifier should possess the adjustable gain capability. Furthermore, it is desirable to have a very high input impedance and very low output impedance at each input lead. An instrumentation amplifier that possesses these basic requirements is shown in Figure 16.3(b). The amplifier gain can be adjusted using the precisely variable resistor, R_2 . Impedance requirements are provided by two voltage-follower-type amplifiers, one for each input, as shown. The variable resistance, δR_4 , is necessary to compensate for errors due to unequal *common-mode gain*. Let us first consider this aspect and then obtain an equation for the instrumentation amplifier.

16.2.4.2 Common Mode

The voltage that is “common” to both input leads of a differential amplifier is known as the *common-mode voltage*. This is equal to the smaller of the two input voltages. If the two inputs are equal, then the common-mode voltage is obviously equal to each one of the two inputs. When $v_{i1} = v_{i2}$, ideally, the output voltage v_o should be zero. In other words, ideally, *common-mode signals* are rejected by a

differential amplifier. However, since the operational amplifiers are not ideal and since they usually do not have exactly identical gains with respect to the two input leads, the output voltage v_o will not be zero when the two inputs are identical. This *common-mode error* can be compensated for by providing a variable resistor with fine resolution at one of the two input leads of the differential amplifier. As shown in Figure 16.3(b), to compensate for the common-mode error (i.e., to achieve a satisfactory level of common-mode rejection), first the two inputs are made equal and then δR_4 is varied carefully until the output voltage level is sufficiently small (minimum). Usually, the δR_4 that is required to achieve this compensation is small compared with the nominal feedback resistance R_4 .

Since ideally $\delta R_4 = 0$, we shall neglect δR_4 in the derivation of the instrumentation amplifier equation. Now, note from the basic characteristics of an opamp with no saturation (voltages at the two input leads have to be almost identical) that, in Figure 16.3(b), the voltage at point 2 should be v_{i2} and the voltage at point 1 should be v_{i1} . Furthermore, current through each input lead of an opamp is negligible. Hence, current through the circuit path $B \rightarrow 2 \rightarrow 1 \rightarrow A$ has to be the same. This gives the current continuity equations

$$\frac{v_B - v_{i2}}{R_1} = \frac{v_{i2} - v_{i1}}{R_2} = \frac{v_{i1} - v_A}{R_1}$$

in which V_A and V_B are the voltages at points A and B, respectively. Hence, we obtain the two equations

$$v_B = v_{i2} + \frac{R_1}{R_2}(v_{i2} - v_{i1})$$

$$v_A = v_{i1} - \frac{R_1}{R_2}(v_{i2} - v_{i1})$$

Now, by subtracting the second equation from the first, we have the equation for the first stage of the amplifier; thus

$$v_B - v_A = \left(1 + \frac{2R_1}{R_2}\right)(v_{i2} - v_{i1}) \quad (i)$$

From the previous result (see Equation 16.13) for a differential amplifier, we have (with $\delta R_4 = 0$)

$$v_o = \frac{R_4}{R_3}(v_B - v_A) \quad (ii)$$

Note that only the resistor R_2 is varied to adjust the gain (differential gain) of the amplifier. In Figure 16.3(b), the two input opamps (the voltage-follower opamps) do not have to be exactly identical as long as the resistors R_1 and R_2 are chosen so that they are accurate. This is so because the opamp parameters such as open-loop gain and input impedance do not enter the amplifier equations provided that their values are sufficiently high, as noted earlier.

16.2.5 Amplifier Performance Ratings

Main factors that affect the performance of an amplifier are:

1. Stability
2. Speed of response (bandwidth, slew rate)
3. Unmodeled signals

We have already discussed the significance of some of these factors.

The level of stability of an amplifier, in the conventional sense, is governed by the dynamics of the amplifier circuitry and may be represented by a *time constant*. However, a more important consideration for an amplifier is the “parameter variation” due to aging, temperature, and other environmental factors. Parameter variation is also classified as a stability issue in the context of devices such as amplifiers, because it pertains to the steadiness of the response when the input is maintained steady. Of particular importance is *temperature drift*. This may be specified as drift in the output signal per unit change in temperature (e.g., $\mu V/^\circ C$).

The speed of response of an amplifier dictates the ability of the amplifier to faithfully respond to transient inputs. Conventional time-domain parameters such as *rise time* may be used to represent this. Alternatively, in the frequency domain, speed of response may be represented by a *bandwidth* parameter. For example, the frequency range over which the frequency-response function is considered constant (flat) may be taken as a measure of bandwidth. Since there is some nonlinearity in any amplifier, bandwidth can depend on the signal level itself. Specifically, *small-signal bandwidth* refers to the bandwidth that is determined using small input signal amplitudes.

Another measure of the speed of response is the slew rate. Slew rate is defined as the largest possible rate of change in the amplifier output for a particular frequency of operation. Since, for a given input amplitude, the output amplitude depends on the amplifier gain, slew rate is usually defined for unity gain.

Ideally, for a linear device, the frequency-response function (transfer function) does not depend on the output amplitude (i.e., the product of the DC gain and the input amplitude). However, for a device that has a limited slew rate, the bandwidth, or the maximum operating frequency at which output distortions may be neglected, will depend on the output amplitude. The larger the output amplitude, the smaller the bandwidth for a given slew rate limit.

We have noted that stability problems and frequency-response errors are prevalent in the open-loop form of an operational amplifier. These problems can be eliminated using feedback because the effect of the open-loop transfer function on the closed loop transfer function is negligible if the open-loop gain is very large, which is the case for an operational amplifier.

Unmodeled signals can be a major source of amplifier error. Unmodeled signals include:

1. Bias currents
2. Offset signals
3. Common-mode output voltage
4. Internal noise

In analyzing operational amplifiers, we assume that the current through the input leads is zero. This is not strictly true because bias currents for the transistors within the amplifier circuit have to flow through these leads. As a result, the output signal of the amplifier will deviate slightly from the ideal value.

Another assumption that we make in analyzing opamps is that the voltage is equal at the two input leads. However, in practice, offset currents and voltages are present at the input leads, due to minute discrepancies inherent to the internal circuits within an opamp.

16.2.5.1 Common-Mode Rejection Ratio

Common-mode error in a differential amplifier was discussed earlier. We noted that ideally the common-mode input voltage (the voltage common to both input leads) should have no effect on the output voltage of a differential amplifier. However, since a practical amplifier has imbalances in the internal circuitry (for example, gain with respect to one input lead is not equal to the gain with respect to the other input lead and, furthermore, bias signals are needed for operation of the internal circuitry), there will be an error voltage at the output that depends on the common-mode input. The common-mode rejection ratio (CMRR) of a differential amplifier is defined as

$$\text{CMRR} = \frac{K v_{\text{cm}}}{v_{\text{ocm}}} \quad (16.14)$$

in which

- K = gain of the differential amplifier (i.e., differential gain)
- v_{cm} = common-mode voltage (i.e., voltage common to both input leads)
- v_{ocm} = common-mode output voltage (i.e., output voltage due to common-mode input voltage)

Note that, ideally, $v_{\text{ocm}} = 0$ and CMRR should be infinity. It follows that the larger the CMRR, the better the differential amplifier performance.

The three types of unmodeled signals mentioned above can be considered as noise. In addition, there are other types of noise signals that degrade the performance of an amplifier. For example, ground-loop

noise can enter the output signal. Furthermore, stray capacitances and other types of unmodeled circuit effects can generate internal noise. Usually in amplifier analysis, unmodeled signals (including noise) can be represented by a noise voltage source at one of the input leads. Effects of unmodeled signals can be reduced by using suitably connected compensating circuitry, including variable resistors that can be adjusted to eliminate the effect of unmodeled signals at the amplifier output (e.g., see δR_4 in [Figure 16.3\(b\)](#)). Some useful information about operational amplifiers is summarized in Box 16.1.

Box 16.1

OPERATIONAL AMPLIFIERS

Ideal Opamp Properties:

- Infinite open-loop differential gain
- Infinite input impedance
- Zero output impedance
- Infinite bandwidth
- Zero output for zero differential input

Ideal Analysis Assumptions:

- Voltages at the two input leads are equal.
- Current through either input lead is zero.

Definitions:

- Open-loop gain = $\left| \frac{\text{Output voltage}}{\text{Voltage difference at input leads}} \right|$ with no feedback
- Input impedance = $\frac{\text{Voltage between an input lead and ground}}{\text{Current through that lead}}$ with other input lead grounded and the output in open circuit
- Output impedance = $\frac{\text{Voltage between output lead and ground in open circuit}}{\text{Current through that lead}}$ with normal input conditions
- Bandwidth = frequency range in which the frequency response is flat (gain is constant)
- Input bias current = average (DC) current through one input lead
- Input offset current = difference in the two input bias currents
- Differential input voltage = voltage at one input lead with the other grounded when the output voltage is zero
- Common-mode gain = $\frac{\text{Output voltage when input leads are at the same voltage}}{\text{Common input voltage}}$
- Common-mode rejection ratio (CMRR) = $\frac{\text{Open loop differential gain}}{\text{Common-mode gain}}$
- Slew rate = speed at which steady output is reached for a step input

16.2.6 Component Interconnection

When two or more components are interconnected, the behavior of the individual components in the overall system can deviate significantly from their behavior of each component when they operate independently. The matching of components in a multicomponent system should be done carefully in order to improve system performance and accuracy, particularly with respect to their impedance characteristics. This is particularly true in vibration instrumentation.

16.2.6.1 Impedance Characteristics

When components such as measuring instruments, digital processing boards, process (plant) hardware, and signal-conditioning equipment are interconnected, it is necessary to *match* impedances properly at each interface in order to realize the devices' rated performance level. One adverse effect of improper impedance matching is the *loading effect*. For example, in a measuring system, the measuring instrument can distort the signal that is being measured. The resulting error can far exceed other types of measurement error. Loading errors will result from connecting a measuring device with low input impedance to a signal source.

Impedance can be interpreted either in the traditional electrical sense or in the mechanical sense, depending on the signal that is being measured. For example, a heavy accelerometer can introduce an additional dynamic load that will modify the actual acceleration at the monitoring location. Similarly, a voltmeter can modify the currents (and voltages) in a circuit. In mechanical and electrical systems, loading errors can appear as phase distortions as well. Digital hardware also can produce loading errors. For example, an ADC board can load the amplifier output from a strain-gage bridge circuit, thereby significantly affecting digitized data.

Another adverse effect of improper impedance consideration is inadequate output signal levels, which can make signal processing and transmission very difficult. Many types of transducers (e.g., piezoelectric accelerometers, impedance heads, and microphones) have high output impedances in the order of a thousand megohms. These devices generate low output signals, and they require conditioning to step up the signal level. *Impedance-matching amplifiers*, which have high input impedances (megohms) and low output impedances (a few ohms), are used for this purpose (e.g., charge amplifiers are used in conjunction with piezoelectric sensors). A device with a high input impedance has the further advantage that it usually consumes less power (v^2/R is low) for a given input voltage. The fact that a low input impedance device extracts a high level of power from the preceding output device may transpire to be the reason for a loading error.

16.2.6.2 Cascade Connection of Devices

Consider a standard two-port electrical device. The *output impedance*, Z_o , of such a device is defined as the ratio of the open-circuit (i.e., no-load) voltage at the output port to the short-circuit current at the output port.

Open-circuit voltage at the output is the output voltage present when there is no current flowing at the output port. This is the case if the output port is not connected to a load (impedance). As soon as a load is connected at the output of the device, a current will flow through it and the output voltage will drop to a value less than that of the open-circuit voltage. To measure open-circuit voltage, the rated input voltage is applied at the input port and maintained constant, and the output voltage is measured using a voltmeter that has a very high (input) impedance. To measure short-circuit current, a very low-impedance ammeter is connected at the output port.

The *input impedance*, Z_i , is defined as the ratio of the rated input voltage to the corresponding current through the input terminals while the output terminals are maintained as an open circuit.

Note that these definitions are associated with electrical devices. A generalization is possible that includes both electrical and mechanical devices; one must interpret voltage and velocity as *across variables*, and current and force as *through variables*. Then, mechanical *mobility* can be used in place of electrical impedance in the associated analysis.

Example 16.2

Input impedance, Z_i , and output impedance, Z_o , can be represented schematically as in Figure 16.4(a). Note that v_o is the open-circuit output voltage. When a load is connected at the output port, the voltage across the load will be different from v_o . This is caused by the presence of a current through Z_o . In the frequency domain, v_i and v_o are represented by their respective *Fourier spectra*. The corresponding transfer relation can be expressed in terms of the complex frequency-response (transfer) function $G(j\omega)$ under open-circuit (no-load) conditions:

$$v_o = Gv_i \quad (16.15)$$

Now, consider two devices connected in cascade, as shown in Figure 16.4(b). It can be easily verified that the following relations apply:

$$v_{o1} = G_1 v_i \quad (i)$$

$$v_{i2} = \frac{Z_{i2}}{Z_{o1} + Z_{i2}} v_{o1} \quad (ii)$$

$$v_o = G_2 v_{i2} \quad (iii)$$

These relations can be combined to give the overall input/output relation

$$v_o = \frac{Z_{i2}}{Z_{o1} + Z_{i2}} G_2 G_1 v_i \quad (16.16a)$$

We see from Equation 16.16a that the overall frequency-transfer function differs from the ideally expected product ($G_2 G_1$) by the factor

$$\frac{Z_{i2}}{Z_{o1} + Z_{i2}} = \frac{1}{Z_{o1}/Z_{i2} + 1} \quad (16.16b)$$

Note that cascading has “distorted” the frequency-response characteristics of the two devices. If $Z_{o1}/Z_{i2} \ll 1$, this deviation becomes insignificant. From this observation, it can be concluded that, when frequency-response characteristics (i.e., dynamic characteristics) are important in a cascaded device, cascading should be done such that the output impedance of the first device is much smaller than the input impedance of the second device.

16.2.6.3 AC-Coupled Amplifiers

The DC component of a signal can be blocked off by connecting that signal through a capacitor. (Note that the impedance of a capacitor is $1/(j\omega C)$ and, hence, at zero frequency there will be an infinite impedance.) If the input lead of a device has a series capacitor, we say that the input is AC coupled and, if the output lead has a series capacitor, then the output is AC coupled. Typically, an AC-coupled amplifier has a series capacitor both at the input lead and the output lead. Hence, its frequency-response function will have a high-pass characteristic; in particular, the DC components will be filtered out. Errors due to bias currents and offset signals are negligible for an AC-coupled amplifier. Furthermore, in an AC-coupled amplifier, stability problems are not very serious.

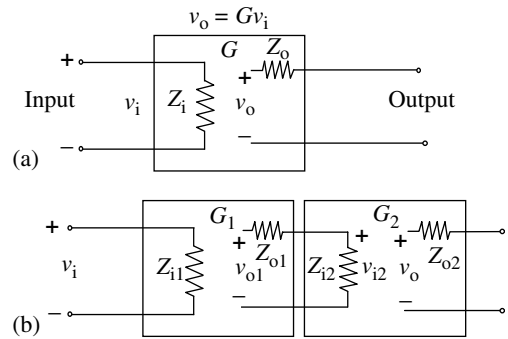

FIGURE 16.4 (a) Schematic representation of input impedance and output impedance; (b) the influence of cascade connection of devices on the overall impedance characteristics.

16.3 Analog Filters

Unwanted signals can seriously degrade the performance of a vibration monitoring and analysis system. External disturbances, error components in excitations, and noise generated internally within system components and instrumentation are such spurious signals. A filter is a device that allows only the desirable part of a signal to pass through, rejecting the unwanted part.

In typical applications of acquisition and processing of a vibration signal, the filtering task requires allowing certain frequency components through and filtering out certain other frequency components in the signal. In this context, we can identify four broad categories of filters:

1. Low-pass filters
2. High-pass filters
3. Band-pass filters
4. Band-reject (or notch) filters

The ideal frequency-response characteristic of each of these four types of filter is shown in Figure 16.5. Note that only the magnitude of the frequency-response function is shown.

It is understood, however, that the phase distortion of the input signal also should be small, within the *pass band* (the allowed frequency range). Practical filters are less than ideal. Their frequency-response functions do not exhibit sharp cutoffs as in Figure 16.5 and, furthermore, some phase distortion will be unavoidable.

A special type of band-pass filter that is widely used in acquisition and monitoring of vibration signals (e.g., in vibration testing) is the *tracking filter*. This is simply a band-pass filter with a narrow pass band that is frequency tunable. The center frequency (the mid-value) of the pass band is variable, usually by coupling it to the frequency of a carrier signal. In this manner, signals whose frequency varies with some basic variable in the system (e.g., rotor speed, frequency of a harmonic excitation signal, frequency of a sweep oscillator) can be accurately tracked in the presence of noise. The inputs to a tracking filter are the signal that is being tracked and the variable *tracking frequency* (*carrier input*). A typical tracking filter that can simultaneously track two signals is schematically shown in Figure 16.6.

Filtering can be achieved using *digital filters* as well as *analog filters*. Before digital signal processing became efficient and economical, analog filters were exclusively used for signal filtering and they are still widely used. In an analog filter, the signal is passed through an analog circuit.

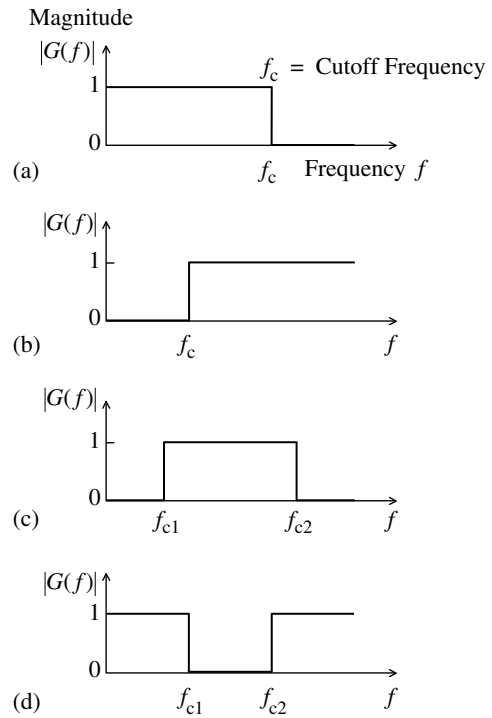

FIGURE 16.5 Ideal filter characteristics: (a) low-pass filter; (b) high-pass filter; (c) band-pass filter; (d) band-reject (notch) filter.

FIGURE 16.6 Schematic representation of a two-channel tracking filter.

The dynamics of the circuit will be such that the desired signal components will be passed through and the unwanted signal components will be rejected. Earlier versions of analog filters employed discrete circuit elements such as discrete transistors, capacitors, resistors, and even discrete inductors. Since inductors have several shortcomings, including susceptibility to electromagnetic noise, unknown resistance effects, and large size. These days, they are rarely used in filter circuits. Furthermore, owing to well-known advantages of IC devices, analog filters in the form of monolithic IC chips are today extensively used in modem applications and are preferred over discrete-element filters. Digital filters that employ digital signal processing to achieve filtering are also widely used nowadays.

16.3.1 Passive Filters and Active Filters

Passive analog filters employ analog circuits containing only passive elements, such as resistors and capacitors (and sometimes inductors). An external power supply is not needed in a passive filter. Active analog filters employ active elements and components, such as transistors and operational amplifiers in addition to passive elements. Since external power is needed for the operation of the active elements and components, an active filter is characterized by the need of an external power supply. Active filters are widely available in a monolithic IC form and are usually preferred over passive filters.

Advantages of active filters include the following:

1. Loading effects are negligible because active filters can provide a very high input impedance and very low output impedance.
2. They can be used with low-level signals because signal amplification and filtering can be provided by the same active circuit.
3. They are widely available in a low cost and compact IC form.
4. They can be easily integrated with digital devices.
5. They are less susceptible to noise from electromagnetic interference than passive filters.

Commonly mentioned disadvantages of active filters are the following:

1. They need an external power supply.
2. They are susceptible to "saturation"-type nonlinearity at high signal levels.
3. They can introduce many types of internal noise and unmodeled signal errors (offset, bias signals, etc.).

Note that advantages and disadvantages of passive filters can be directly inferred from the disadvantages and advantages of active filters as given above.

16.3.1.1 Number of Poles

Analog filters are dynamic systems and they can be represented by transfer functions, assuming linear dynamics. The number of poles of a filter is the number of poles in the associated transfer function. This is also equal to the order of the characteristic polynomial of the filter transfer function (i.e., *order of the filter*). Note that poles (or eigenvalues) are the roots of the characteristic equation.

In our discussion, we will show simplified versions of filters, typically consisting of a single filter stage. The performance of such a basic filter can be improved at the expense of circuit complexity (and an increased pole count). Only simple discrete-element circuits are shown for passive filters. Simple operational-amplifier circuits are given for active filters. Even here, much more complex devices are commercially available, but our purpose is to illustrate underlying principles rather than to provide descriptions and data sheets for commercial filters.

16.3.2 Low-Pass Filters

The purpose of a low-pass filter is to allow through all signal components below a certain (cutoff) frequency and block all signal components above that cutoff. Analog low-pass filters are widely used as *antialiasing filters* in digital signal processing. An error known as *aliasing* will enter the digitally processed results of a signal if the original signal has frequency components above half the *sampling frequency*. (Half the sampling frequency is called the *Nyquist frequency*.) Hence, aliasing distortion can be eliminated if, prior to sampling and digital processing, the signal is filtered using a low-pass filter with its cutoff set at Nyquist frequency. This is one of numerous applications of analog low-pass filters. Another typical application would be to eliminate high-frequency noise in a measured vibration response.

A single-pole, passive low-pass filter circuit is shown in Figure 16.7(a). An active filter corresponding to the same low-pass filter is shown in Figure 16.7(b). It can be shown that the two circuits have identical transfer functions. Hence, it might seem that the opamp in Figure 16.7(b) is redundant. This is not true, however. If two passive filter stages, each similar to Figure 16.7(a), are connected together, the overall transfer function is not equal to the product of the transfer functions of the individual stages. The reason for this apparent ambiguity is the circuit loading that arises due to the fact that the input impedance of the second stage is not sufficiently larger than the output impedance of the first stage. However, if two active filter stages, similar to those in Figure 16.7(b), are connected together, such loading errors will be negligible because the opamp with feedback (i.e., a voltage follower) introduces a very high input impedance and very low output impedance, while maintaining the voltage gain at unity.

To obtain the filter equation for the scenario depicted in Figure 16.7(a), note that, since the output is open circuit (zero load current), the current through capacitor C is equal to the current through resistor R . Hence,

$$C \frac{dv_o}{dt} = \frac{v_i - v_o}{R}$$

or

$$\tau \frac{dv_o}{dt} + v_o = v_i \quad (16.17)$$

where the filter time constant is

$$\tau = RC \quad (16.18)$$

From Equation 16.17, it follows that the filter transfer function is

$$\frac{v_o}{v_i} = G(s) = \frac{1}{(\tau s + 1)} \quad (16.19)$$

From this transfer function, it is clear that an analog low-pass filter is essentially a *lag circuit* (i.e., it provides a phase lag).

It can be shown that the active filter stage in Figure 16.7(b) has the same input/output equation. First, since current through an opamp lead is almost zero, we have from the previous analysis of the passive circuit stage

$$\frac{v_A}{v_i} = \frac{1}{(\tau s + 1)} \quad (i)$$

in which v_A is the voltage at the node point A. Now, since the opamp with feedback resistor is in fact a voltage follower, we have

$$\frac{v_o}{v_A} = 1 \quad (ii)$$

Next, by combining Equation i and Equation ii, we obtain Equation 16.19, as required. As mentioned earlier, a main advantage of the active filter version is that the resulting loading error is negligible.

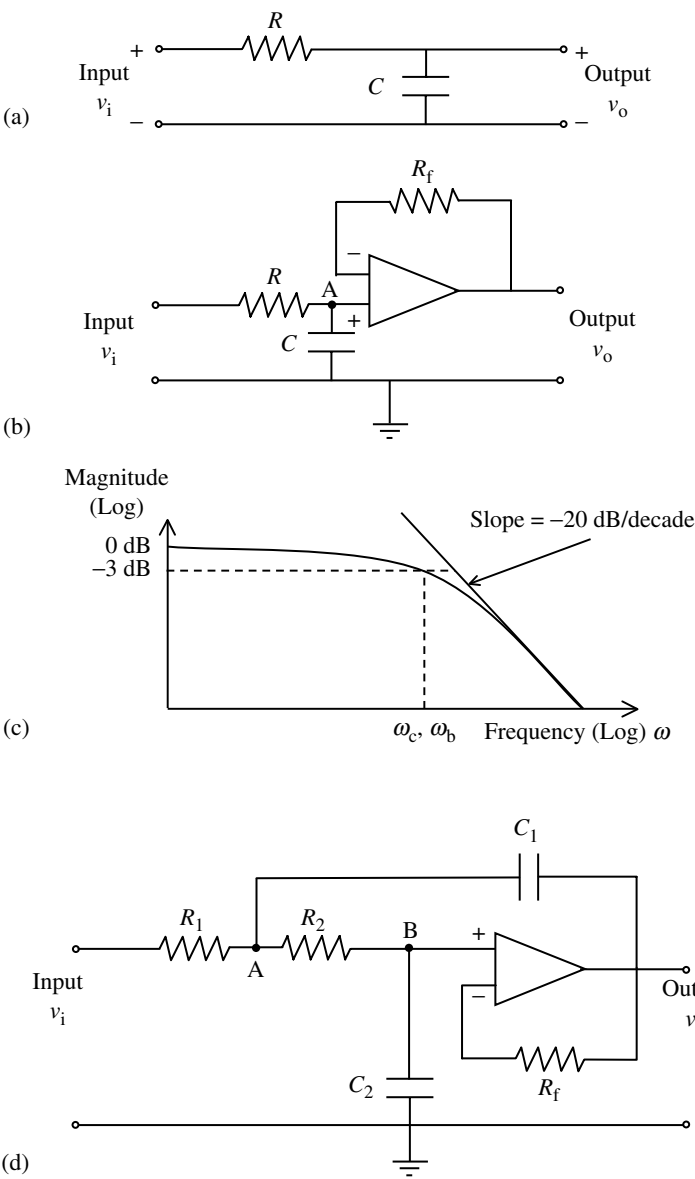

FIGURE 16.7 A single-pole low-pass filter: (a) a passive filter stage; (b) an active filter stage; (c) the frequency-response characteristic; (d) a two-pole, low-pass Butterworth filter.

The frequency-response function corresponding to Equation 16.19 is obtained by setting $s = j\omega$; thus

$$G(j\omega) = \frac{1}{(\tau j\omega + 1)} \tag{16.20}$$

This gives the response of the filter when a sinusoidal signal of frequency, ω , is applied. The magnitude $|G(j\omega)|$ of the frequency-transfer function gives the signal amplification and phase angle $\angle G(j\omega)$ gives the phase lead of the output signal with respect to the input. The magnitude curve (*Bode magnitude curve*) is shown in Figure 16.7(c). Note from Equation 16.20 that, for small frequencies (i.e., $\omega \ll 1/\tau$), the magnitude is approximately unity. Hence, $1/\tau$ can be considered the

cutoff frequency ω_c :

$$\omega_c = \frac{1}{\tau} \quad (16.21)$$

Example 16.3

Show that the cutoff frequency given by Equation 16.21 is also the *half-power bandwidth* for the low-pass filter. Show that, for frequencies much larger than this, the filter transfer function on the Bode magnitude plane (i.e., log magnitude vs. log frequency) can be approximated by a straight line with slope -20 dB/decade. This slope is known as the *roll-off rate*.

Solution

The frequency corresponding to half power (or $1/2$ magnitude) is given by

$$\frac{1}{|\tau j\omega + 1|} = \frac{1}{\sqrt{2}}$$

or

$$\frac{1}{\tau^2 \omega^2 + 1} = \frac{1}{2}$$

or

$$\tau^2 \omega^2 + 1 = 2$$

or

$$\tau^2 \omega^2 = 1$$

Hence, the half-power bandwidth is

$$\omega_b = \frac{1}{\tau} \quad (16.22)$$

This is identical to the cutoff frequency given by Equation 16.11.

Now, for $\omega \gg 1/\tau$ (i.e., $\tau\omega \gg 1$) Equation 16.20 can be approximated by

$$G(j\omega) = \frac{1}{\tau j\omega}$$

This has the magnitude

$$|G(j\omega)| = \frac{1}{\tau\omega}$$

In the log scale

$$\log_{10}|G(j\omega)| = -\log_{10} \omega - \log_{10} \tau$$

It follows that the \log_{10} (magnitude) vs. \log_{10} (frequency) curve is a straight line with slope -1 . In other words, when frequency increases by a factor of ten (i.e., a decade), the \log_{10} magnitude decreases by unity (i.e., by 20 dB). Hence, the roll-off rate is -20 dB/decade. These observations are shown in [Figure 16.7\(c\)](#). Note that an amplitude change by a factor of $\sqrt{2}$ (or power by a factor of 2) corresponds to 3 dB. Hence, when the DC (zero-frequency) magnitude is unity (0 dB), the half power magnitude is -3 dB.

Cutoff frequency and the roll-off rate are the two main design specifications for a low-pass filter. Ideally, we would like a low-pass filter magnitude curve to be flat until the required pass-band limit (cutoff frequency) and then roll off very rapidly. The low-pass filter shown in Figure 16.7 only

approximately meets these requirements. In particular, the roll-off rate is not as large as is desirable. We would like a roll-off rate of at least -40 dB/decade and, preferably, -60 dB/decade in practical filters.

This can be realized by using a higher order filter (i.e., a filter having many poles). The low-pass Butterworth filter is a widely used filter of this type.

16.3.2.1 Low-Pass Butterworth Filter

A low-pass Butterworth filter having two poles can provide a roll-off rate of -40 dB/decade, and one having three poles can provide a roll-off rate of -60 dB/decade. Furthermore, the steeper the slope of the roll-off, the flatter is the filter magnitude curve within the pass band.

A two-pole, low-pass Butterworth filter is shown in Figure 16.7(d). We could construct a two-pole filter simply by connecting two single-pole stages of the type shown in Figure 16.7(b). Then, we would require two opamps, whereas the circuit shown in Figure 16.7(d) achieves the same objective by using only one opamp (i.e., at a lower cost).

Example 16.4

Show that the opamp circuit in Figure 16.7(d) is a low-pass filter having two poles. What is the transfer function of the filter? Estimate the cutoff frequency under suitable conditions. Show that the roll-off rate is -40 dB/decade.

Solution

To obtain the filter equation, we write the current balance equations. Specifically, the sum of the currents through R_1 and C_1 passes through R_2 . The same current passes through C_2 because current through the opamp lead must be zero. Hence,

$$\frac{v_i - v_A}{R_1} + C_1 \frac{d}{dt}(v_o - v_A) = \frac{v_A - v_B}{R_2} = C_2 \frac{dv_B}{dt} \quad (i)$$

Also, since the opamp with a feedback resistor R_f is a voltage follower (with unity gain), we have

$$v_B = v_o \quad (ii)$$

From Equation i and Equation ii, we obtain

$$\frac{v_i - v_A}{R_1} + C_1 \frac{dv_o}{dt} - C_1 \frac{dv_A}{dt} = C_2 \frac{dv_o}{dt} \quad (iii)$$

$$\frac{v_A - v_o}{R_2} = C_2 \frac{dv_o}{dt} \quad (iv)$$

Now, defining the constants

$$\tau_1 = R_1 C_1 \quad (16.23)$$

$$\tau_2 = R_2 C_2 \quad (16.24)$$

$$\tau_3 = R_1 C_2 \quad (16.25)$$

and introducing the Laplace variable, s , we can eliminate v_A by substituting Equation iv into Equation iii; thus

$$\frac{v_o}{v_i} = \frac{1}{[\tau_1 \tau_2 s^2 + (\tau_2 + \tau_3)s + 1]} = \frac{\omega_n^2}{[s^2 + 2\zeta\omega_n^2 + \omega_n^2]} \quad (16.26)$$

This second-order transfer function becomes oscillatory if $(\tau_2 + \tau_3)^2 < 4\tau_1 \tau_2$. Ideally, we would like to have a zero resonant frequency, which corresponds to a damping ratio value $\zeta = 1/\sqrt{2}$. Since the undamped natural frequency is

$$\omega_n = \frac{1}{\sqrt{\tau_1 \tau_2}} \quad (16.27)$$

the damping ratio is

$$\zeta = \frac{\tau_2 + \tau_3}{\sqrt{4\tau_1\tau_2}} \quad (16.28)$$

and the resonant frequency is

$$\omega_r = \sqrt{1 - 2\zeta^2} \omega_n \quad (16.29)$$

we have, under ideal conditions (i.e., for $\omega_r = 0$),

$$(\tau_2 + \tau_3)^2 = 2\tau_1\tau_2 \quad (16.30)$$

The frequency-response function of the filter is (see Equation 16.26)

$$G(j\omega) = \frac{\omega_n^2}{[\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega]} \quad (16.31)$$

Now, for $\omega \ll \omega_n$, the filter frequency response is flat with a unity gain. For $\omega \gg \omega_n$, the filter frequency response can be approximated by

$$G(j\omega) = -\frac{\omega_n^2}{\omega^2}$$

In a log (magnitude) vs. log (frequency) scale, this function is a straight line with slope equals to -2 . Hence, when the frequency increases by a factor of ten (i.e., one decade), the \log_{10} (magnitude) drops by 2 units (i.e., 40 dB). In other words, the roll-off rate is -40 dB/decade. Also, ω_n can be taken as the filter cutoff frequency. Hence,

$$\omega_c = \frac{1}{\sqrt{\tau_1\tau_2}} \quad (16.32)$$

It can be easily verified that, when $\zeta = 1/\sqrt{2}$, the frequency is identical to the half-power bandwidth (i.e., the frequency at which the transfer function magnitude becomes $1/\sqrt{2}$).

Note that, if two single-pole stages (of the type shown in Figure 16.7(b)) are cascaded, the resulting two-pole filter has an overdamped (nonoscillatory) transfer function, and it is not possible to achieve $\zeta = 1/\sqrt{2}$, as in the present case. Also, note that a three-pole, low-pass Butterworth filter can be obtained by cascading the two-pole unit shown in Figure 16.7(d) with a single-pole unit as shown in Figure 16.7(b). Higher order low-pass Butterworth filters can be obtained in a similar manner by cascading an appropriate selection of basic units.

16.3.3 High-Pass Filters

Ideally, a high-pass filter allows through it all signal components above a certain (cutoff) frequency and blocks off all signal components below that frequency. A single-pole, high-pass filter is shown in Figure 16.8. As for the low-pass filter that was discussed earlier, the passive filter stage (Figure 16.8(a)) and the active filter stage (Figure 16.8(b)) have identical transfer functions. The active filter is desirable, however, because of its many advantages, including negligible loading error due to the high input impedance and low output impedance of the opamp voltage follower that is present in this circuit.

The filter equation is obtained by considering current balance in Figure 16.8(a), noting that the output is in open circuit (zero load current). Accordingly,

$$C \frac{d}{dt} (v_1 - v_o) = \frac{v_o}{R}$$

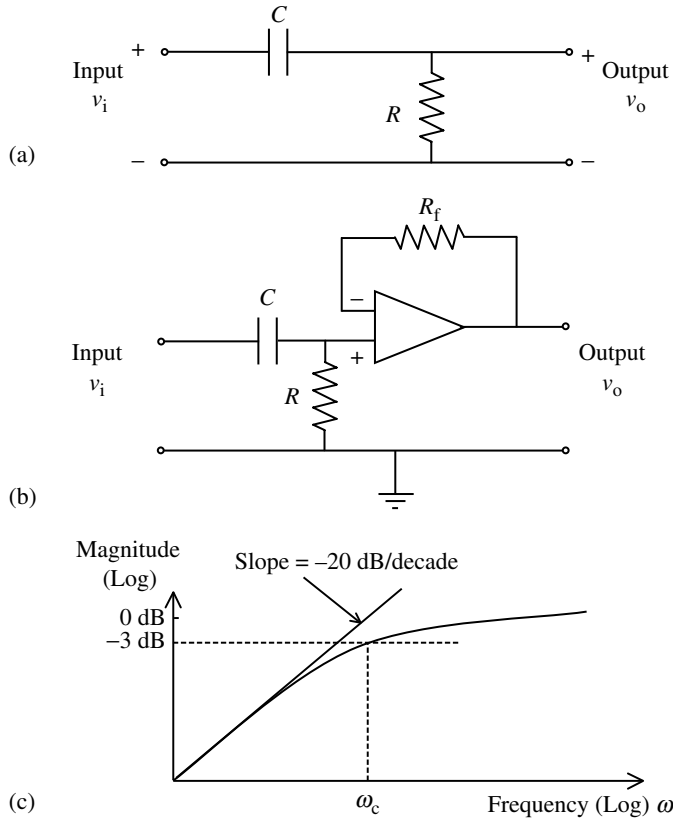

FIGURE 16.8 A single-pole high-pass filter: (a) a passive filter stage; (b) an active filter stage; (c) frequency-response characteristic.

or

$$\tau \frac{dv_o}{dt} + v_o = \tau \frac{dv_i}{dt} \quad (16.33)$$

in which the filter time constant is

$$\tau = RC \quad (16.34)$$

Introducing the Laplace variable, s , the filter transfer function is obtained as

$$\frac{v_o}{v_i} = G(s) = \frac{\tau s}{(\tau s + 1)} \quad (16.35)$$

Note that this corresponds to a *lead circuit* (i.e., an overall phase lead is provided by this transfer function). The frequency-response function is

$$G(j\omega) = \frac{\tau j\omega}{(\tau j\omega + 1)} \quad (16.36)$$

Since its magnitude is zero for $\omega \ll 1/\tau$ and is unity for $\omega \gg 1/\tau$, we have the cutoff frequency

$$\omega_c = \frac{1}{\tau} \quad (16.37)$$

Signals above this cutoff frequency are allowed undistorted by an ideal high-pass filter, and signals below the cutoff are completely blocked off. The actual behavior of the basic high-pass filter discussed

above is not perfect, as observed from the frequency-response characteristic shown in Figure 16.8(c). It can be easily verified that the half-power bandwidth of the basic high-pass filter is equal to the cutoff frequency given by Equation 16.37, as in the case of the basic low-pass filter. The roll-up slope of the single-pole high-pass filter is 20 dB/decade. Steeper slopes are desirable. Multiple-pole, high-pass Butterworth filters can be constructed to give steeper roll-up slopes and reasonably flat pass-band magnitude characteristics.

16.3.4 Band-Pass Filters

An ideal band-pass filter passes all signal components within a finite frequency band and blocks off all signal components outside that band. The lower frequency limit of the pass band is called the *lower cutoff frequency* (ω_{c1}), and the upper frequency limit of the band is called the *upper cutoff frequency* (ω_{c2}).

The most straightforward way to form a band-pass filter is to cascade a high-pass filter of cutoff frequency ω_{c1} with a low-pass filter of cutoff frequency ω_{c2} . Such an arrangement is shown in Figure 16.9. The passive circuit shown in Figure 16.9(a) is obtained by connecting the circuits shown in Figure 16.7(a) and Figure 16.8(a). The passive circuit shown in Figure 16.9(b) is obtained by connecting a voltage follower opamp circuit to the original passive circuit. Passive and active filters have the same transfer function, assuming that loading problems are not present in the passive filter. Since loading errors can be serious in practice, however, the active version is preferred.

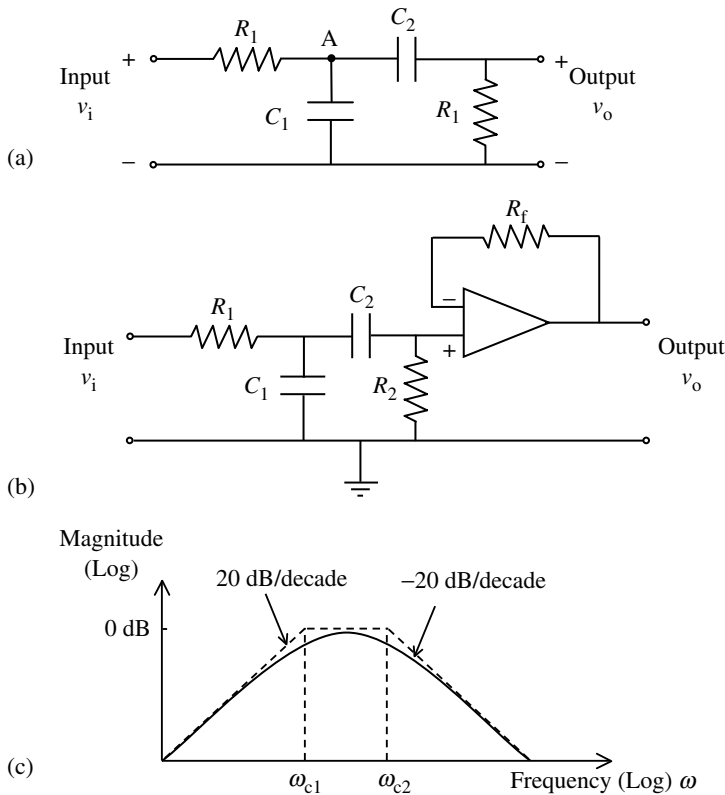

FIGURE 16.9 Band-pass filter: (a) a basic passive filter stage; (b) a basic active filter stage; (c) frequency-response characteristic.

To obtain the filter equation, first consider the high-pass portion of the circuit shown in Figure 16.9(a). Since the output is open circuit (zero current), we have from Equation 16.35:

$$\frac{v_o}{v_A} = \frac{\tau_2 s}{(\tau_2 s + 1)} \quad (i)$$

in which

$$\tau_2 = R_2 C_2 \quad (16.38)$$

Next, writing the current balance at node A of the circuit, we have

$$\frac{v_i - v_A}{R_1} = C_1 \frac{dv_A}{dt} + C_2 \frac{d}{dt}(v_A - v_o) \quad (ii)$$

Introducing the Laplace variable, s , we obtain

$$v_i = (\tau_1 s + \tau_3 s + 1)v_A - \tau_3 s v_o \quad (iii)$$

in which

$$\tau_1 = R_1 C_1 \quad (16.39)$$

and

$$\tau_3 = R_1 C_2 \quad (16.40)$$

Now, on eliminating v_A by substituting Equation i in Equation iii, we obtain the band-pass filter transfer function

$$\frac{v_o}{v_i} = G(s) = \frac{\tau_2 s}{[\tau_1 \tau_2 s^2 + (\tau_1 + \tau_2 + \tau_3)s + 1]} \quad (16.41)$$

We can show that the roots of the characteristic equation

$$\tau_1 \tau_2 s^2 + (\tau_1 + \tau_2 + \tau_3)s + 1 = 0 \quad (16.42)$$

are real and negative. The two roots are denoted by $-\omega_{c1}$ and $-\omega_{c2}$ and they provide the two cutoff frequencies shown in Figure 16.9(c). It can be verified that, for this basic band-pass filter, the roll-up slope is +20 dB/decade and the roll-down slope is -20 dB/decade. These slopes are not sufficient in many applications. Furthermore, the flatness of the frequency response within the pass band of the basic filter is not adequate either. More complex (higher order) band-pass filters with sharper cutoffs and flatter pass bands are commercially available.

16.3.4.1 Resonance-Type Band-Pass Filters

There are many applications where a filter with a very narrow pass band is required. The tracking filter mentioned in the beginning of the section on analog filters is one such application. A filter circuit with a sharp resonance can serve as a narrow-band filter. Note that the cascaded RC circuit shown in Figure 16.9 does not provide an oscillatory response (the filter poles are all real) and, hence, it does not form a resonance-type filter. A slight modification to this circuit using an additional resistor, R_1 , as shown in Figure 16.10(a), will produce the desired effect.

To obtain the filter equation, note that, for the voltage follower unit

$$v_A = v_o \quad (i)$$

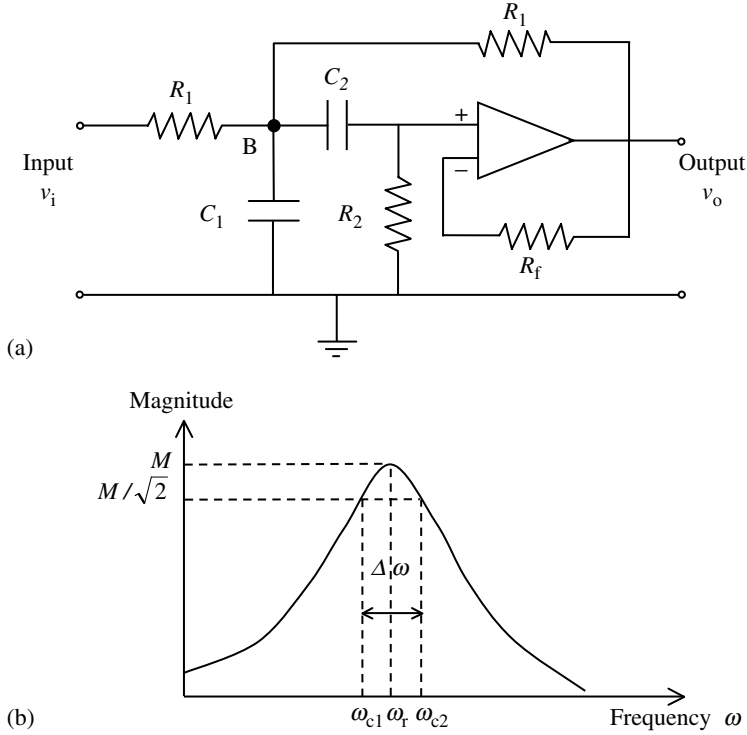

FIGURE 16.10 A resonance-type narrow-band-pass filter: (a) an active filter stage; (b) frequency-response characteristic.

Next, since current through an opamp lead is zero, for the high-pass circuit unit (see Equation 16.35), we have

$$\frac{v_A}{v_B} = \frac{\tau_2 s}{(\tau_2 s + 1)} \quad (\text{ii})$$

in which

$$\tau_2 = R_2 C_2$$

Finally, current balance at node B gives

$$\frac{v_i - v_B}{R_1} = C_1 \frac{dv_B}{dt} + C_2 \frac{d}{dt}(v_B - v_A) + \frac{v_B - v_o}{R_1}$$

or, by using the Laplace variable, we obtain

$$v_i = (\tau_1 s + \tau_3 s + 2)v_B - \tau_3 s v_A - v_o \quad (\text{iii})$$

Now, by eliminating v_A and v_B in the equations from Equation i to Equation iii, we obtain the filter transfer function

$$\frac{v_o}{v_i} = G(s) = \frac{\tau_2 s}{[\tau_1 \tau_2 s^2 + (\tau_1 + \tau_2 + \tau_3)s + 2]} \quad (16.43)$$

It can be shown that, unlike Equation 16.41, the present characteristic equation

$$\tau_1 \tau_2 s^2 + (\tau_1 + \tau_2 + \tau_3)s + 2 = 0 \quad (16.44)$$

can possess complex roots.

Example 16.5

Verify that the band-pass filter shown in Figure 16.10(a) can have a frequency response with a resonant peak as shown in Figure 16.10(b). Verify that the half-power bandwidth $\Delta\omega$ of the filter is given by $2\zeta\omega_r$ at low damping values. (Note: ζ = damping ratio and ω_r = resonant frequency.)

Solution

We may verify that the transfer function given by Equation 16.43 can have a resonant peak by showing that the characteristic equation (Equation 16.44) can have complex roots. For example, if we use parameter values $C_1 = 2$, $C_2 = 1$, $R_1 = 1$, and $R_2 = 2$, we have $\tau_1 = 2$, $\tau_2 = 2$, and $\tau_3 = 1$. The corresponding characteristic equation is

$$4s^2 + 5s + 2 = 0$$

It has the roots

$$-\frac{5}{8} \pm j\frac{\sqrt{7}}{8}$$

is obviously complex.

To obtain an expression for the half-power bandwidth of the filter, note that the filter transfer function may be written as

$$G(s) = \frac{ks}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} \quad (16.45)$$

in which

ω_n = undamped natural frequency

ζ = damping ratio

k = a gain parameter

The frequency-response function is given by

$$G(j\omega) = \frac{kj\omega}{[\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega]} \quad (16.46)$$

For low damping, resonant frequency $\omega_r \cong \omega_n$. The corresponding peak magnitude M is obtained by substituting $\omega = \omega_n$ in Equation 16.46 and taking the transfer function magnitude; thus

$$M = \frac{k}{2\zeta\omega_n} \quad (16.47)$$

At half-power frequencies, we have

$$|G(j\omega)| = \frac{M}{\sqrt{2}}$$

or

$$\frac{k\omega}{\sqrt{(\omega_n^2 - \omega^2)^2 + 4\zeta^2\omega_n^2\omega^2}} = \frac{k}{2\sqrt{2}\zeta\omega_n}$$

This gives

$$(\omega_n^2 - \omega^2)^2 = 4\zeta^2 \omega_n^2 \omega^2 \quad (16.48)$$

the positive roots of which provide the pass band frequencies ω_{c1} and ω_{c2} . Note that the roots are given by

$$\omega_n^2 - \omega^2 = \pm 2\zeta \omega_n \omega$$

Hence, the two roots, ω_{c1} and ω_{c2} , satisfy the following two equations:

$$\omega_{c1}^2 + 2\zeta \omega_n \omega_{c1} - \omega_n^2 = 0$$

$$\omega_{c2}^2 - 2\zeta \omega_n \omega_{c2} - \omega_n^2 = 0$$

Accordingly, by solving these two quadratic equations and selecting the appropriate sign, we obtain

$$\omega_{c1} = -\zeta \omega_n + \sqrt{\omega_n^2 + \zeta^2 \omega_n^2} \quad (16.49)$$

$$\omega_{c2} = \zeta \omega_n + \sqrt{\omega_n^2 + \zeta^2 \omega_n^2} \quad (16.50)$$

The half-power bandwidth is

$$\Delta\omega = \omega_{c2} - \omega_{c1} = 2\zeta \omega_n \quad (16.51)$$

Now, since $\omega_n \cong \omega_r$, for low ζ we have

$$\Delta\omega = 2\zeta \omega_r \quad (16.52)$$

A notable shortcoming of a resonance-type filter is that the frequency response within the bandwidth (pass band) is not flat. Hence, quite nonuniform signal attenuation takes place inside the pass band.

16.3.5 Band-Reject Filters

Band-reject filters, or *notch filters*, are commonly used to filter out a narrow band of noise components from a signal. For example, 60 Hz line noise in signals can be eliminated by using a notch filter with a notch frequency of 60 Hz.

An active circuit that could serve as a notch filter is shown in [Figure 16.11\(a\)](#). This is known as the Twin T circuit because its geometric configuration resembles two T-shaped circuits connected together. To obtain the filter equation, note that the voltage at point P is v_o because of unity gain of the voltage follower. Now, we write the current balance at nodes A and B; thus

$$\begin{aligned} \frac{v_i - v_B}{R} &= 2C \frac{dv_B}{dt} + \frac{v_B - v_o}{R} \\ C \frac{d}{dt}(v_i - v_A) &= \frac{v_A}{R/2} + C \frac{d}{dt}(v_A - v_o) \end{aligned}$$

Next, since the current through the positive lead of the opamp (voltage follower) is zero, we have the current through point P as

$$\frac{v_B - v_o}{R} = C \frac{d}{dt}(v_o - v_A)$$

These three equations are written in the Laplace form as

$$v_i = 2(\tau s + 1)v_B - v_o \quad (i)$$

$$\tau s v_i = 2(\tau s + 1)v_A - \tau s v_o \quad (ii)$$

$$v_B = (\tau s + 1)v_o - \tau s v_A \quad (iii)$$

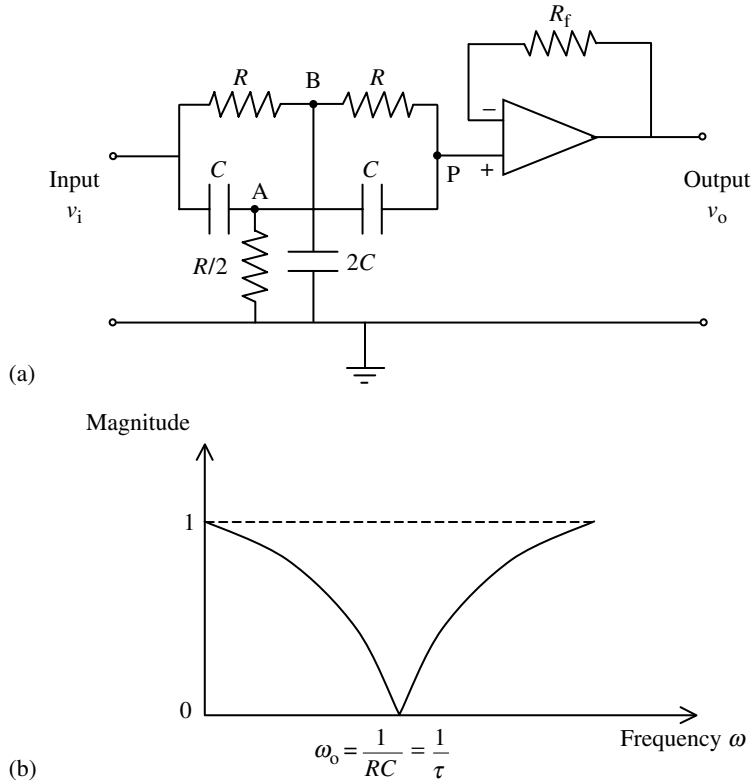

FIGURE 16.11 A notch filter: (a) an active Twin T filter circuit; (b) frequency-response characteristic.

in which

$$\tau = RC \quad (16.53)$$

Finally, eliminating v_A and v_B in Equation i to Equation iii, we obtain

$$\frac{v_o}{v_i} = G(s) = \frac{(\tau^2 s^2 + 1)}{(\tau^2 s^2 + 4\tau s + 1)} \quad (16.54)$$

The frequency-response function of the filter is

$$G(j\omega) = \frac{(1 - \tau^2 \omega^2)}{(1 - \tau^2 \omega^2 + 4j\tau\omega)} \quad (16.55)$$

with $s = j\omega$. Note that the magnitude of this function becomes zero at frequency

$$\omega_o = \frac{1}{\tau} \quad (16.56)$$

This is known as the notch frequency. The magnitude of the frequency-response function of the notch filter is sketched in Figure 16.11(b). It is noticed that any signal component at frequency ω_o will be completely eliminated by the notch filter. Sharp roll-down and roll-up are needed to allow the other (desirable) signal components through without too much attenuation.

Whereas the previous three types of filters achieve their frequency-response characteristics through the poles of the filter transfer function, a notch filter achieves its frequency-response characteristic through its zeros (roots of the numerator polynomial equation). Some useful information about filters is summarized in Box 16.2.

Box 16.2

FILTERS

Active Filters (Need External Power)**Advantages:**

- Smaller loading errors (have high input impedance and low output impedance, and hence do not affect the input circuit conditions and output signals)
- Lower cost
- Better accuracy

Passive Filters (No External Power, Use Passive Elements)**Advantages:**

- Useable at very high frequencies (e.g., radio frequency)
- No need for a power supply

Filter Types

- Low pass: Allows frequency components up to cutoff and rejects the higher frequency components
- High pass: Rejects frequency components up to cutoff and allows the higher frequency components
- Band pass: Allows frequency components within an interval and rejects the rest
- Notch (or band reject): Rejects frequency components within an interval (usually narrow) and allows the rest

Definitions

- Filter order: Number of poles in the filter circuit or transfer function
- Antialiasing filter: Low-pass filter with cutoff at less than half the sampling rate (i.e., Nyquist frequency), for digital processing
- Butterworth filter: A high-order filter with a very flat pass band
- Chebyshev filter: An optimal filter with uniform ripples in the pass band
- Sallen-Key filter: An active filter whose output is in phase with input

16.4 Modulators and Demodulators

Sometimes signals are deliberately modified to maintain the accuracy during signal transmission, conditioning, and processing. In signal *modulation*, the data signal, known as the *modulating signal*, is used to vary a property (such as amplitude or frequency) of a *carrier signal*. We say that the carrier signal is modulated by the data signal. After transmitting or conditioning the modulated signal, the data signal is usually recovered by removing the carrier signal. This is known as *demodulation* or *discrimination*.

Many modulation techniques exist, and several other types of signal modification (e.g., digitizing) could be classified as signal modulation even though they might not be commonly termed as such. Four types of modulation are illustrated in [Figure 16.12](#). In *amplitude modulation* (AM), the amplitude of a periodic carrier signal is varied according to the amplitude of the data signal (modulating signal), frequency of the carrier signal (*carrier frequency*) being kept constant. Suppose that the transient signal

FIGURE 16.12 (a) Modulating signal (data signal); (b) amplitude-modulated (AM) signal; (c) frequency-modulated (FM) signal; (d) pulse-width-modulated (PWM) signal; (e) pulse-frequency-modulated (PFM) signal.

shown in Figure 16.12(a) is used as the modulating signal. A high-frequency sinusoidal signal is used as the carrier signal. The resulting amplitude-modulated signal is shown in Figure 16.12(b). Amplitude modulation is used in telecommunications, radio and TV signal transmission, instrumentation, and signal conditioning. The underlying principle is useful in other applications such as fault detection and diagnosis in rotating machinery.

In *frequency modulation* (FM), the frequency of the carrier signal is varied in proportion to the amplitude of the data signal (modulating signal), while the amplitude of the carrier signal is kept constant. If the data signal shown in Figure 16.12(a) is used to frequency modulate a sinusoidal carrier signal, then the result will appear as shown in Figure 16.12(c). Since information is carried as frequency rather than amplitude, any noise that might alter the signal amplitude will have virtually no effect on the transmitted data. Hence, FM is less susceptible to noise than AM. Furthermore, since the carrier amplitude is kept constant in FM, signal weakening and noise effects that are unavoidable in long-distance data communication will have less effect than in the case of AM, particularly if the data signal level is low in the beginning. However, more sophisticated techniques and hardware are needed for signal recovery (demodulation) in FM transmission, because FM demodulation involves frequency discrimination rather than amplitude detection. Frequency modulation is also widely used in radio transmission and in data recording and replay.

In *pulse-width modulation* (PWM), the carrier signal is a pulse sequence. The pulse width is changed in proportion to the amplitude of the data signal, while keeping the pulse spacing constant. This is illustrated in Figure 16.12(d). Pulse-width modulated signals are extensively used in controlling electric motors and other mechanical devices such as valves (hydraulic, pneumatic) and machine tools. Note that, in a given short time interval, the average value of the pulse-width modulated signal is an estimate of the average value of the data signal in that period. Hence, PWM signals can be used directly in controlling a process without one having to demodulate it. Advantages of PWM include better energy efficiency (less dissipation) and better performance with nonlinear devices. For example, a device may stick at low speeds due to Coulomb friction. This can be avoided by using a PWM signal that provides the signal amplitude that is necessary to overcome friction while maintaining the required average control signal, which might be very small.

In *pulse-frequency modulation* (PFM) as well, the carrier signal is a pulse sequence. In this method, the frequency of the pulses is changed in proportion to the data signal level, while the pulse width is kept constant. PFM has the advantage of ordinary frequency modulation. Additional advantages result due to the fact that electronic circuits (digital circuits, in particular) can handle pulses very efficiently. Furthermore, pulse detection is not susceptible to noise because it involves distinguishing between the presence and absence of a pulse rather than accurate determination of the pulse amplitude (or width). PFM may be used in place of PWM in most applications with better results.

Another type of modulation is *phase modulation* (PM). In this method, the phase angle of the carrier signal is varied in proportion to the amplitude of the data signal.

Conversion of discrete (sampled) data into the digital (binary) form is also considered to be modulation. In fact, this is termed *pulse-code modulation* (PCM). In this case, each discrete data sample is represented by a binary number containing a fixed number of binary digits (bits). Since each digit in the binary number can take only two values, 0 or 1, it can be represented by the absence or presence of a voltage pulse. Hence, each data sample can be transmitted using a set of pulses. This is known as *encoding*. At the receiver, the pulses have to be interpreted (or decoded) in order to determine the data value. As with any other pulse technique, PCM is quite immune to noise because decoding involves detection of the presence or absence of a pulse rather than determination of the exact magnitude of the pulse signal level. Also, since pulse amplitude is constant, long-distance signal transmission (of this digital data) can be accomplished without the danger of signal weakening and associated distortion. Of course, there will be some error introduced by the digitization process itself, which is governed by the finite word size (or dynamic range) of the binary data element. This is known as quantization error and is unavoidable in signal digitization.

In any type of signal modulation, it is essential to preserve the algebraic sign of the modulating signal (data). Different types of modulators handle this in different ways. For example, in PCM an extra *sign bit* is added to represent the sign of the transmitted data sample. In AM and FM, a *phase-sensitive demodulator* is used to extract the original (modulating) signal with the correct algebraic sign. Note that, in these two modulation techniques, a sign change in the modulating signal can be represented by a 180° phase change in the modulated signal. This is not noticeable in Figure 16.12(b) and (c). In PWM and PFM, a sign change in the modulating signal can be represented by changing the sign of the pulses, as shown in Figure 16.12(d) and (e). In PM, a positive range of phase angles (say 0 to π) can be assigned for the positive values of the data signal and a negative range of phase angles (say $-\pi$ to 0) can be assigned for the negative values of the signal.

16.4.1 Amplitude Modulation

Amplitude modulation can naturally enter into many physical phenomena. More important, perhaps, is the deliberate (artificial) use of AM to facilitate data transmission and signal conditioning. Let us first examine the related mathematics.

Amplitude modulation is achieved by multiplying the data signal (modulating signal), $x(t)$, by a high frequency (periodic) carrier signal, $x_c(t)$. Hence, amplitude-modulated signal, $x_a(t)$, is given by

$$x_a(t) = x(t)x_c(t) \quad (16.57)$$

Note that the carrier could be any periodic signal such as one which is harmonic (sinusoidal), square wave, or triangular. The main requirement is that the fundamental frequency of the carrier signal (*carrier frequency*), f_c , be significantly larger (say, by a factor of five or ten) than the highest frequency of interest (*bandwidth*) of the data signal. Analysis can be simplified by assuming a sinusoidal carrier frequency; thus

$$x_c(t) = a_c \cos 2\pi f_c t \quad (16.58)$$

16.4.1.1 Modulation Theorem

Modulation theorem is also known as the *frequency-shifting theorem*, and it relates the fact that if a signal is multiplied by a sinusoidal signal, the Fourier spectrum of the product signal is simply the Fourier spectrum of the original signal shifted through the frequency of the sinusoidal signal. In other words, the Fourier spectrum, $X_a(f)$, of the amplitude-modulated signal, $x_a(t)$, can be obtained from the Fourier spectrum, $X(f)$, of the data signal, $x(t)$, simply by shifting through the carrier frequency, f_c .

To mathematically explain the modulation theorem, we use the definition of the Fourier integral transform to obtain

$$X_a(f) = a_c \int_{-\infty}^{\infty} x(t) \cos 2\pi f_c t \exp(-j2\pi ft) dt$$

However, since

$$\cos 2\pi f_c t = \frac{1}{2} [\exp(j2\pi f_c t) + \exp(-j2\pi f_c t)]$$

we have

$$\begin{aligned} X_a(f) &= \frac{1}{2} a_c \int_{-\infty}^{\infty} x(t) \exp[-j2\pi(f - f_c)t] dt + \frac{1}{2} a_c \int_{-\infty}^{\infty} x(t) \exp[-j2\pi(f + f_c)t] dt \\ X_a(f) &= \frac{1}{2} a_c [X(f - f_c) + X(f + f_c)] \end{aligned} \quad (16.59)$$

Equation 16.59 is the mathematical statement of the modulation theorem. It is illustrated by an example in Figure 16.13. Consider a transient signal, $x(t)$, with a (continuous) Fourier spectrum, $X(f)$, whose magnitude, $|X(f)|$, is as shown in Figure 16.13(a). If this signal is used to modulate the AM of a high-frequency sinusoidal signal, the resulting modulated signal, $x_a(t)$, and the magnitude of its

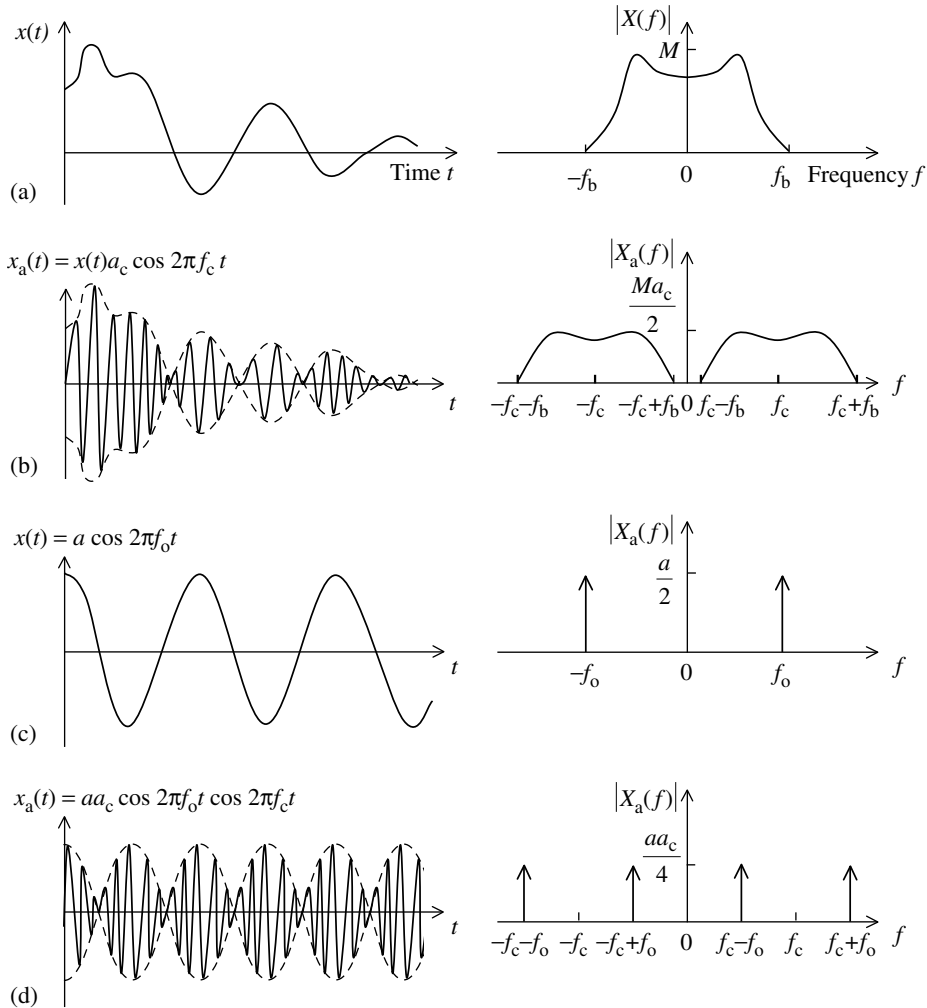

FIGURE 16.13 Illustration of the modulation theorem: (a) a transient data signal and its Fourier spectrum magnitude; (b) amplitude-modulated signal and its Fourier spectrum magnitude; (c) a sinusoidal data signal; (d) amplitude modulation by a sinusoidal signal.

Fourier spectrum are as shown in Figure 16.13(b). It should be kept in mind that the magnitude has been multiplied by $a_c/2$. Note that the data signal is assumed to be *band limited*, with bandwidth f_b . Of course, the theorem is not limited to band-limited signals but, for practical reasons, we need to have some upper limit on the useful frequency of the data signal. Also for practical reasons (not for the theorem itself), the carrier frequency, f_c , should be several times larger than f_b so that there is a reasonably wide frequency band from 0 to $(f_c - f_b)$, within which the magnitude of the modulated signal is virtually zero. The significance of this should be clear when we discuss applications of amplitude modulation.

Figure 16.13 shows only the magnitude of the frequency spectra. It should be remembered, however, that every Fourier spectrum has a phase angle spectrum as well. This is not shown for conciseness, but clearly the phase-angle spectrum is also similarly affected (frequency shifted) by AM.

16.4.1.2 Side Frequencies and Side Bands

The modulation theorem, as described above, assumed transient data signals with associated continuous Fourier spectra. The same ideas are applicable to periodic signals (with discrete spectra) as well. The case

of periodic signals is merely a special case of what was discussed above. This case can be analyzed by using Fourier integral transform itself, from the beginning. If this method is chosen, however, we will have to cope with impulsive spectral lines. Alternatively, Fourier series expansion could be employed to avoid the introduction of impulsive discrete spectra into the analysis. However, as shown in Figure 16.13(c) and (d), no analysis is actually needed for the periodic signal case because a final answer can be deduced from the transient signal results. Specifically, each frequency component, f_o , that has amplitude $a/2$ in the Fourier series expansion of the data signal will be shifted by $\pm f_c$ to the two new frequency locations $f_c + f_o$ and $-f_c + f_o$ with an associated amplitude $aa_c/4$. The negative frequency component $-f_o$ should also be considered in the same way, as illustrated in Figure 16.13(d). Note that the modulated signal does not have a spectral component at carrier frequency, f_c , but rather on each side of it, at $f_c \pm f_o$. Hence, these spectral components are termed side frequencies. When a band of *side frequencies* is present, we have a *side band*. Side frequencies are very useful in fault detection and diagnosis of rotating machinery.

16.4.2 Application of Amplitude Modulation

The main hardware component of an amplitude modulator is an *analog multiplier*. They are commercially available in the monolithic IC form, or one can be assembled using IC opamps and other discrete circuit elements. A schematic representation of an amplitude modulator is shown in Figure 16.14. In practice, to achieve satisfactory modulation, other components such as signal preamplifiers and filters are needed.

There are many applications of AM. In some applications, modulation is performed intentionally. In others, modulation occurs naturally as a consequence of the physical process, and the resulting signal is used to meet a practical objective. Typical applications of AM include the following:

1. Conditioning of general signals (including DC, transient, and low-frequency) by exploiting the advantages of AC signal conditioning hardware
2. Improvement of the immunity of low-frequency signals to low-frequency noise
3. Transmission of general signals (DC, low-frequency, etc.) by exploiting the advantages of AC signals
4. Transmission of low-level signals under noisy conditions
5. Transmission of several signals simultaneously through the same medium (e.g., same telephone line, same transmission antenna, etc.)
6. Fault detection and diagnosis of rotating machinery

The role of AM in many of these applications should be obvious if one understands the frequency-shifting property of AM. Several other types of application are also feasible due to the fact that the power of the carrier signal can be increased somewhat arbitrarily, irrespective of the power level of the data (modulating) signal. Let us discuss, one by one, the six categories of application mentioned above.

AC signal conditioning devices such as AC amplifiers are known to be more “stable” than their DC counterparts. In particular, *drift* problems are not as severe and nonlinearity effects are lower in AC signal conditioning devices. Hence, instead of conditioning a DC signal using DC hardware, we can first use the

FIGURE 16.14 Representation of an amplitude modulator.

signal to modulate a high-frequency carrier signal. Then, the resulting high-frequency modulated signal may be conditioned more effectively using AC hardware.

The frequency-shifting property of AM can be exploited in making low-frequency signals immune to low-frequency noise. Note from Figure 16.13 that, by AM, low-frequency spectrum of the modulating signal can be shifted into a very high-frequency region by choosing a sufficiently large carrier frequency, f_c . Then, any low-frequency noise (within the band 0 to $f_c - f_b$) will not distort the spectrum of the modulated signal. Hence, this noise can be removed by a high-pass filter (with cutoff at $f_c - f_b$) without affecting the data. Finally, the original data signal can be recovered by demodulation. Note that the frequency of a noise component can be within the bandwidth, f_b , of the data signal and, hence, if AM is not employed, noise can directly distort the data signal.

Transmission of AC signals is more efficient than that of DC signals. Advantages of AC transmission include lower problems with energy dissipation. Hence, a modulated signal can be transmitted over long distances more effectively than could the original data signal alone. Furthermore, transmission of low-frequency (large wave-length) signals requires large antennas. Hence, when AM is employed (with an associated reduction in signal wave length), the size of broadcast antenna can be effectively reduced.

Transmission of weak signals over long distances is not desirable because signal weakening and corruption by noise could produce disastrous results. By increasing the power of the carrier signal to a sufficiently high level, the strength of the modulated signal can be elevated to an adequate level for long-distance transmission.

It is impossible to transmit two or more signals in the same frequency range simultaneously using a single telephone line. This problem can be resolved by using carrier signals with significantly different carrier frequencies to modulate the amplitude of the data signals. By choosing carrier frequencies that are sufficiently farther apart, the spectra of the modulated signals can be made nonoverlapping, thereby making simultaneous transmission possible. Similarly, with AM, simultaneous broadcasting by several radio (AM) broadcast stations in the same broadcast area has become possible.

16.4.2.1 Fault Detection and Diagnosis

A use of the AM principle that is particularly important in the practice of mechanical vibration is in the fault detection and diagnosis of rotating machinery. In this method, modulation is not deliberately introduced, but rather results from the dynamics of the machine. Flaws and faults in a rotating machine are known to produce periodic forcing signals at frequencies higher than, and typically at an integer multiple of, the rotating speed of the machine. For example, backlash in a gear pair will generate forces at the tooth-meshing frequency (equal to the number of teeth \times gear rotating speed). Flaws in roller bearings can generate forcing signals at frequencies proportional to the rotating speed times the number of rollers in the bearing race. Similarly, blade passing in turbines and compressors and eccentricity and unbalance in rotors can produce forcing components at frequencies that are integer multiples of the rotating speed. The resulting vibration response will be an amplitude-modulated signal, where the rotating response of the machine modulates the high-frequency forcing response. This can be confirmed experimentally by Fourier analysis (fast Fourier transform or FFT) of the resulting vibration signals. For a gear box, for example, it will be noticed that, instead of obtaining a spectral peak at the gear tooth-meshing frequency, two side bands are produced around that frequency. Faults can be detected by monitoring the evolution of these side bands. Furthermore, since side bands are the result of modulation of a specific forcing phenomenon (e.g., gear-tooth meshing, bearing-roller hammer, turbine-blade passing, imbalance, eccentricity, misalignment, etc.), one can trace the source of a particular fault (i.e., diagnose the fault) by studying the Fourier spectrum of the measured vibrations.

Amplitude modulation is an integral part of many types of sensors. In these sensors, a high-frequency carrier signal (typically the AC excitation in a primary winding) is modulated by the motion. Actual motion can be detected by demodulation of the output. Examples of sensors that generate modulated outputs are differential transformers (LVDT, RVDT), magnetic-induction proximity sensors, eddy-current proximity sensors, AC tachometers, and strain-gage devices that use AC bridge circuits.

Signal conditioning and transmission is facilitated by AM in these cases. However, the signal has to be demodulated at the end for most practical purposes such as analysis and recording.

16.4.3 Demodulation

Demodulation, or discrimination or detection, is the process of extracting the original data signal from a modulated signal. In general, demodulation must be phase sensitive in the sense that the algebraic sign of the data signal should be preserved and determined by the demodulation process. In *full-wave demodulation*, an output is generated continuously. In *half-wave demodulation*, no output is generated for every alternate half-period of the carrier signal.

A simple and straightforward method of demodulation is by the detection of the envelope of the modulated signal. For this method to be feasible, the carrier signal must be quite powerful (i.e., the signal level has to be high) and the carrier frequency also should be very high. An alternative method of demodulation that generally provides more reliable results involves the further step of modulation performed on the already-modulated signal, followed by low-pass filtering. This method will be explained by referring to Figure 16.13.

Consider the amplitude-modulated signal, $x_a(t)$, shown in Figure 16.13(b). If this signal is multiplied by the sinusoidal carrier signal, $2/a_c \cos 2\pi f_c t$, we obtain

$$\tilde{x}(t) = \frac{2}{a_c} x_a(t) \cos 2\pi f_c t \quad (16.60)$$

Now, by applying the modulation theorem (Equation 16.59) to Equation 16.60, we obtain the Fourier spectrum of $\tilde{x}(t)$ as

$$\tilde{X}(f) = \frac{1}{2} \frac{2}{a_c} \left[\frac{1}{2} a_c \{X(f - 2f_c) + X(f)\} + \frac{1}{2} a_c \{X(f) + X(f + 2f_c)\} \right]$$

or

$$\tilde{X}(f) = X(f) + \frac{1}{2} X(f - 2f_c) + \frac{1}{2} X(f + 2f_c) \quad (16.61)$$

The magnitude of this spectrum is shown in Figure 16.15(a). Note that we have recovered the spectrum, $X(f)$, of the original data signal, except for the two side bands that are present at locations far removed (centered at $\pm 2f_c$) from the bandwidth of the original signal. Hence, we can easily use a low-pass filter on this signal, $\tilde{x}(t)$, using a filter with cutoff at f_b to recover the original data signal. A schematic representation of this method of amplitude demodulation is shown in Figure 16.15(b).

FIGURE 16.15 Amplitude demodulation: (a) spectrum of the signal after the second modulation; (b) demodulation schematic diagram (modulation + filtering).

16.5 Analog–Digital Conversion

Data-acquisition systems in machine condition monitoring, fault detection and diagnosis, and vibration testing employ digital computers for various tasks including signal processing, data analysis and reduction, parameter identification, and decision making. Typically, the measured response (output) of a dynamic system is available in the analog form as a continuous signal (function of continuous time). Furthermore, typically, the excitation signals (inputs) for a dynamic system have to be provided in the analog form.

Inputs to a digital device, say from a digital computer, and outputs from a digital device are necessarily present in the digital form. Hence, when a digital device is interfaced with an analog device, the interface hardware and associated driver software must perform several important functions. Two of the most important interface functions are *digital-to-analog conversion* (DAC) and *analog-to-digital conversion* (ADC). A digital output from a digital device has to be converted into the analog form for it to be fed into an analog device such as actuator or analog recording or display unit. Also, an analog signal has to be converted into the digital form according to an appropriate code before it is read by a digital processor or computer. Digital-to-analog converters are simpler and lower in cost than analog-to-digital converters. Furthermore, some types of analog-to-digital converters employ a digital-to-analog converter to perform their function. For these reasons, we will first discuss DAC.

16.5.1 Digital-to-Analog Conversion

The function of a DAC is to convert a sequence of digital words stored in a data register (called a DAC register), typically in straight binary form, into an analog signal. The data in the DAC register may come from a data bus of a computer. Each binary digit (bit) of information in the register may be present as a state of a *bistable* (two-stage) logic device, which can generate a voltage pulse or a voltage level to represent that bit. For example, the *off* state of a bistable logic element, the absence of a voltage pulse, a low level of a voltage signal, or no change in a voltage level can represent binary 0. Then, the *on* state of a bistable device, the *presence* of a voltage pulse, a *high level* of a voltage signal, or a *change* in a voltage level will represent binary 1. The combination of these bits, which form the digital word in the DAC register, will correspond to some numerical value for the output signal. The purpose of DAC is to generate an output voltage (signal level) that has this numerical value and maintain the value until the next digital word is converted. Since a voltage output cannot be arbitrarily large or small, for practical reasons, some form of scaling will have to be employed in the DAC process. This scale will depend on the reference voltage, v_{ref} , used in the particular DAC circuit.

A typical DAC unit is an active circuit in the IC form, which may consist of a data register (digital circuits), solid-state switching circuits, resistors, and operational amplifiers powered by an external power supply that can provide a reference voltage. The reference voltage will determine the maximum value of the output (*full-scale voltage*). An IC chip that represents the DAC is usually one of many components mounted on a *printed circuit* (PC) board. This PC board may be identified by several names including input/output (I/O) board, I/O card, interface board, and data acquisition and control board. Typically, the same board will provide both DAC and ADC capabilities for many output and input channels.

There are many types and forms of DAC circuits. The form will depend mainly on the manufacturer, the requirements of the user, or of the particular application. Most DACs are variations of two basic types: the *weighted* (or *summer* or *adder*) type and the *ladder* type. The latter type of DAC is more desirable, though the former can be somewhat simpler and less expensive.

16.5.1.1 DAC Error Sources

For a given digital word, the analog output voltage from a DAC is not exactly equal to what is given by the analytical formulas. The difference between the actual output and the ideal output is the error. The DAC error can be normalized with respect to the full-scale value.

There are many causes of DAC error. Typical error sources include parametric uncertainties and variations, circuit time constants, switching errors, and variations and noise in the reference voltage. Several types of error sources and representations are discussed below.

1. **Code ambiguity:** In many digital codes (for example, in the straight binary code), incrementing a number by a least significant bit (LSB) will involve more than one bit-switching. If the speed of switching from 0 to 1 is different from that for 1 to 0, and if switching pulses are not applied to the switching circuit simultaneously, the bit-switchings will not take place simultaneously. For example, in a 4-bit DAC, incrementing from decimal 2 to decimal 4 will involve changing the digital word from 0011 to 0100. This requires two bit-switchings from 1 to 0 and one bit-switching from 0 to 1. If 1 to 0 switching is faster than the 0 to 1 switching, then an intermediate value given by 0000 (decimal 0) will be generated, with a corresponding analog output. Hence, there will be a momentary code ambiguity and associated error in the DAC signal. This problem can be reduced (and eliminated in single bit increments) if a *gray code* is used to represent the digital data. Improved switching circuitry will also help reduce this error.
2. **Settling time:** The circuit hardware in a DAC unit will have some dynamics, with associated time constants and perhaps oscillations (underdamped response). Hence, the output voltage cannot instantaneously settle to its ideal value upon switching. The time required for the analog output to settle within a certain band (say $\pm 2\%$ of the final value or $\pm 1/2$ resolution), following the application of the digital data, is termed settling time. Naturally, settling time should be smaller for better (faster and more accurate) performance. As a guideline, the settling time should be approximately half the data arrival time. Note that the data arrival time is the time interval between the arrival of two successive data values, and is given by the inverse of the data arrival rate.
3. **Glitches:** Switching of a circuit will involve sudden changes in magnetic flux due to current changes. This will induce voltages that produce unwanted signal components. In a DAC circuit, these induced voltages due to rapid switching can cause signal spikes that will appear in the output. The error due to these noise signals is not significant at low conversion rates.
4. **Parametric errors:** Resistor elements in a DAC might not be precise, particularly when resistors within a wide range of magnitudes are employed, as in the case in a weighted-resistor DAC. These errors appear in the analog output. Furthermore, aging and environmental changes (primarily, change in temperature) will change the values of circuit parameters, resistance in particular. This also will result in DAC error. These types of error, which are due to the imprecision of circuit parameters and variations of parameter values, are termed parametric errors. Effects of such errors can be reduced by several ways, including the use of compensation hardware (and perhaps software) and directly, by using precise and robust circuit components and employing good manufacturing practices.
5. **Reference voltage variations:** Since the analog output of a DAC is proportional to the reference voltage, v_{ref} , any variations in the voltage supply will directly appear as an error. This problem can be overcome by using stabilized voltage sources with sufficiently low output impedance.
6. **Monotonicity:** Clearly, the output of a DAC should change by its resolution ($\delta y = v_{\text{ref}}/2^n$) for each step of one LSB increment in the digital value. This ideal behavior might not exist in some real DACs due to errors such as those mentioned above. At least the analog output should not decrease as the value of the digital input increases. This is known as the monotonicity requirement that should be met by a practical DAC.
7. **Nonlinearity:** Suppose that the digital input to a DAC is varied from [0 0...0] to [1 1...1] in steps of one LSB. Ideally the analog output should increase in constant jumps of $\delta y = v_{\text{ref}}/2^n$, giving a staircase-shaped analog output. If we draw the best linear fit for this ideally monotonic staircase response, it will have a slope equal to the resolution/step. This slope is known as the ideal scale factor. Nonlinearity of a DAC is measured by the largest deviation of the DAC output from this best linear fit. Note that, in the ideal case, the nonlinearity is limited to half the resolution $(1/2)\delta y$.

One cause of nonlinearity is clearly the faulty bit-transitions. Another cause is circuit nonlinearity in the conventional sense. Specifically, owing to nonlinearities in circuit elements such as opamps and resistors, the analog output will not be proportional to the value of the digital word dictated by the bit-switchings (faulty or not). This latter type of nonlinearity can be accounted for by using calibration.

16.5.2 Analog-to-Digital Conversion

Analog signals, which are continuously defined with respect to time, have to be sampled at discrete time points and the sample values have to be represented in the digital form (according to a suitable code) to be read into a digital system such as a microcomputer. An ADC is used to accomplish this. For example, since response measurements of dynamic systems are usually available as analog signals, these signals have to be converted into the digital form before passing on to a signal analysis computer. Hence, the computer interface for the measurement channels should contain one or more ADCs.

DACs and ADCs are usually situated on the same digital interface board. However, the ADC process is more complex and time consuming than the DAC process. Furthermore, many types of ADCs use DACs to accomplish the analog-to-digital conversion. Hence, ADCs are usually more costly than and their conversion rate is usually slower than that of DACs. Several types of ADCs are commercially available. The principle of operation varies depending on the type.

16.5.3 Analog-to-Digital Converter Performance Characteristics

For ADCs that use a DAC internally, the same error sources that were discussed previously for DACs apply. Code ambiguity at the output register is not a problem because the converted digital quantity is transferred instantaneously to the output register. Code ambiguity in the DAC register can still cause error in ADCs that use a DAC. Conversion time is a major factor as it is much larger for an ADC. In addition to resolution and dynamic range, quantization error will be applicable to an ADC. These considerations that govern the performance of an ADC are discussed below.

16.5.3.1 Resolution and Quantization Error

The number of bits, n , in an ADC register determines the resolution and dynamic range of the ADC. For an n -bit ADC, the output register size is n bits. Hence, the smallest possible increment of the digital output is one LSB. The change in the analog input that results in a change of one LSB at the output is the resolution of the ADC. The range of digital outputs is from 0 to $2^n - 1$ for the unipolar (unsigned) case. This represents the dynamic range. Hence, as for a DAC, the dynamic range of an n -bit ADC is given by the ratio

$$DR = 2^n - 1 \quad (16.62)$$

or, in decibels

$$DR = 20 \log_{10}(2^n - 1) \text{ dB} \quad (16.63)$$

The *full-scale value* of an ADC is the value of the analog input that corresponds to the maximum digital output.

Suppose that an analog signal within the dynamic range of the ADC is converted. Since the analog input (sample value) has infinitesimal resolution and the digital representation has a finite resolution (one LSB), an error is introduced in the ADC process. This is known as the *quantization error*. A digital number increments in constant steps of 1 LSB. If an analog value falls at an intermediate point within a single-LSB step, then there is a quantization error. Rounding of the digital output can be accomplished as follows. The magnitude of the error when quantized up is compared with that when quantized down, say, using two hold elements and a differential amplifier. Then, we retain the digital value corresponding to the lower error magnitude. If the analog value is below the 1/2 LSB mark, then the corresponding digital value is represented by the value in the beginning of the step. If the analog value is above the 1/2

LSB mark, then the corresponding digital value is the value at the end of the step. It follows that, with this type of rounding, the quantization error does not exceed $1/2$ LSB.

16.5.3.2 Monotonicity, Nonlinearity, and Offset Error

Considerations of monotonicity and nonlinearity are important for an ADC as well as for a DAC. The input is an analog signal and the output is digital in the case of ADC. Disregarding quantization error, the digital output of an ADC will increase in constant steps in the shape of an ideal staircase when the analog input is increased from zero in steps of the device resolution (δy). This is the ideally *monotonic* case. The best straight-line fit to this curve has a slope equal to $1/\delta y$ (LSB/V). This is the ideal gain or ideal scale factor. However, there will still be an *offset error* of $1/2$ LSB because the best linear fit will not pass through the origin. Adjustments can be made for this offset error.

Incorrect bit-transitions can take place in an ADC due to various errors that might be present and due to circuit malfunctions. The best linear fit under such faulty conditions will have a slope different from the ideal gain. The difference is the gain error. Nonlinearity is the maximum deviation of the output from the best linear fit. It is clear that, with perfect bit transitions, in the ideal case, a nonlinearity of $1/2$ LSB will be present. Nonlinearities larger than this result from incorrect bit-transitions. As in the case of DAC, another source of nonlinearity in an ADC is the existence of circuit nonlinearities that would deform the analog input signal before being converted into the digital form.

16.5.3.3 Analog-to-Digital Converter Conversion Rate

It is clear that ADC is much more time consuming than DAC. The conversion time is a very important factor because the rate at which conversion can take place governs many aspects of data acquisition, particularly in real-time applications. For example, the data sampling rate has to synchronize with the ADC conversion rate. This, in turn, will determine the Nyquist frequency (half the sampling rate) which is the maximum value of useful frequency present in the sampled signal. Furthermore, the sampling rate will dictate storage and memory requirements. Another important consideration related to the ADC conversion rate is the fact that a signal sample must be maintained at that value during the entire process of conversion into the digital form. This requires a hold circuit and this circuit should be able to perform accurately at the largest possible conversion time for the particular ADC unit.

The total time taken to convert an analog signal will depend on other factors besides the time taken for conversion from sampled data to digital data. For example, in multiple-channel data acquisition, the time taken to select the channel has to be counted. Furthermore, time needed to sample the data and time needed to transfer the converted digital data into the output register have to be included. The *conversion rate* for an ADC is the inverse of the overall time needed for a conversion cycle. Typically, however, conversion rate depends primarily on the bit conversion time in the case of one comparison-type ADC and on the integration time in the case of an integration-type ADC. A typical time period for a comparison step or counting step in an ADC is $\Delta t = 5 \mu\text{sec}$. Hence, for an eight-bit successive-approximation ADC the conversion time is $40 \mu\text{sec}$. The corresponding sampling rate is in the order of (less than) $1/40 \times 10^{-6} = 25 \times 10^3$ samples/sec (or 25 kHz). The maximum conversion rate for an eight-bit counter ADC is about $5 \times (2^8 - 1) = 1275 \mu\text{sec}$. The corresponding sampling rate would be of the order of 780 samples/sec. Note that this is considerably slow. The maximum conversion time for a dual-slope ADC can be still larger (slower).

16.5.4 Sample-and-Hold Circuitry

In typical applications of data acquisition that use ADC, the analog input to ADC can be very transient. Furthermore, ADC is not instantaneous (conversion time is much larger than the DAC time). Specifically, the incoming analog signal might be changing at a rate higher than the ADC conversion rate. Then, the input signal value will vary during the conversion period and there will be an ambiguity as to the input value corresponding to a digital output value. Hence, it is necessary to sample the analog input signal and maintain the input to the ADC at this value until the ADC is completed. In other words,

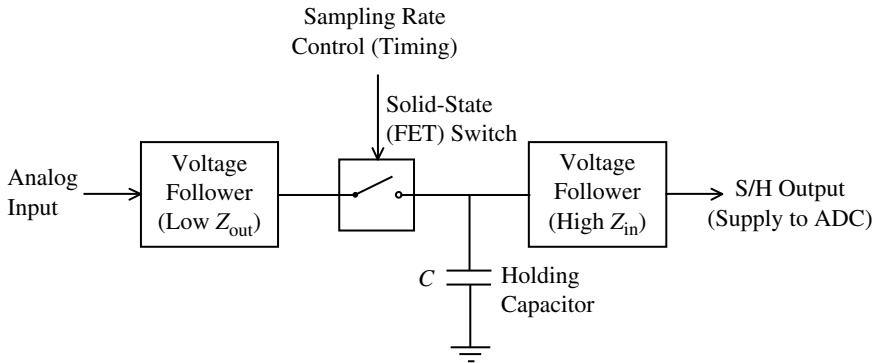

FIGURE 16.16 A sample and hold circuit.

since we are typically converting analog signals that can vary at a high speed, it is often necessary to *sample and hold* (S/H) the input signal for each ADC cycle. Each data sample must be generated and captured by the S/H circuit on the issue of the “start conversion” (SC) control signal, and the captured voltage level has to be maintained constant until the “conversion complete” (CC) control signal is issued by the ADC unit.

The main element in an S/H circuit is the holding capacitor. A schematic diagram of a S/H circuit is shown in Figure 16.16. The analog input signal is supplied through a voltage follower to a solid-state switch. The switch typically uses a field-effect transistor (FET), such as the metal-oxide semiconductor field effect transistor (MOSFET).

The switch is closed in response to a “sample pulse” and is opened in response to a “hold pulse.” Both control pulses are generated by the control logic unit of the ADC. During the time interval between these two pulses, the holding capacitor is charged to the voltage of the sampled input. This capacitor voltage is then supplied to the ADC through a second voltage follower.

The functions of the two voltage followers are now explained. When the FET switch is closed in response to a sample command (pulse), the capacitor must be charged as quickly as possible. The associated time constant (charging time constant) τ_c is given by

$$\tau_c = R_s C \quad (16.64)$$

in which

R_s = source resistance

C = capacitance of the holding capacitor

Since τ_c must be very small for fast charging and, since C is fixed by the holding requirements (typically C is of the order of 100 pF where $1 \text{ pF} = 1 \times 10^{-12} \text{ F}$), we need a very small source resistance. The requirement is met by the input voltage follower (which is known to have a very low output impedance), thereby providing a very small R_s . Furthermore, since a voltage follower has a unity gain, the voltage at the output of this input voltage follower is equal to the voltage of the analog input signal, as required.

Next, once the FET switch is opened in response to a hold command (pulse), the capacitor should not discharge. This requirement is met due to the presence of the output voltage follower. Since the input impedance of a voltage follower is very high, the current through its leads is almost zero. Because of this, the holding capacitor has a virtually zero discharge rate under hold conditions. Furthermore, we like the output of this second voltage follower to be equal to the voltage of the capacitor. This condition is also satisfied due to the fact that a voltage follower has a unity gain. Hence, the sampling will be almost instantaneous and the output of the S/H circuit will be maintained (almost) constant during the holding period due to the presence of the two voltage followers. Note that the practical S/H circuits are *zero-order-hold* devices by definition.

16.5.5 Digital Filters

A filter is a device that eliminates undesirable frequency components in a signal and passes only the desirable frequency components through. In *analog filtering*, the filter is a physical, dynamic system, typically an electric circuit. The signal to be filtered is applied (input) to this dynamic system. The output of the dynamic system is the filtered signal. It follows that any physical dynamic system can be interpreted as an analog filter.

An analog filter can be represented by a differential equation with respect to time. It takes an analog input signal, $u(t)$, that is defined continuously in time, t , and generates an analog output, $y(t)$. A digital filter is a device that accepts a sequence of discrete input values (say, sampled from an analog signal at sampling period Δt).

$$\{u_k\} = \{u_0, u_1, u_2, \dots\} \quad (16.65)$$

and generates a sequence of discrete output values:

$$\{y_k\} = \{y_0, y_1, y_2, \dots\} \quad (16.66)$$

Hence, a digital filter is a discrete-time system and it can be represented by a *difference equation*.

An n th order linear difference equation can be written in the form

$$a_0 y_k + a_1 y_{k-1} + \dots + a_n y_{k-n} = b_0 u_k + b_1 u_{k-1} + \dots + b_m u_{k-m} \quad (16.67)$$

This is a *recursive algorithm* in the sense that it generates one value of the output sequence using previous values of the output sequence and all values of the input sequence up to the present time point. Digital filters represented in this manner are termed *recursive digital filters*. There are filters that employ digital processing, in which a block (a collection of samples) of the input sequence is converted in a one-shot computation into a block of the output sequence. Such filters are not recursive filters. Nonrecursive filters usually employ *digital Fourier analysis*, the FFT algorithm in particular. We restrict our discussion below to recursive digital filters. Our intention in the present section is to give a brief (and nonexhaustive) introduction to the subject of digital filtering.

16.5.5.1 Software Implementation and Hardware Implementation

In digital filters, signal filtering is accomplished through digital processing of the input signal. The sequence of input data (usually obtained by sampling and digitizing the corresponding analog signal) is processed according to the recursive algorithm of the particular digital filter. This generates the output sequence. This digital output can be converted into an analog signal using a DAC if so desired.

A recursive digital filter is an implementation of a recursive algorithm that governs the particular filtering (e.g., low-pass, high-pass, band-pass, and band-reject). The filter algorithm can be implemented either by *software* or by *hardware*. In software implementation, the filter algorithm is programmed into a digital computer. The *processor* (e.g., the microprocessor) of the computer can process an input data sequence according to the run-time filter program stored in the memory (in machine code) to generate the filtered output sequence.

Digital processing of data is accomplished by means of logic circuitry that can perform basic arithmetic operations such as addition. In the software approach, the processor of a digital computer makes use of these basic logic circuits to perform digital processing according to the instructions of a software program stored in the computer memory. Alternatively, a hardware digital processor can be put together to perform a somewhat complex, yet fixed, processing operation. In this approach, the program of computation is said to be in hardware. The hardware processor is then available as an IC chip whose processing operation is fixed and cannot be modified. The logic circuitry in the IC chip is designed to accomplish the required processing function. Digital filters implemented by this hardware approach are termed *hardware digital filters*.

The software implementation of digital filters has the advantage of flexibility; the filter algorithm can be easily modified by changing the software program that is stored in the computer. If, on the other hand, a large number of filters of a particular (fixed) structure are needed commercially, then it is economical to

design the filter as an IC chip and replicate the chip in mass production. In this manner, very low-cost digital filters can be produced. A hardware filter can operate at a much faster speed than a software filter because, in the former case, processing takes place automatically through logic circuitry in the filter chip without having to access the processor, a software program, and various data items stored in the memory. The main disadvantage of a hardware filter is that its algorithm and parameter values cannot be modified, and the filter is dedicated to a fixed function.

16.6 Bridge Circuits

A full bridge is a circuit having four arms which are connected in a lattice form. Four nodes are formed in this manner. Two opposite nodes are used for the excitation (voltage or current supply) of the bridge and the remaining two opposite nodes provide the bridge output.

A bridge circuit is used to make some form of measurement. Typical measurements include change in resistance, change in inductance, change in capacitance, oscillating frequency, or some variable (stimulus) that causes these. There are two basic methods of making the measurement:

1. Bridge balance method
2. Imbalance output method

A bridge is said to be balanced when the output voltage is zero. In the bridge-balance method, we start with a balanced bridge. Then, when one is preparing to make a measurement, the balance of the bridge will be upset due to the associated variation, resulting in a nonzero output voltage. The bridge can be balanced again by varying one of the arms of the bridge (assuming, of course, that some means is provided for the fine adjustments that may be required). The change that is required to restore the balance provides the measurement. In this method, the bridge can be balanced precisely using a servo device.

In the imbalance output method, we usually start with a balanced bridge. However, the bridge is not balanced again after undergoing the change due to the variable that is being measured. Instead, the output voltage of the bridge due to the resulting imbalance is measured and used as an indication of the measurement.

There are many types of bridge circuits. If the supply to the bridge is DC, then we have a *DC bridge*. Similarly, an *AC bridge* has an AC excitation. A *resistance bridge* has only resistance elements in its four arms. An *impedance bridge* has impedance elements consisting of resistors, capacitors, and inductors in one or more of its arms. If the bridge excitation is a constant-voltage supply, we have a *constant-voltage bridge*. If the bridge supply is a constant current source, we have a *constant-current bridge*.

16.6.1 Wheatstone Bridge

The Wheatstone bridge is a resistance bridge with a constant DC voltage supply (i.e., a constant-voltage resistance bridge). A Wheatstone bridge is used in strain-gage measurements, and also in force, torque, and tactile sensors that employ strain-gage techniques. Since a Wheatstone bridge is used primarily in the measurement of small changes in resistance, it could be used in other types of sensing applications as well (for example, in resistance temperature detectors or RTDs).

Consider the Wheatstone bridge circuit shown in [Figure 16.17\(a\)](#). The bridge output, v_o , may be expressed as

$$v_o = \frac{(R_1 R_4 - R_2 R_3)}{(R_1 + R_2)(R_3 + R_4)} v_{\text{ref}} \quad (16.68)$$

Note that the bridge-balance requirement is

$$\frac{R_1}{R_2} = \frac{R_3}{R_4} \quad (16.69)$$

Suppose that $R_1 = R_2 = R_3 = R_4 = R$ in the beginning. The bridge is balanced according to Equation 16.69 and then R_1 is increased by δR . For example, R_1 may represent the only active strain gage and the remaining three elements in the bridge are identical, dummy elements. Then, in view of Equation 16.68, the change in output due to the change δR is given by

$$\delta v_o = \frac{[(R + \delta R)R - R^2]}{(R + \delta R + R)(R + R)} v_{\text{ref}} - 0$$

or

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{\delta R/R}{(4 + 2\delta R/R)} \quad (16.70)$$

Note that the output is nonlinear in $\delta R/R$. If, however, $\delta R/R$ is assumed to be small in comparison to 2, we have the linearized relationship.

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{\delta R}{4R} \quad (16.71)$$

The error due to linearization, which is a measure of nonlinearity, may be given as the percentage

$$N_p = 100 \left(1 - \frac{\text{Linearized output}}{\text{Actual output}} \right) \% \quad (16.72)$$

Hence, from Equation 16.70 and Equation 16.71, we have

$$N_p = 50 \frac{\delta R}{R} \% \quad (16.73)$$

16.6.2 Constant-Current Bridge

When large resistance variations δR are required for a measurement, the Wheatstone bridge may not be satisfactory due to its nonlinearity, as indicated by Equation 16.70. The constant-current bridge has less nonlinearity and is preferred in such applications. However, it requires a current-regulated power supply, which is typically more costly than a voltage-regulated power supply.

As shown in Figure 16.17(b), the constant-current bridge uses a constant-current excitation, i_{ref} , instead of a constant-voltage supply. Note that the output equation for the constant-current bridge can be determined from Equation 16.68 simply by knowing the voltage at the current source. Suppose that this is the voltage, v_{ref} , with the polarity as shown in Figure 16.17(a). Now, since the load current is assumed small (high-impedance load), the current through R_2 is equal to the current through R_1 and is

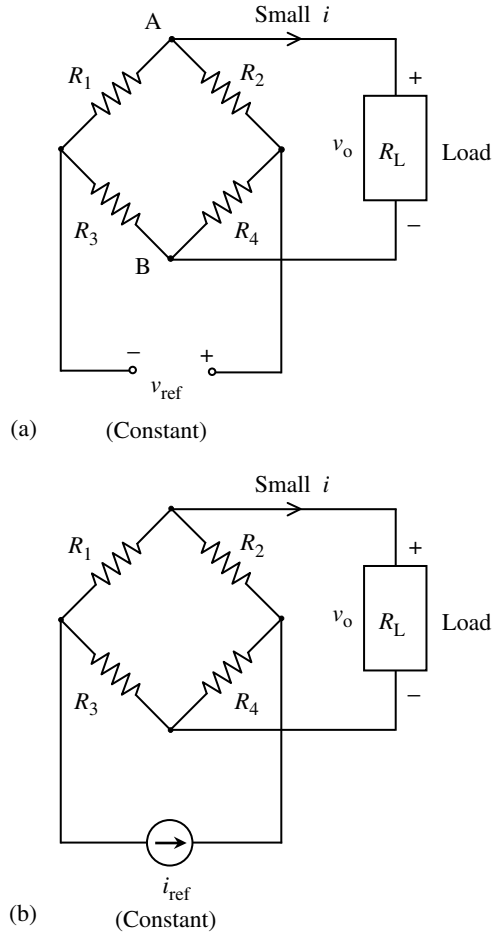

FIGURE 16.17 (a) Wheatstone bridge (the constant-voltage resistance bridge); (b) the constant-current bridge.

given by

$$\frac{v_{\text{ref}}}{(R_1 + R_2)}$$

Similarly, current through R_4 and R_3 is given by

$$\frac{v_{\text{ref}}}{(R_3 + R_4)}$$

Accordingly,

$$i_{\text{ref}} = \frac{v_{\text{ref}}}{(R_1 + R_2)} + \frac{v_{\text{ref}}}{(R_3 + R_4)}$$

or

$$v_{\text{ref}} = \frac{(R_1 + R_2)(R_3 + R_4)}{(R_1 + R_2 + R_3 + R_4)} i_{\text{ref}} \quad (16.74)$$

Substituting Equation 16.74 in Equation 16.68, we have the output equation for the constant-current bridge; thus,

$$v_o = \frac{(R_1 R_4 - R_2 R_3)}{(R_1 + R_2 + R_3 + R_4)} i_{\text{ref}} \quad (16.75)$$

Note that the bridge-balance requirement is again given by Equation 16.69.

To estimate the nonlinearity of a constant-current bridge, suppose that $R_1 = R_2 = R_3 = R_4 = R$ in the beginning and R_1 is changed by δR while the other resistors remain inactive. Again, R_1 will represent the active element (the sensing element) and may correspond to an active strain gage. The change in output, δv_o , is given by

$$\delta v_o = \frac{[(R + \delta R)R - R^2]}{(R + \delta R + R + R + R)} i_{\text{ref}} - 0$$

or

$$\frac{\delta v_o}{R i_{\text{ref}}} = \frac{\delta R/R}{(4 + \delta R/R)} \quad (16.76)$$

By comparing the denominator on the RHS of this equation with Equation 16.70, we observe that the constant-current bridge is more linear. Specifically, using the definition given by Equation 16.72, the *percentage nonlinearity* may be expressed as

$$N_p = 25 \frac{\delta R}{R} \% \quad (16.77)$$

It is noted that the nonlinearity is halved by using a constant-current excitation instead of a constant-voltage excitation.

16.6.3 Bridge Amplifiers

The output from a resistance bridge is usually very small in comparison to the reference, and it has to be amplified in order to increase the voltage level to a useful value (for example, in system monitoring or data logging). A *bridge amplifier* is used for this purpose. This is typically an *instrumentation amplifier* or a *differential amplifier*. The bridge amplifier is modeled as a simple gain, K_a , that multiplies the bridge output.

16.6.3.1 Half-Bridge Circuits

A half bridge may be used in some applications that require a bridge circuit. A half bridge has only two arms and the output is tapped from the mid-point of the two arms. The ends of the two arms are excited

by a positive voltage and a negative voltage. Initially, the two arms have equal resistances so that, nominally, the bridge output is zero. One of the arms has the active element. Its change in resistance results in a nonzero output voltage. It is noted that the half-bridge circuit is somewhat similar to a potentiometer circuit.

A half-bridge amplifier consisting of a resistance half-bridge and an output amplifier is shown in Figure 16.18. The two bridge arms have resistances R_1 and R_2 , and the amplifier uses a feedback resistance R_f . To obtain the output equation, we use the two basic facts for an unsaturated opamp; the voltages at the two leads are equal (due to high gain) and current in both leads is zero (due to high input impedance). Hence, voltage at node A is zero and the current balance equation at node A is

FIGURE 16.18 A half bridge with an output amplifier.

$$\frac{v_{\text{ref}}}{R_1} + \frac{(-v_{\text{ref}})}{R_2} + \frac{v_o}{R_f} = 0$$

This gives

$$v_o = R_f \left(\frac{1}{R_2} - \frac{1}{R_1} \right) v_{\text{ref}} \quad (16.78)$$

Now, suppose that initially $R_1 = R_2 = R$ and the active element R_1 changes by δR . The corresponding change in output is

$$\delta v_o = R_f \left(\frac{1}{R} - \frac{1}{R + \delta R} \right) v_{\text{ref}} - 0$$

or

$$\frac{\delta v_o}{v_{\text{ref}}} = \frac{R_f}{R} \frac{\delta R/R}{(1 + \delta R/R)} \quad (16.79)$$

Note that R_f/R is the amplifier gain. Now, in view of Equation 16.72, the percentage nonlinearity of the half-bridge circuit is

$$N_p = 100 \frac{\delta R}{R} \% \quad (16.80)$$

It follows that the nonlinearity of a half-bridge circuit is worse than that of the Wheatstone bridge.

16.6.4 Impedance Bridges

An impedance bridge contains general impedance elements, Z_1 , Z_2 , Z_3 , and Z_4 , in its four arms, as shown in Figure 16.19(a). The bridge is excited by an AC supply, v_{ref} . Note that v_{ref} represents a carrier signal and the output, v_o , has to be demodulated if a transient signal representative of the variation in one of the bridge elements is needed. Impedance bridges can be used, for example, to measure capacitances in *capacitive sensors* and changes of inductance in variable-inductance sensors and *eddy-current sensors*. Also, impedance bridges can be used as oscillator circuits. An oscillator circuit can serve as a constant-frequency source of a signal generator (in vibration testing) or it can be used to determine an unknown circuit parameter by measuring the oscillating frequency.

Analyzing using frequency-domain concepts, it is seen that the frequency spectrum of the impedance-bridge output is given by

$$v_o(\omega) = \frac{(Z_1 Z_4 - Z_2 Z_3)}{(Z_1 + Z_2)(Z_3 + Z_4)} v_{\text{ref}}(\omega) \quad (16.81)$$

This reduces to Equation 16.68 in the DC case of a Wheatstone bridge. The balanced condition is given by

$$\frac{Z_1}{Z_2} = \frac{Z_3}{Z_4} \quad (16.82)$$

This is used to measure an unknown circuit parameter in the bridge. Let us consider two examples.

16.6.4.1 Owen Bridge

The Owen bridge shown in Figure 16.19(b) may be used to measure the inductance L_4 or capacitance C_3 , by the bridge-balance method. To derive the necessary equation, note that the voltage–current relation for an inductor is

$$v = L \frac{di}{dt} \quad (16.83)$$

and for a capacitor it is

$$i = C \frac{dv}{dt} \quad (16.84)$$

It follows that the voltage/current transfer function (in the Laplace domain) for an inductor is

$$\frac{v(s)}{i(s)} = Ls \quad (16.85)$$

and that for a capacitor is

$$\frac{v(s)}{i(s)} = \frac{1}{Cs} \quad (16.86)$$

Accordingly, the impedance of an inductor element at frequency ω is

$$Z_L = j\omega L \quad (16.87)$$

and the impedance of a capacitor element at frequency ω is

$$Z_C = \frac{1}{j\omega C} \quad (16.88)$$

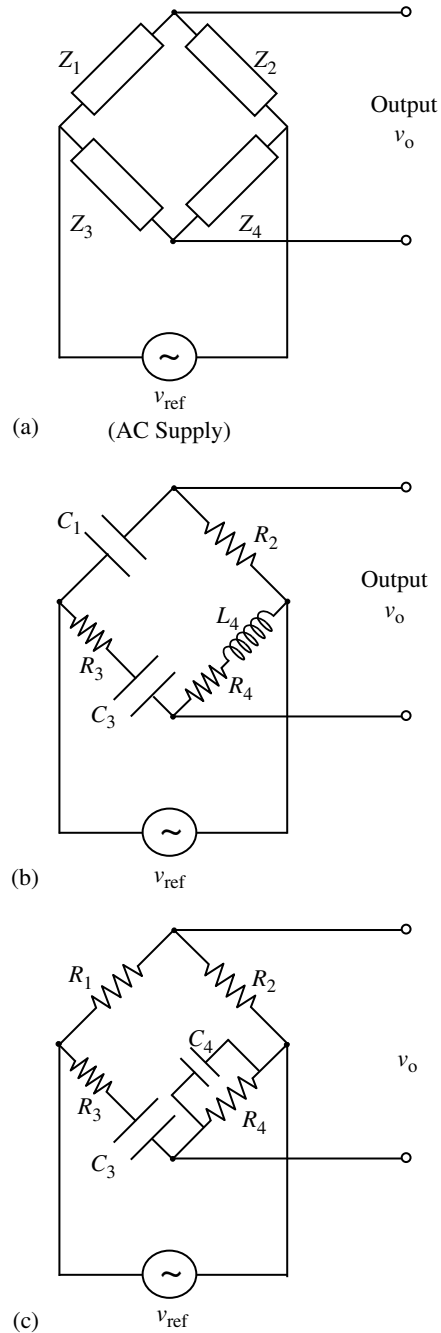

FIGURE 16.19 (a) General impedance bridge; (b) Owen bridge; (c) Wien-bridge oscillator.

Applying these results to the Owen bridge, we have

$$Z_1 = \frac{1}{j\omega C_1}$$

$$Z_2 = R_2$$

$$Z_3 = R_3 + \frac{1}{j\omega C_3}$$

$$Z_4 = R_4 + j\omega L_4$$

in which ω is the excitation frequency. Now, from Equation 16.82, we have

$$\frac{1}{j\omega C_1}(R_4 + j\omega L_4) = R_2 \left(R_3 + \frac{1}{j\omega C_3} \right)$$

By equating the real parts and the imaginary parts of this equation, we obtain the two equations

$$\frac{L_4}{C_1} = R_2 R_3$$

and

$$\frac{R_4}{C_1} = \frac{R_2}{C_3}$$

Hence, we have

$$L_4 = C_1 R_2 R_3 \quad (16.89)$$

and

$$C_3 = C_1 \frac{R_2}{R_4} \quad (16.90)$$

It follows that L_4 and C_3 can be determined with the knowledge of C_1 , R_2 , R_3 , and R_4 under balanced conditions. For example, with fixed C_1 and R_2 , an adjustable R_3 could be used to measure the variable L_4 , and an adjustable R_4 could be used to measure the variable C_3 .

16.6.4.2 Wien-Bridge Oscillator

Now consider the Wien-bridge oscillator shown in [Figure 16.19\(c\)](#). For this circuit, we have

$$Z_1 = R_1$$

$$Z_2 = R_2$$

$$Z_3 = R_3 + \frac{1}{j\omega C_3}$$

$$\frac{1}{Z_4} = \frac{1}{R_4} + j\omega C_4$$

Hence, from Equation 16.82, the bridge-balance requirement is

$$\frac{R_1}{R_2} = \left(R_3 + \frac{1}{j\omega C_3} \right) \left(\frac{1}{R_4} + j\omega C_4 \right)$$

Equating the real parts, we obtain

$$\frac{R_1}{R_2} = \frac{R_3}{R_4} + \frac{C_4}{C_3} \quad (16.91)$$

and, by equating the imaginary parts, we obtain

$$0 = \omega C_4 R_3 - \frac{1}{\omega C_3 R_4}$$

Hence,

$$\omega = \frac{1}{\sqrt{C_3 C_4 R_3 R_4}} \quad (16.92)$$

Equation 16.92 tells us that the circuit is an oscillator whose natural frequency is given by this equation under balanced conditions. If the frequency of the supply is equal to the natural frequency of the circuit, large-amplitude oscillations will take place. The circuit can be used to measure an unknown resistance (e.g., in strain-gage devices) by first measuring the frequency of the bridge signals at resonance (natural frequency). Alternatively, an oscillator that is excited at its natural frequency can be used as an accurate source of periodic signals (a signal generator).

16.7 Linearizing Devices

Nonlinearity is present in any physical device, to varying levels. If the level of nonlinearity in a system (component, device, or equipment) can be neglected without exceeding the error tolerance, then the system can be assumed to be linear.

In general, a linear system is one that can be expressed as one or more *linear differential equations*. Note that the *principle of superposition* holds for linear systems. Specifically, if the system response to an input, u_1 , is y_1 and the response to another input, u_2 , is y_2 , then the response to $a_1 u_1 + a_2 u_2$ is $a_1 y_1 + a_2 y_2$.

Nonlinearities in a system can appear in two forms:

1. Dynamic manifestation of nonlinearities
2. Static manifestation of nonlinearities

The useful operating region of many systems can exceed the frequency range where the frequency-response function is flat. The operating response of such a system is said to be dynamic. Examples include a typical dynamic system (e.g., automobile, aircraft, chemical process plant, robot), actuator (e.g., hydraulic motor), and controller (e.g., PID control circuitry). Nonlinearities of such systems can manifest themselves in a dynamic form such as the *jump phenomenon* (also known as the *fold catastrophe*), *limit cycles*, and *frequency creation*. Design changes, extensive adjustments, or reduction of the operating signal levels and bandwidths are generally necessary to reduce or eliminate these dynamic manifestations of nonlinearity. In many instances, such changes are not practical and we have to somehow manage with the presence of these nonlinearities under dynamic conditions. Design changes might involve replacing conventional gear drives with devices such as harmonic drives in order to reduce backlash, replacing nonlinear actuators with linear actuators, and using components that have negligible Coulomb friction and that make small motion excursions.

A wide majority of sensors, transducers, and signal-modification devices are expected to operate in the flat region of the frequency-response function. The input/output relation of these types of devices, in the operating range, is expressed (modeled) as a *static curve* rather than a differential equation. Nonlinearities in these devices will manifest themselves in the static operating curve in many forms. These manifestations include *saturation*, *hysteresis*, and *offset*.

In the first category of systems (plants, actuators, and compensators), if a nonlinearity is exhibited in the dynamic form, proper modeling and control practices should be employed in order to avoid unsatisfactory degradation of the system performance. In the second category of systems (sensors, transducers and signal modification devices), if nonlinearities are exhibited in the “static” operating curve, again the overall performance of the system will be degraded. Hence, it is important to “linearize” the output of such devices. Note that, in dynamic manifestations, it is not realistic to linearize the output because the response is in the dynamic form. The solution in that case is either to minimize nonlinearities

through design modifications and adjustments so that a linear approximation would be valid, or to take the nonlinearities into account in system modeling and control. In the present section, we are not concerned with this aspect. Instead, we are interested in the linearization of devices in the second category, whose operating characteristics can be expressed by static input–output curves.

Linearization of a static device can be attempted by making design changes and adjustments, as in the case of dynamic devices. However, since the response is static, and since we normally deal with an available (fixed) device whose internal hardware cannot be modified, we should consider ways of linearizing the input–output characteristic by modifying the output itself.

Static linearization of a device can be made in three ways:

1. Linearization using digital software
2. Linearization using digital (logic) hardware
3. Linearization using analog circuitry

In the software approach to linearization, the output of the device is read into a processor with software-programmable memory and the output is modified according to the program instructions. In the hardware approach, the device output is read by a device having fixed logic circuitry that processes (modifies) the data. In the analog approach, a linearizing circuit is directly connected at the output of the device so that the output of the linearizing circuit is proportional to the input of the device. We shall discuss these three approaches in the rest of this section, heavily emphasizing the analog-circuit approach.

Hysteresis-type static nonlinearity characteristics have the property that the input–output curve is not one to one. In other words, one input value may correspond to more than one (static) output value, and one output value may correspond to more than one input value. Let us disregard these types of nonlinearities. Our main concern is the linearization of a device having a single-valued static response curve that is not a straight line. An example of a typical nonlinear input–output characteristic is shown in Figure 16.20(a). Strictly speaking, a straight-line characteristic with a simple *offset*, as shown in Figure 16.20(b), is also a nonlinearity. In particular, note that superposition does not hold for an input–output characteristic of this type, given by

$$y = ku + c \quad (16.93)$$

It is very easy, however, to linearize such a device because the simple addition of a DC component will convert the characteristic into the linear form given by

$$y = ku \quad (16.94)$$

This method of linearization is known as offsetting. Linearization is more difficult in the general case where the characteristic curve could be much more complex.

16.7.1 Linearization by Software

If the nonlinear relationship between the input and the output of a nonlinear device is known, the input can be “computed” for a known value of the output. In the software approach of linearization, system

FIGURE 16.20 (a) A general static nonlinear characteristic; (b) an offset nonlinearity.

composed of a processor and memory that can be programmed using software (i.e., a digital computer) is used to compute the input using output data. Two approaches can be used. They are

1. Equation inversion
2. Table lookup

In the first method, the nonlinear characteristic of the device is known in the analytic (equation) form:

$$y = f(u) \quad (16.95)$$

in which

u = device input

y = device output

Assuming that this is a one-to-one relationship, a unique inverse given by the equation

$$u = f^{-1}(y) \quad (16.96)$$

can be determined. This equation is programmed into the read-and-write memory (RAM) of the computer as a *computation algorithm*. When the output values, y , are supplied to the computer, the processor will compute the corresponding input values, u , using the instructions (executable program) stored in the RAM.

In the table lookup method, a sufficiently large number of pairs of values (y, u) are stored in the memory of the computer in the form of a table of ordered pairs. These values should cover the entire operating range of the device. When a value for y is entered into the computer, the processor scans the stored data to check whether that value is present. If so, the corresponding value of u is read and this is the linearized output. If the value of y is not present in the data table, then the processor will *interpolate* the data in the vicinity of the value and will compute the corresponding output. In the *linear interpolation* method, the area of the data table where the y value falls is fitted with a straight line and the corresponding u value is computed using this straight line. Higher order interpolations use nonlinear interpolation curves such as quadratic and cubic polynomial equations (splines).

Note that the equation inversion method is usually more accurate than the table lookup method and it does not need excessive memory for data storage. However, it is relatively slow because data are transferred and processed within the computer using program instructions that are stored in the memory and that typically have to be accessed in a sequential manner. The table lookup method is fast. Since the accuracy depends on the number of stored data values, this is a memory-intensive method. For better accuracy, more data should be stored. However, since the entire data table has to be scanned to check for a given data value, this increase in accuracy is derived at the expense of speed as well as memory requirements.

16.7.2 Linearization by Hardware Logic

The software approach to linearization is flexible in the sense that the linearization algorithm can be modified (e.g., improved, changed) simply by modifying the program stored in the RAM. Furthermore, highly complex nonlinearities can be handled by the software method. As mentioned before, the method is relatively slow, however.

In the hardware logic method of linearization, the linearization algorithm is permanently implemented in the IC form using appropriate *digital logic circuitry* for data processing, and memory elements (e.g., *flip-flops*). Note that the algorithm and numerical values of parameters (except input values) cannot be modified without redesigning the IC chip, because a hardware device typically does not have *programmable memory*. Furthermore, it will be difficult to implement very complex linearization algorithms by this method and, unless the chips are mass produced for an extensive commercial market, the initial cost of chip development will make the production of linearizing chips economically infeasible. In bulk production, however, the per-unit cost will be very small. Furthermore, since the access of stored

program instructions and extensive data manipulation are not involved, the hardware method of linearization can be substantially faster than the software method.

A digital linearizing unit that has a processor and a read-only memory (ROM), whose program cannot be modified, also lacks the flexibility of a programmable software device. Hence, such a ROM-based device also falls into the category of hardware logic devices.

16.7.3 Analog Linearizing Circuitry

Three types of analog linearizing circuitry can be identified:

1. Offsetting circuitry
2. Circuitry that provides a proportional output
3. Curve shapers

We will describe each of these categories now.

An offset is a nonlinearity that can be easily removed using an analog device. This is accomplished by simply adding a DC offset of equal value to the response, but in the opposite direction. Deliberate addition of an offset in this manner is known as *offsetting*. The associated removal of original offset is known as *offset compensation*. There are many applications of offsetting. Unwanted offsets such as those present in ADC and DAC results can be removed by analog offsetting. Constant (DC) error components such as steady-state errors in dynamic systems due to load changes, gain changes, and other disturbances can be eliminated by offsetting. Common-mode error signals in amplifiers and other analog devices can also be removed by offsetting. In measurement circuitry such as potentiometer (ballast) circuits, where the actual measurement signal is a change, δv_o , in a steady output signal, v_o , the measurement can be completely wiped out due to noise. To reduce this problem, first the output should be offset by $-v_o$ so that the net output is δv_o and not $v_o + \delta v_o$. This output is subsequently conditioned by filtering and amplification. Another application of offsetting is the additive change of scale of a measurement, for example from a relative scale (e.g., velocity) to an absolute scale. In summary, some of the applications of offsetting are:

1. Removal of unwanted offsets and DC components in signals (e.g., in ADC, DAC, signal integration).
2. Removal of steady-state error components in dynamic system responses (e.g., due to load changes and gain changes in Type 0 systems. Note: Type 0 systems are open-loop systems having no free integrators).
3. Rejection of common-mode levels (e.g., in amplifiers and filters).
4. Error reduction when a measurement is an increment of a large steady output level (e.g., in ballast circuits for strain-gage and RTD sensors).
5. Scale changes in an additive manner (e.g., conversion from relative to absolute units or from absolute to relative units).

We can remove unwanted offsets in the simple manner as discussed above. Let us now consider more complex nonlinear responses that are nonlinear in the sense that the input–output curve is not a straight line. Analog circuitry can be used to linearize this type of response as well. The linearizing circuit used will generally depend on the particular device and the nature of its nonlinearity. Hence, often linearizing circuits of this type have to be discussed with respect to a particular application. For example, such linearization circuits are useful in *transverse-displacement capacitive sensor*. Several useful circuits are described below.

Consider the type of linearization that is known as *curve shaping*. A *curve shaper* is a linear device whose gain (output/input) can be adjusted so that response curves with different slopes can be obtained. Suppose that a nonlinear device having an irregular (nonlinear) input–output characteristic is to be linearized. First, we apply the operating input simultaneously to the device and the curve shaper, and the gain of the curve shaper is adjusted such that it closely matches that of the device in a small range

of operation. Now, the output of the curve shaper can be utilized for any task that requires the device output. The advantage here is that linear assumptions are valid with the curve shaper, which is not the case for the actual device. When the operating range changes, the curve shaper must be returned to the new range. Comparison (calibration) of the curve shaper and the nonlinear device can be done off line and, once a set of gain values corresponding to a set of operating ranges is determined in this manner for the curve shaper, it is possible to completely replace the nonlinear device with the curve shaper. Then the gain of the curve shaper can be adjusted depending on the actual operating range during system operation. This is known as *gain scheduling*. Note that we can replace a nonlinear device with a linear device (curve shaper) within a multicomponent system in this manner without greatly sacrificing the accuracy of the overall system.

16.7.4 Offsetting Circuitry

Common-mode outputs and offsets in amplifiers and other analog devices can be minimized by including a *compensating resistor* that can provide fine adjustments at one of the input leads. Furthermore, the larger is the feedback signal level in a feedback system, the smaller is the steady-state error. Hence, steady-state offsets can be reduced by reducing the *feedback resistance* (thereby increasing the feedback signal). Furthermore, since a ballast (potentiometer) circuit provides an output of $v_o + \delta v_o$ and a bridge circuit provides an output of δv_o , the use of a *bridge circuit* can be interpreted as an offset compensation method.

The most straightforward way of offsetting is by using a *differential amplifier* (or a *summing amplifier*) to subtract (or add) a DC voltage to the output of the nonlinear device. The DC level has to be variable so that various levels of offset can be provided using the same circuit. This is accomplished by using an adjustable resistance at the DC input lead of the amplifier.
